Binary Adsorbent Photocatalyst Hybrid Nanomaterial for Improved Degradation of Tetracycline from Water

By

Ayesha Ikram

(Registration No: 00000328449)

A thesis submitted to the National University of Sciences and Technology, Islamabad,

in partial fulfillment of the requirements for the degree of

Master of Science in
Chemical Engineering

Supervisor: Dr. Erum Pervaiz

School of Chemical and Materials Engineering

National University of Sciences & Technology (NUST)

Islamabad, Pakistan

(2024)

THESIS ACCEPTANCE CERTIFICATE

1

THESIS ACCEPTANCE CERTIFICATE

Certified that final copy of MS thesis written by Ms **Ayesha Ikram** (Registration No 00000328449), of School of Chemical & Materials Engineering (SCME) has been vetted by undersigned, found complete in all respects as per NUST Statues/Regulations, is free of plagiarism, errors, and mistakes and is accepted as partial fulfillment for award of MS degree. It is further certified that necessary amendments as pointed out by GEC members of the scholar have also been incorporated in the said thesis.

AUTHOR'S DECLARATION

With this statement, I, Ayesha Ikram, declare that my master's thesis, entitled “Binary Adsorbent Photocatalyst Hybrid Nanomaterial for Improved Degradation of Tetracycline from Water” is my original work that I haven't submitted before to the National University of Sciences and Technology in Islamabad, Pakistan, or any other place in the world.

The university has the right to revoke my MS degree at any point, even after I graduate, if it turns out that my statement was false.

Name of Student: Ayesha Ikram

Date: _____ 12-03-2024

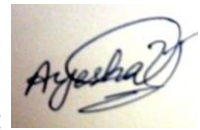

PLAGIARISM UNDERTAKING

I hereby formally affirm that the research described in this thesis is “Binary Adsorbent Photocatalyst Hybrid Nanomaterial for Improved Degradation of Tetracycline from Water” is entirely my own research, with no noteworthy assistance from other individuals. I have written a complete thesis and I have duly acknowledged any minor contributions or help which I received.

I am conscious of the National University of Sciences and Technology (NUST), Islamabad, and HEC's zero-tolerance stance regarding plagiarism. As a result, I, author of thesis, with same title, hereby declare that my thesis has not been copied in any way and that all sources have been properly cited.

I agree, HEC and NUST, Islamabad have right to publish my name on HEC/University website, that lists the names of students who turned in plagiarized theses, and that University reserves right to revoke my MS degree, if I am, found guilty of formal plagiarism in mentioned thesis, even after I have received degree.

DEDICATION

This study is honoring my parents who have always provided me with direction and encouragement. To my supervisor who shared her knowledge, gave advice, and encouraged me to fulfill my objectives. And to all my fellows I worked with whom I've enjoyed wonderful memories.

ACKNOWLEDGEMENTS

There is none other but Almighty Allah, whose will be required for everything and anything in this world, who blessed us with the ability to think and made us willing to explore the entire universe. Infinite greetings to the Holy Prophet Muhammad (PBUH), cause of the universe's creation and a fountain of knowledge and blessing for all of humanity.

Dr. Erum Pervaiz, my renowned supervisor, deserves credit for trusting in my talents. Her constant guidance, encouragement, and support was vital to the project's success. Erum Pervaiz, the author, thanks NUST Pakistan for marking the HEC for financial assistance. I would like to show my appreciation for the worthy Co-Supervisor Dr. Waheed Miran, GEC members, Dr. Sara Farrukh and Dr. Sher Ahmed. I've never given it much thought. Having said that, the unwavering moral support that my family and friends have always provided will always be my light in the dark. My heartfelt gratitude goes out to all the personnel and lab attendants. Thank you!

Ayesha Ikram

ABSTRACT

Water contamination is a major worldwide issue that endangers human and environmental health at risk. Water supplies are rendered unfit for intake or reuse by pollutants like as organic waste & heavy metals, necessitating efficient wastewater treatment techniques. For this issue, several solutions have been put forth, namely membrane separation, adsorption, & photocatalysis. Photocatalysis is an innovative method in which nano-adsorbent particles degrade tetracycline (TC) without the usage of any further treatment. Antibiotic usage has significantly increased recently because of bacterial infectious diseases that affect both humans and animals. But this use is resulting in harmful effects to the water quality, aquatic environment, and soil microbial communities. In this work, I have focused on the tetracycline removal from water using advanced oxidation process by synthesizing efficient nanohybrids. The most effective way to treat water so that it can be used again for irrigation and drinking is the advanced oxidation process. These nanohybrids act both as photocatalyst and adsorbent thereby enhancing the percentage degradation of tetracycline. This study created a new photo-adsorbent via a hydrothermal and in-situ technique. Results of X-ray diffraction and scanning electron microscopy show that photo-adsorbents are synthesized efficiently. UV-Visible spectrophotometry is used to evaluate degradation performance. By using 100 mg of CdS@ZIF-67 hybrid, 96% of tetracycline has been successfully degraded in 110 minutes. By increasing the quantity of CdS, percentage removal of tetracycline has been increased. CdS is found to be potential highly efficient photocatalyst for tetracycline degradation.

CHAPTER 1: INTRODUCTION

1.1 Background

The evidence that pharmaceutical antibiotics are part of a class of extremely toxic pollutants has brought increased attention to these drugs, which are widely used in medical therapy and agriculture worldwide, in recent years [1]. Given that many Merely absorbed antibiotics, such as tetracyclines, and metabolized by animals and patients they treat, a significant portion of them is expelled through feces and urine as the original parent component. In the downstream river near the 10 million city of Lahore, high concentrations of antibiotics were found to be “2700, 1700, and 1100 ng L⁻¹” for “sulfamethoxazole, trimethoprim and oxytetracycline”, in that order. With measured levels of "1100, 4100, 6200, 7300, 8000, 27000, 28000, and 49000 ng L⁻¹," respectively, a facility of making drugs had the highest amounts of "erythromycin, lincomycin, ciprofloxacin, ofloxacin, levofloxacin, oxytetracycline, trimethoprim, and sulfamethoxazole" [2]. Tetracycline is the second most consumed and produced antibiotic worldwide due to some exceptional properties like nontoxic nature, broad spectrum activity, and economic in nature. TC has been widely used and has a high adsorption capacity, which has led to its frequent detection in both surface and groundwater [3].

On the other hand, domestic wastewater contains antibiotic residue because wastewater treatment facilities are unable to remove these micropollutants from the wastewater [4]. This antibiotic residue may exist as a parent drug, a metabolite, Sometimes it occurs as a TC-metal complex within their environment's water matrix, and it may pose serious environmental risks to animals and humans as a kind of antibiotic-resistant bacteria or emergence of new disease [5]. Therefore, searching for immediate alternative techniques that are cost-effective and environmentally sustainable for removing TC from wastewater is essential. It is critically necessary to gain a better understanding of tetracycline residues in water matrix of environment, since they may contribute to the emergence of bacteria and genes resistant to TC [6].

Figure 1.1: Structure of Tetracycline

Diverse methods were employed by numerous researchers to extract TC from water. For example, Photolysis, photo-Fenton, Fenton, ozonation reactions, as well as antibiotic oxidation in existence of ozone/ultraviolet/hydrogen peroxide light [7]. Among them the best technique with the greater efficiency is the technique of photocatalysis [8]. In Photocatalysis a light driven reaction is used to remove TC from the solution with the help of some catalyst. Different catalysts have been used for this like recto rite, coal humic acid, single-walled-carbon-nanotubes, chitosan particles, montmorillonite, multi-walled-carbon-nanotubes, palygorskite (hydrated magnesium aluminum silicate). But in order to remove these contaminants, there is increasing need for development of effective and affordable remediation technologies. [9].

Cadmium Sulfide (CdS) has significantly increased interest in the recent year because of low cost, and remarkable catalytic performance. The CB energy level of CdS, which is 0.41 eV is significantly, more negative than potential for hydrogen evolution, suggesting that organic pollutant photodegradation and H₂ evolution are promising prospects. [1]. CdS-based hybrids with different materials for a variety of applications have been credited with exceptional results [10]. Despite these properties photo-corrosion is the

biggest problem related to CdS. A number of techniques are being employed to address this issue, including heterojunction creation, heteroatom doping and loading of co-catalyst, as well as the introduction of various components to satisfy heterojunction creation or to differ the electron motion to enhance their properties and for their activity [11, 12]. Ag/TiO₂ nanoparticles on the exterior and microorganisms on the inside of polyurethane cubes, which were being employed as transporters allowed Xiong et al. to degrade TC using a combined photocatalysis and biodegradation system [12]. Cadmium sulfides and carbon nitride nanocomposite (CdS/g-C₃N₄) were synthesized by pulsed liquid ablation in liquid. CdS nanostructures are grown on graphitic carbon nitride nanosheets [13]. Graphitic carbon nitride (g-C₃N₄) a prominent photocatalyst for environmental remediation and semiconductor-based photocatalyst [14, 15]. The g-C₃N₄ demonstrated band gap 2.7eV, indicating greater visible light absorption [16]. The strong covalent connection that exists between carbon and nitrogen atoms in conjugated g-C₃N₄ framework, g-C₃N₄ possesses relatively greater thermal and chemical stability [17]. Regardless of these benefits, g-C₃N₄ catalytic activity is hindered by a lower reusability, a smaller surface area, and higher ratio of recombination of charge carrier [18].

g-C₃N₄ has gained popularity recently a non-metallic, visible light activated semiconductor and has garnered a lot of interest as a potentially useful substance for a range of environmental remediation applications [19, 20]. Of the seven phases of carbon nitride, g-C₃N₄ has the most stability at room temperature and has 2D layered allotrope like graphite. This allotrope has drawn a lot of interest. g-C₃N₄ consists of tri-s-triazine or s-triazine units, which are building blocks connected by tertiary amines, to create π -conjugation system. One can create g-C₃N₄ among a range of N- and C-rich precursors [21] using different methodologies [22, 23]. Numerous investigations have been carried out to examine the effects of the precursors and treatment processes on morphology, structure, and optical and physicochemical properties of g-C₃N₄ [24] [25].

The tertiary amino groups that link the π -conjugated layers make it easier to modify g-C₃N₄ to be able to boost specific surface area and electron mobility [26, 27]. This semiconductor's tunable band gap enhances its metal doping adaptability, enabling it to produce more active sites and form heterojunctions with other semiconductors, thereby

expanding its application range and photocatalytic activity [28]. Moreover, g-C₃N₄ has outstanding thermal endurance to six hundred degree Celsius, water resistivity, super-hardness, and high chemical resistance, especially in harsh media [29]. Due to these exceptional qualities, g-C₃N₄ has been thoroughly investigated in a great deal of research as the most alluring non-metallic visible light activated photocatalyst. Although g-C₃N₄ has been subject of numerous reviews, many of them focus on describing its structure, physicochemical properties, or use in straightforward photocatalysis for water treatment. A recent publication discussed the application of g-C₃N₄ to advanced oxidation processes (AOPs) to degrade of organic contaminants present in water [30, 31]. Nevertheless, uses of g-C₃N₄ have expanded beyond straightforward photocatalysis procedures for encompassing alternative H₂O treatment systems, like utilizing hybrid AOP-photocatalysis and photo electrocatalysis (PEC). Thus, more conversation is warranted regarding these additional crucial uses for g-C₃N₄. Because of its π -conjugated system's layered, planar structure, g-C₃N₄ is preferred as adsorbent for aromatic pollutants and heavy metals [32]. Furthermore, g-C₃N₄'s distinct electronic structure, high chemical stability, excellent material compatibility, and adaptability in morphological modification make it the perfect material for high-performance PEC electrodes and catalytic activation of oxidants [33].

However, because of its poor electrical conductivity, rapid charge carrier recombination, and inefficient absorption of solar light, bulk g-C₃N₄'s photocatalytic activity is far from satisfactory for practical applications [34]. Generally speaking, surface active sites distribution, mass transport mechanisms, catalyst morphologies, and visible light absorption capacity are primary factors influencing photocatalytic reactions [35]. Therefore, significant efforts have been made to alter g-C₃N₄ to achieve a moderate electronic energy level and exceptional surface properties. These efforts include heteroatom doping, designing nanostructures, and incorporating other materials [36, 37]. Among them, creating target-specific morphologies or heterojunctions in nanostructure materials appears to be an efficient modification technique to maximize its photoactivity. This will introduce an internal electric field or conducting media that will inhibit photoinduced charge-carrier recombination [38, 39]. Regarding the creation of nanoarchitecture design, several synthetic pathways, including supramolecular self-assembly and exfoliation strategies, have been investigated to achieve controllable

morphologies of g-C₃N₄. Therefore, to modify g-C₃N₄ and achieve better performances, it is essential to create tailoring nanostructures with surface functionality and appropriate interfacial contacts at heterojunctions [35, 40, 41].

Especially in the last few years, several noteworthy and intriguing discoveries regarding the superior architectures of g-C₃N₄ and its hybrid composites have been reported to date. Even though several outstanding reviews have been published regarding the efficient modification of pure g-C₃N₄ for the treatment of wastewater [42, 43]. It is urgently necessary to conduct a thorough and systematic review of heterojunction design and construction to spur additional advancements for its intended photocatalytic applications. This review has not yet been published. g-C₃N₄-based multicomponent systems are covered, such as heterostructures made of metal and g-C₃N₄, nanohybrids made of inorganic semiconductor and g-C₃N₄, hybrids made of g-C₃N₄ and C-based materials, multifarious complex hybrids, and so forth. Next, functional nanostructure designs for graphene-(C₃N₄) are also showcased. These include porous structures, 2D g-C₃N₄ nanosheets, 1D g-C₃N₄ nanomaterials (such as nanotubes, nanofibers, and nanowires), and other tunable morphologies. Lastly, a succinct overview of upcoming challenges and some stimulating viewpoints on further studies concerning the creation of visible-light-induced g-C₃N₄-based photocatalysts are presented. Recent developments in materials science and engineering research have aided in the advancement of g-C₃N₄'s use in water purification [44]. A new integrated PEC system with a g-C₃N₄-based membrane photoanode demonstrated improved antifouling properties and a phenol removal capacity ten times greater than that of a standard filtration system. [45]. In this article, we give a thorough review of the most recent uses of g-C₃N₄-based materials for oxidation and photoelectrocatalysis-based water treatment systems, as well as their removal mechanisms and performances. Specifically, the functions of g-C₃N₄ in the systems of enhanced photoelectrocatalysis and oxidizing agent activation are also emphasized. This review ends with an overview of the main obstacles to and prospects for further research on the uses of g-C₃N₄-based materials in water treatment, as well as our assessment of these materials' prospects.

Recent years have seen a notable increase in interest in cadmium sulfide (CdS) due to its exceptional catalytic activity and reasonable cost. The conduction band energy level (ECB) of CdS, which is 0.41 eV, is significantly more negative than the potential for hydrogen evolution, suggesting that organic pollutant photodegradation and H₂ evolution are promising prospects [1]. Its excellent visible light response, charge transfer capabilities, and suitable energy band structure have led to its widespread application in photocatalytic water purification and H₂ evolution. CdS-based hybrids with various materials have demonstrated remarkable performance for a range of applications [46]. Despite these qualities, the largest issue with CdS is photo-corrosion. Several methods are being used to deal with this problem, such as the formation of heterojunctions, the loading of co-catalyst, the doping of heteroatoms, and the introduction of different components to ensure heterojunction formation or to change the electron motion for their activity and improve their characteristics [11] [47]. Ag/TiO₂ nanoparticles on the exterior and microorganisms on the inside of polyurethane cubes, which were used as carriers, allowed Xiong et al. to degrade TC using a combined photocatalysis and biodegradation system. The intimately coupled photocatalysis and biodegradation (ICPB) system's TC removal efficiency approached 95% when sodium acetate was employed as a co-substrate [47]. Cadmium sulfide nanostructures are grown on graphitic carbon nitride nanosheets. It has reduced electron hole pair recombination and increased visible light absorption [48].

An emerging material called “ZIF-67”, a subclass of MOF, is made up of “divalent ions (Co)” connected by an organic linker. In MOF, “metal-ligand-metal bonds” resemble Si-O-Si bonds, which result in topologies resembling zeolites. More than 150 ZIFs have been created to date and are employed in a variety of applications as cutting-edge functional materials [49, 50]. It was shown that “MOF-235, MIL-53, ZIF-67, and ZIF-8” exhibited photocatalytic activity [46] [51, 52]. Of them, ZIF-67 is thought to be a photocatalyst because of its several absorption bands in the UV-VIS-near-IR region [53] [54]. ZIF-67 exhibits a photocatalytic band gap of 1.98 eV, whereas ZIF-8 has a band gap of 4 eV due to ligand to metal transfer. It has good thermal and chemical stability [55].

1.1.1 Photocatalysis

Photo catalyst can be described by four main steps. Four steps are as follows:

1. Effective absorption of photons of light to create hole and electrons
2. Segregation of charges which are excited
3. electron migration to photo catalyst's exterior surface
4. migration of holes on photo catalysts
5. Initiation of reduction oxidation reaction by using hole and subsequently electrons.

The third step signifies progress and survival of photocatalytic process. It basically talks about the recombined of photoexcitation. The larger the time for photoemission to exist as hole pair in separated state higher would be the efficacy of process. Most of catalyst when the rate of recombining is high the photocatalysis process decays[56].

Figure 1.2: Photocatalysis reaction schematic diagram.

1.1.2 Advance Oxidation Process

Surface of photo catalyst semiconductor material contain water.it is commonly knowns absorbed water. This water which is acting as reaction medium is susceptible to oxidation by positive holes created by photoexcitation process in valence band of semiconductor. This reaction produces hydroxyl radicals, which can oxidize organic materials.

Dissolved oxygen is also present in photocatalyst reaction[57]. Electrons convert the dissolved oxygen to oxygen radicals which are necessary so that charge recombination can be avoided. Superoxide. Anions get linked or attracted to the intermediates in oxidation reaction and then form peroxide. Peroxide further transform to hydrogen peroxide[58]. The last stage in turning hydrogen peroxide into water. In organic material, the reduction is likely to happen more easily than in water. There will be more positive holes because of the higher organic matter concentration. This brings down the carrier recombination.it increases the activity of photocatalyst. This process led to complete mineralization to form carbon dioxide and water. This process is called as advance oxidation. [59]

1.2 Problem Statement

The increasing crisis of global water scarcity is having an impact on ecosystems, agriculture, and human populations across the globe. More than 2 billion people experience water scarcity because of declining freshwater resources. Numerous factors are contributing to the intensification of this crisis: pollution is poisoning available water sources, rapid urbanization is straining the supply, and climate change is changing precipitation patterns. Antibiotics play a major role in water scarcity when they are present in water sources for a variety of reasons. The widespread use of antibiotics in agriculture and livestock farming is one important factor. These antibiotics frequently contaminate surface and groundwater when they enter water systems through runoff from farms or improper disposal of animal waste. Another factor in this problem is the overuse of antibiotics in medical care. Antibiotics can enter water bodies through improper disposal of leftover medication or wastewater from pharmaceutical and medical facilities that has not been properly treated.

Conventional methods used to remove antibiotics are membrane technology, ozonation etc., but they have plenty of drawbacks. Fouling, in which the drug compounds clog or block the membrane pores, can result from the degradation of tetracycline using membranes. This lowers process efficiency and necessitates frequent membrane replacement or cleaning, which can raise operating expenses. Membrane technology has the potential to affect water quality because it can remove beneficial compounds or essential ions from the water in addition to tetracycline. Water must be forced through membranes, which can be an energy-intensive process depending on the size and kind of membrane used. This increases operating costs and the environmental impact of the process. Tetracycline molecules might not be entirely broken down by ozonation, which could result in the generation of transformation products that may remain biologically active or dangerous for the environment. Hazardous byproducts may result from ozonation, especially if the water also contains other organic materials. A few of these byproducts might be more harmful than the tetracycline compound itself. The production of ozone uses a lot of energy and specific machinery. Installing and running it can be expensive, particularly for large-scale water treatment plants. So, there is a need for a more effective method. In this research CdS based hybrids will be used as a catalyst to degrade tetracycline from wastewater as CdS is potential photocatalyst due to its photocatalytic properties. The Advanced oxidation method will be used in this research which is basically degradation of tetracycline through heterogeneous photocatalysis.

1.3 Research Objectives

The research objective is as follow:

1. Synthesis of efficient hybrid structure for removal of TC from water
2. Physical and chemical characterization techniques of the prepared hybrid structure i.e., XRD and SEM analysis
3. Kinetic study for TC removal from water

1.4 Scope of Study

Pakistan is a developing country with a scarcity of clean and pure water. The abundance of various pollutants within water sources puts a threat to both the human and environmental well-being, making the water unsuitable for consumption or any other form of reuse. To resolve this issue, this work will play an important role. 96% tetracycline has been successfully degraded from wastewater to provide clean water for drinking and irrigation purposes. One of the best advantages is that catalyst synthesized is reusable and is highly efficient even after a few times use.

1.5 Chapter Summary

This thesis consists of 5 chapters. The acquaintance of each chapter is given in the following chapters.

1. **Chapter 1** delivers a vision of subject, background and contemporary problems related to the work. It also clarifies the problem statement, research objectives and the planned study's scope.
2. **Chapter 2** will outline the results of the literature review completed to describe the previous work done on the synthesis of photocatalytic hybrids, previous method techniques and tetracycline degradation. It also includes review based to compare g-C₃N₄ based hybrids with different hybrid photocatalysts.
3. **Chapter 3** covers the methodology related to the synthesis of pure CdS, pure g-C₃N₄, pure ZIF-67 and hybrids.
4. **Chapter 4** expands on the discussion and outcome. The phases of crystal structures, and morphology of synthesized catalysts are described by analysis using XRD and SEM. The photocatalytic studies of the active catalysts and their stability also elaborated in this chapter.
5. **Chapter 5** reviews all findings and conclusions in the current study and provides the future recommendation for the related work.

CHAPTER 2: LITERATURE REVIEW

2.1 Background

Table 2.1: Different Photocatalyst and Their Removal Efficiency

2.1.1 g-C₃N₄-based Materials for Wastewater Remediation and Pollutants Removal

Since g-C₃N₄-based materials have a suitable band gap, many reactive sites and high chemical stability, and are thought to be the best materials for eliminating a variety of contaminants from wastewater, organics, and heavy metal ions. Additionally, they have been extensively used in the fields of pollutant removal and water remediation.

2.1.2 g-C₃N₄-based Materials for Removing Organic Pollutants

Numerous hazardous and flammable contaminants, including pesticides and dyes have been discharged into environment, resulting in significant damage. Furthermore, one of main obstacles in field of environmental repair is now pollution. g-C₃N₄-based materials are primarily used in adsorption, photocatalysis, and synergistic adsorption, and photocatalysis treatment to remove organic pollutants from wastewater.

2.1.3 Metal/g-C₃N₄- Heterostructure

Generally speaking, it is a good idea to decorate g-C₃N₄ with noble or non-noble metal nanoparticles (NPs) to increase its photodegradation activity by increasing visible light absorption and creating a coherent interface [66]. To date, numerous researchers have altered g-C₃N₄ by adding metal nanoparticles (such as Ag, Au, Pt, Pd, and Ni) to its surface in order to remove organic contaminants from wastewater that is exposed to visible light [67, 68]. Yang and colleagues produced Ag/g-C₃N₄ by employing AgNO₃ and urea as precursors and silver sources, respectively, in a combined thermal polymerization and photo-deposition procedure. Heterostructure formation resulted from sphere-like Ag NPs

being uniformly loaded on the g-C₃N₄ surface following exposure to a 300 W Xe lamp. Ag/g-C₃N₄ clearly showed an increase in photocurrent and an extension of the visible light response from 450 nm to 800 nm when compared to pure g-C₃N₄. This suggested that higher light absorption and quicker charge separation upon g-C₃N₄'s close contact with Ag resulted in higher photodegradation efficiencies for methyl orange (MO) and p-nitrophenol (PNP). Additionally, Ag NPs could be widely distributed on g-C₃N₄ in the presence of NaBH₄ as a reducing agent [69, 70]. According to Tian et al., the agglomeration of excess Ag as e-h⁺ recombination sites caused a noticeable decrease in the photocatalytic activities of these samples with increasing Ag NPs contents after the Ag loading amount was increased to 0.048% [70]. Ag₄₈/C₃N₄ showed the highest photocatalytic activity at the ideal Ag loading amount (0.048%) and could completely degrade rhodamine B (RhB) under visible light irradiation in 60 minutes, whereas only 30% was removed for raw g-C₃N₄ after 180 minutes [70].

2.2 Techniques to Remove Tetracycline

2.2.1 Adsorption

Adsorbent-based wastewater treatment has emerged as one of the most successful techniques. The excellent characteristics of g-C₃N₄-based materials include their high specific surface area, an abundance of functional groups, and active sites. These interactions, which can include hydrogen bonding, hydrophobic interaction, electrostatic attraction, and others, allow the materials and pollutants to effectively remove organic pollutants from wastewater. Furthermore, the structure of organic pollutants, the solution environment, and the functional groups and structures on the surface of g-C₃N₄-based materials are all strongly correlated with the adsorption performance [71]. g-C₃N₄'s multifunctional groups, defect sites, and 2D layered structure make it a superior adsorbent. Strong electrostatic attraction allowed the two-dimensional porous g-C₃N₄ nanosheets produced using an acidic hydrothermal process to perform well in selectively adsorbing anionic methyl orange [9]. Additionally, rhodamine B, methyl orange, and other organic dyes demonstrated good adsorption performance at the g-C₃N₄-ZnO@graphene aerogel heterojunction, providing a solid foundation for additional photocatalytic degradation

[72]. At a pH of 6, the g-C₃N₄/MoO₃ nanocomposites, which were created using the co-precipitation method, demonstrated an adsorption capacity of 162 mg/g⁻¹ for 300 mg/L⁻¹ diclofenac [73]. A one-step hydrothermal method was used to fabricate the Cu₂MoS₄/g-C₃N₄, which has a unique flower structure. This material demonstrated good cycle stability and higher adsorption properties than other adsorbents, with rhodamine B adsorption reaching 420.2 mg/g⁻¹ [60]. However, because organic molecular structures are so similar, g-C₃N₄-based materials still face difficulties in the selective adsorption of organic pollutants [71].

2.2.2 Photocatalysis

When exposed to visible light, g-C₃N₄-based materials with an appropriate optical bandgap and strong light absorption capacity can effectively mineralize organic pollutants into non-toxic compounds like CO₂ and H₂O. Several researchers have investigated its use in water remediation. After 15 minutes of exposure to visible light, the porous g-C₃N₄ nanosheets made from the thermal condensation of melamine and cyanuric acid exhibited excellent degradation activity against tetracycline (above 60%) and rhodamine B (100%), primarily because of the superoxide radicals and holes produced by the photocatalytic process [62]. The Eu(III)-doped g-C₃N₄ has a higher carrier separation efficiency and tetracycline and rhodamine B degradation rates in wastewater as high as 82% and 98%, respectively, thanks to the synergistic effect of Eu(III) doping and hollow structure [74]. Furthermore, the Ag-deposited g-C₃N₄ shows a 3.15-fold increase in bisphenol A degradation efficiency compared to the pristine g-C₃N₄ because of the Schottky barrier formation at the interface, which facilitates the separation of photogenerated carrier [75]. The g-C₃N₄/CdS/Bi₄O₅I₂ heterojunction offers several pathways for photogenerated charge transfer and has the ability to break down acetaminophen at a rate of 80% in less than 25 minutes [76]. Additionally, Li et al. used the as-prepared CDs/g-C₃N₄/SnO₂ composites for the photocatalytic degradation of indomethacin under visible light irradiation, utilizing the special up-conversion photoluminescence properties and effective charge separation ability of CDs. The degradation rate was 5.62 times higher than that of pristine g-C₃N₄ [77].

2.2.3 *Adsorption and Photocatalysis Synergistic Treatment*

Due to their superior structural qualities, g-C₃N₄-based materials also exhibit synergistic adsorption and photocatalysis of organic pollutants in wastewater (first enriching and adsorbing organic pollutants, followed by photocatalytic decomposition and mineralization of organic pollutants). This can effectively address issues with adsorption saturation and regeneration and achieve long-term recycling. In a two-step hydrothermal process, a 3D–2D–3D BiOI/porous g-C₃N₄ /graphene hydrogel composite photocatalyst was created. It demonstrated good adsorption performance and charge separation ability, as well as straightforward recycling. The synergistic degradation efficiencies of methylene blue and levofloxacin hydrochloride when applied to a static wastewater system were 7.2 and 2.7 times higher than that of BiOI, respectively [78].

2.2.4 *Membrane Technology*

Membrane is selective barrier to remove the particle from incoming stream. Today membrane hybrid system is used for removing pharmaceutical. MBR is a replaced version of activated sludge technology. MBR is essentially composed of convention treatment facility mostly biological treatment coupled with physical liquid and solid separation membrane system. Membrane bioreactors combine membrane techniques like microfiltration or ultrafiltration with biological wastewater treatment methods like activated sludge. These days, a lot of wastewater treatment facilities in cities and businesses use these technologies. MBR is better as compared to activated sludge technology in following ways:

1. can manage high flow rate as compared to activated sludge.
2. has high volumetric rates
3. has high hydraulic retention times
4. has high solid retention time
5. leads to less sludge production
6. It has potential for denitrification/nitrification.

Most of the applications to treat wastewater by using MBR come in two types of configurations. As shown in figure the diagram of left side represents the submerged MBR system whereas the diagram of right side is known as external MBR configuration.[79-81]

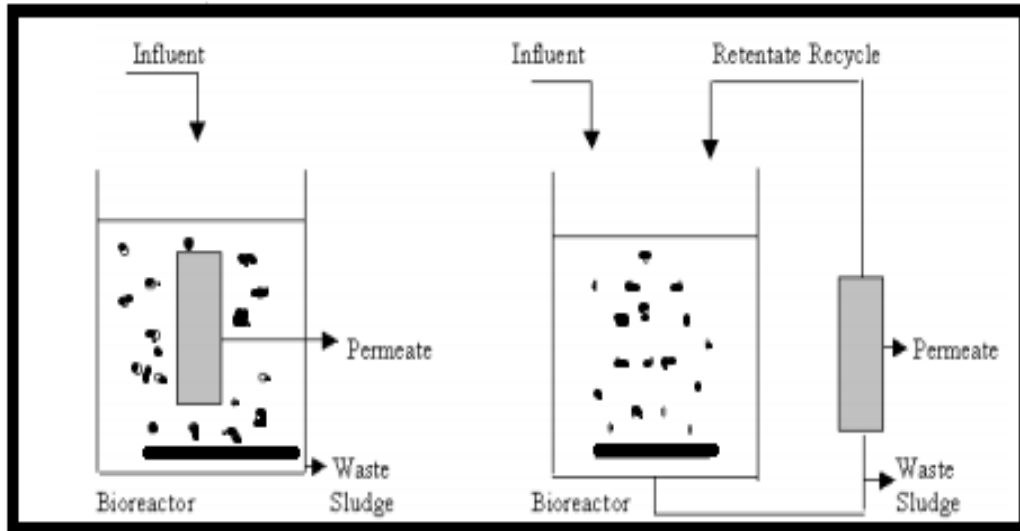

Figure 2.1: Membrane Bioreactor System

2.2.5 Activated Carbon

Removal of synthetic and natural organic contaminant have long been attained by use of activated sludge. Packed bed filter is used to support powder or pellet form the activated carbon. Phenomena of adsorption and filtration are simultaneously used in granular activated carbon. Regeneration of adsorbent and environmental problem are main concerns for this process [82]. Biological activated carbon used the coupled effect of adsorption and biodegradation to purify water. For such process activated carbon work as carrier. Carrier activated carbon major role is to accumulate the friendly microorganism on its surface such that a number of microorganism get accumulate on activated carbon[83]. This is done by providing proper parameters such as temperature and nutrient on surface of activated carbon to allow the suitable and friendly microorganism grown on surface of activated carbon. Due to favorable condition microorganism can useful grown and reproduce on surface of activated carbon. Such a combination will exert combined effect of adsorption

and biodegradation due to action of activated carbon high surface area and bio action of microorganism respectively. Activated carbon can adsorbent dissolved oxygen on its surface and microorganisms will grow on this dissolved oxygen. Such a combination will destroy and degrade pharmaceutical and bio organism harmful to water purification. [84, 85].

2.2.6 *Disinfection by Ozonation*

The decomposition of ozone in water gives radical i.e., OH, and hydrogen peroxide. Both species have great oxidation capability. It is extremely important to the disinfection of water process. Bacteria are killed by because of protoplasmic oxidation of ozone [86]. The efficiency of disinfection process depends upon probability of target pathogen, pharmaceuticals. The feed gas source for the ozone generator is air or pure oxygen, which is fed through it at a set flow rate. Electrical discharge or electrical energy is used to create ozone by passing current through the oxygen [87]. After generation of ozone, it is used as feed inside the wastewater chamber contain organic waste. Here sufficient time is provided for the contact of wastewater and ozone. Optimal ozone dosage is maintained for efficiency of process. Main parameters are ozone dosage, mixing and contact time. Medium to large size plant use the ozone process.[88]

2.3 **Other Hybrids for Tetracycline Removal**

Many researchers made hybrids of different catalysts to enhance the adsorption ability and as a result an increment in the removal of tetracycline can be seen. A researcher Hyun Min Jang et al prepare hybrid from agriculture waste (activated biochar through NaOH) for the same case and he concluded that the findings of the batch experiments showed that with its large BET surface area ($796.50 \text{ m}^2/\text{g}$), high hydrophobicity, and pore volume ($0.087 \text{ cm}^3/\text{g}$), NaOH-activated AF-BC (BCA) was effective at adsorbing TC in water ($Q_m = 302.37 \text{ mg/g}$). figure 1 shows the adsorption of different catalyst used by the author [89]. Jang et al. (2018b) demonstrated a significant increase in surface area (“685.64-fold increase; from $1.4 \text{ m}^2/\text{g}$ to $959.9 \text{ m}^2/\text{g}$ ”) and Q_e value for TC adsorption (9.34-fold increase; from 29.42 mg/g to 274.81 mg/g) following the NaOH activation of

pinewood virgin BC [90]. Once beetroot pulp was steam activated, lvarez-Torrellas et al. (2016) found that the Q_e value for tetracycline adsorption had dramatically risen (“288.3 mg/g for steam-activated beetroot pulp BC”) [91]. John Hoslett et al synthesize biochar from the food and trees trimmings in a heat pipe reactor. From his experiments he finds out that the produced biochar has outstanding ability to bind tetracycline up to 9.45 mg/g in the conditions mentioned. It was determined that the greatest explanation was given by the Freundlich isotherm., inferring a heterogeneous adsorbent. Tetracycline adsorption properties of the biochar matched those of biochar produced in similar conditions reported in previous studies. Hence, it is possible to lessen the amount of antibiotics in the environment by employing biochar produced by a heat pipe reactor utilizing agricultural waste or food/organic feedstock from residences and businesses [92].

Duanyi Zhang et al used activated carbon of high porous nature for the removal of TC from water. PAC₄ was immersed in TC solutions at different initial concentrations (“60, 75, 100, 125, 150, 175 and 200 mg/L”) for his experiments. As Fig. 6 illustrates, the adsorption capacity increases significantly from 60 to 125 mg/L. As the concentration rises, the adsorption curve flattens, indicating saturated adsorption takes place. He further finds out that the absorption capability is highest at PH value of 3 and if we further increase the Ph to 7 the absorption becomes weak as as shown by figure 6. Also the a drop in the adsorption concentration occur when he increase the concentration of different salts from 0.01 to 0.1 molar [93].

2.4 Photochemical Activity

Figure 2.2: Adsorption kinetics of TC at two distinct initial concentrations for BCR

Figure 2.3: (a) Impact of initial concentration on TC adsorption, (b) impact of solution pH on TC adsorption (c) impact of solution ion strength on TC adsorption

Table 2.2: Different catalysts and their photocatalytic efficiency

S.No	Materials	Loading Catalyst	Antibiotic molecule	Condition	Photocatalytic efficiency	Times (minutes)	Reference
1	Thiourea	0.5 g/L	TC-HCl	Sunlight	70%	120	[94]
2	Melamine	0.5g/L	TC-HCl	Sunlight	63%	120	[94]

3	Urea		TYL	300 W Xe Lamp	99%	120	[95]
4	Dicyandiamide	0.5g/L	OFL	500W			[96]
5	Melamine	1g/L	TC	35 W Xe Lamp	86%	240	[97]

9	L-cysteine	0.5g/L	SMZ	300 W Xe Lamp	99.7%	60	[101]

2.5 g-C₃N₄ as Photocatalyst

Global public health is now seriously threatened by environmental contamination due to the world's fastest-growing population and industrialization. Ever since Frank and Bard's 1977 initial report on the remediation of environmental pollutants (CN⁻ in water) using heterogeneous photocatalysis on titania [102]. Heterogeneous photocatalysis has been extensively employed in the purification of various environmental elements, including water and air [103, 104]. Moreover, numerous strategies have been employed to raise the photodecomposition efficiency of pollutants over g-C₃N₄-based semiconductors [105]. Because of g-C₃N₄'s special qualities—such as its enticing electronic structure, n-type semiconductor status, non-toxicity, earth abundance, and modulated band gap of 2.7 eV—it is a good option for photocatalytic water purification assisted by visible light.

Figure 2.4: Pie chart showcasing the various photoactive uses of g-C₃N₄. [140]

2.6 Mechanism

2.6.1 Adsorption Mechanism, Kinetics, And Thermodynamics

Adsorption typically takes place during the water remediation process. The primary functional groups of g-C₃N₄, which are produced by directly calcining nitrogen-rich precursors, are -NH₂/-NH-/-N-. By creating a heterojunction, these functional groups, as well as others like carboxylic acid and hydroxyl, can be added to enhance the adsorption efficiency for various pollutants. The adsorption mechanism of materials based on g-C₃N₄ is typically examined from two angles: (1) the way pollutants and materials based on g-C₃N₄ interact during the adsorption process; (2) the adsorption process's thermodynamics and kinetics.

Typically, interactions like surface complexation, hydrogen bonding, π - π interaction, and electrostatic attraction cause the adsorption behavior between pollutants and g-C₃N₄-based materials. Surface complexation and electrostatic attraction are typically the primary interactions for the treatment of heavy metal ions and surface-charged organics; these can be verified by FTIR spectroscopy, XPS spectroscopy, and other analyses. Furthermore, one significant element influencing the adsorption efficiency of materials based on g-C₃N₄ is the pH of the solution. It was discovered that the primary cause of the cationic rhodamine B treatment with the negatively charged Cu₂MoS₄/g-C₃N₄

composite is the electrostatic attraction interaction. The adsorption capacity was relatively unaffected by low pH, but at pH = 9, rhodamine B's carboxylic acid groups dissociated faster and the nitrogen groups deprotonated, increasing their electrostatic repulsion and decreasing the adsorption performance [106]. The surface of the g-C₃N₄/β-CD material obtained by β-cyclodextrin modification had many functional groups and active sites (such as C double bond O, C-O-C, -OH, etc.), as indicated by FTIR and XPS spectra. The surface characteristics of g-C₃N₄/β-CD and the degree of protonation of oxygen-containing functional groups may be impacted by pH when treating Pb(II) wastewater. It may also have an impact on Pb(II)'s morphological distribution. When pH is less than 7.0, Pb²⁺ and Pb(OH)⁺ predominate, and the primary adsorption processes involve surface complexation and electrostatic attraction between Pb(II) and hydroxyl or heptazine ring; conversely, when pH is greater than 7.0, Pb(II) primarily undergoes surface complexation with hydroxyl groups. Furthermore, the adsorption behavior of methyl orange on g-C₃N₄/β-CD was primarily attributed to hydrogen bonding and van der Waals forces [107]. Rashid et al. also discovered that the “hydrogen bonding interaction” and “π-π interaction” were the primary causes of the diclofenac adsorption by “g-C₃N₄/MoO₃”. This was further supported by the “diclofenac's π-π stacking” on the nanocomposite and the propensity of -NH to increase the adsorption of diclofenac molecules [73].

2.6.2 Photocatalytic Mechanism

Much attention has also been drawn to the superior photocatalytic treatment performance of materials based on g-C₃N₄. To modify materials to increase photocatalytic activity and enhance wastewater treatment procedures, it is crucial to comprehend the pertinent photocatalytic mechanism. g-C₃N₄ is an n-type semiconductor that responds to visible light and possesses a “photocatalytic degradation mechanism” like heterogeneous catalysis for pollutants in aqueous solution. It consists primarily of five steps: (1) the contaminants are moved from the solution to g-C₃N₄'s surface; (2) Pollutants are adsorbed by g-C₃N₄; (3) pollutants undergo a photocatalytic reaction on the surface of g-C₃N₄; (4) The compounds that break down are removed from the surface of g-C₃N₄; (5) The breakdown products find their way into the solution [108].

The HOMO energy level of the nitrogen and carbon Pz orbitals is joined with the VB of g-C₃N₄. At zero energy, the higher-energy CB is empty and the lower-energy VB is fully occupied by the e⁻ [109]. Fig. 2 depicts the “photocatalytic degradation process” of organic pollutants on the surface of g-C₃N₄. g-C₃N₄ will absorb light energy when exposed to light. The material will become excited when the energy surpasses its threshold, resulting in the production of photogenerated holes (h⁺) and electrons (e⁻). As the relatively stable electrons (e⁻) and holes (h⁺) accumulate in the valence band (VB), the electrons in the conduction band (CB) will experience an influx due to excited transitions. The electrons and holes produced by photolysis then move to the catalyst surface. Given that g-C₃N₄ has valence band potential (EVB) of about 1.3 eV and conduction band potential (ECB) of approximately 1.4 eV, respectively [110] Since the “O₂/•O²⁻” redox potential is -0.33 eV relative to the normal hydrogen electrode, photogenerated electrons can readily combine with adsorbed O₂ molecules to produce •O²⁻. However, compared to the “EVB of g-C₃N₄”, the “•OH/OH⁻ redox potential (+1.99 eV)” is significantly higher, meaning that the residual h⁺ cannot react with H₂O and OH⁻ to produce •OH [111]. Nevertheless, by reducing the adsorbed O₂ via a “multi-electron reaction process”, a tiny amount of “•OH” can still be produced [112], [108], [42]. In the end, the process can break down organic pollutants into harmless byproducts like “CO₂ and H₂O” thanks to the production of “h⁺, •O²⁻ and •OH”.

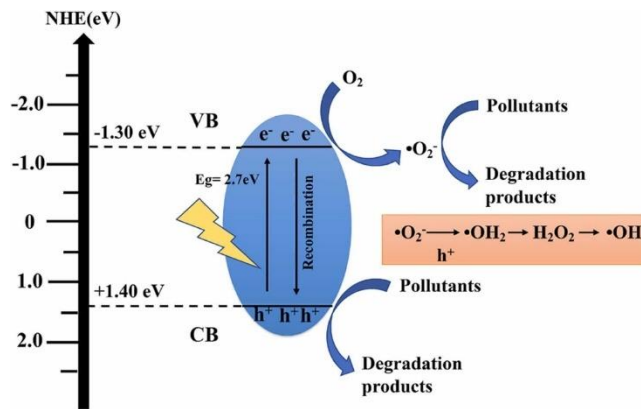

Figure 2.5: Mechanism of using g-C₃N₄ as photocatalyst in the photocatalytic destruction of contaminants under light irradiation [148].

2.6.3 Binary Hybrid Nanocomposites

In order to overcome the application limitations of g-C₃N₄ in photocatalysis, a highly effective modification technique known as constructing binary photocatalytic systems has been introduced. In the last decade, there has been a notable surge in the investigation of “heterostructure photocatalysts” utilizing g-C₃N₄ as a base [113]. For enhanced photodegradation activity through improved spatial separation of charge carriers, it is crucial to establish suitable band structures at the interfaces between g-C₃N₄ and metal particles, inorganic semiconductors, or conducting materials. [69, 114, 115]. This indicates that the creation of heterostructures can serve as a novel approach to modifying g-C₃N₄, thereby broadening its range to incorporate new visible light-driven nanocomposites for applications in solar energy conversion and pollutant degradation.

CHAPTER 3: MATERIAL AND METHODOLOGY

3.1 Catalyst Synthesis

3.1.1 *Synthesis of CdS nanorods*

The synthesis of CdS nanorods involved the utilization of the solvothermal method. A mixture was prepared by combining 1.52 grams of thiourea and 3.088 grams of cadmium nitrate tetrahydrate with 50 ml of ethylene diamine. The resulting solution was continuously stirred for 10 minutes. The mixture solution was then put into a “Teflon-lined stainless-steel autoclave” and heated to 180°C for 12 hours. Subsequently, the autoclave solution was allowed to reach room temperature. Centrifugation was used to separate the resultant mixture, which was then rinsed three times with ethanol and three times with deionized water. The precipitates obtained at the end of the washing process exhibited a yellow color and were then dried in an oven for 12 hours at 80°C. Ultimately, the material that had dried was ground into fine particles.

3.1.2 *Synthesis of g-C₃N₄*

Using an alumina crucible and 10 grams of melamine, the synthesis of g-C₃N₄ was initiated. After that, this crucible was heated in a muffle furnace to 550°C and kept there for three hours. It was then allowed to cool naturally. A light-yellow precipitate of g-C₃N₄ was produced during the cooling process, and it was later ground into a fine powder.

3.1.3 *Synthesis of ZIF-67*

The “solvothermal” method was employed in the synthesis of “ZIF-67”. 50 milliliters of methanol were used to dissolve 0.656 grams of “2-methylimidazole” and 0.585 grams of “cobalt nitrate hexahydrate” in separate beakers. For ten minutes, magnetic stirring was applied to each solution. Both solutions were then combined and agitated for a further thirty minutes. The resulting mixture was left to age for a duration of 72 hours.

After this aging period, the solution was subjected to vacuum filtration using a nylon filter membrane. This process yielded purple-colored precipitates of ZIF-67.

3.1.4 Synthesis of g-C₃N₄@CdS

To synthesize g-C₃N₄@CdS hybrid, the solvothermal method was employed. Initially, 5 mg of the as-synthesized pure g-C₃N₄ catalyst was introduced into 50 ml of ethylene diamine and agitated for half an hour. Following this, a solution mixture was prepared by adding 3.008 grams of cadmium nitrate tetrahydrate and 1.52 grams of thiourea to the g-C₃N₄-ethylene diamine solution, which was then stirred for 10 minutes. The resultant mixture was then put into a “Teflon-lined stainless-steel autoclave” and heated to 180°C for 12 hours. After the heating process, the solution in the autoclave was permitted to cool down to ambient temperature. Centrifugation was used to separate the resulting mixture, which was then rinsed three times with ethanol and washed three times with deionized water. Yellow-colored precipitates obtained at the end of the washing procedure were dried for a while at 80°C. 12 hours in an oven. The dried material was then finely ground into fine particles. The same experimental procedure was repeated for 10 mg and 15 mg of g-C₃N₄ to synthesize hybrids with CdS.

3.1.5 Synthesis of CdS@ZIF-67

To synthesize a CdS hybrid with ZIF-67, the solvothermal method was employed. Initially, 5 mg of CdS was added and agitated for ten minutes in 50 milliliters of methanol. Following that, 0.656 grams of 2-methylimidazole were combined with the same mixture and agitated for an additional 10 minutes. In a separate beaker, 50 milliliters of “methanol” were used to dissolve 0.585 grams of “cobalt nitrate hexahydrate”, and the mixture was also stirred magnetically for ten minutes. Following that, both solutions were integrated and further stirred for half an hour. The resulting mixture was left to age for a period of 72 hours. Following this aging period, the solution was subjected to vacuum filtration using a nylon filter membrane. This process yielded purple-colored precipitates of the CdS@ZIF-67 hybrid. The same experimental procedure was repeated for 10 mg and 15 mg of CdS to synthesize hybrids with ZIF-67.

3.2 Characterization Techniques

The STOE GERMANY diffractometer was used for “X-Ray Diffraction” (XRD) analysis, utilizing copper (Cu) material with $k\alpha$ radiation and a wavelength of 1.5406 Å. The purpose of XRD was to identify the catalyst by examining its diffraction pattern. The catalyst's morphology was examined using “scanning electron microscopy” (SEM) with the JEOL JSM-64900 device. Prior to SEM characterization, a thin conductive layer of gold was applied through sputter coating onto the catalyst and its respective hybrids. To examine photocatalytic activity and degradation, a Cary-100 BIO UV-VIS spectrophotometer was utilized.

3.2.1 SEM

Sample details can be obtained with a scanning electron microscope, or SEM, which is widely studied. It consists of a beam of light. The electrons that make up the SEM beam have a tremendous amount of energy. This beam is applied to the sample surface. In this manner, the sample's structural aspect is disclosed.

An electron beam creates specific features on the material's exterior. The information about the morphology of the sample is transferred using data analyzers. Most of the data is collected inside and outside of the sample's designated range. This device is used to examine and comprehend desired points across the sample's exterior. The SEM's potential is functional like that of the probe electron microscope. By correctly using SEM, morphological and topological features of the sample can be investigated. We're able to SEM can reveal the dimensions, surface and bulk properties, and shape of the sample. When the SEM's light beam incidence causes a difference in the kinetic energy of the incident and transmitted electrons during this process. An image of the sample under investigation is created because of numerous electrons being scattered and secondary electrons being produced. The topography, shape, and other relative features of the samples are revealed by this phenomenon. The influence of the second electron is what causes phase differences. The interaction between an electron in the sample's orbit and an electron in the SEM's striking beam produces X-ray radiation.

3.2.2 XRD

XRD can provide information about the sample's crystallites. It provides important details about the sample. Important characteristics that this machine reveals include crystallography, size of crystal, and Miller indices. Though smaller than UV, X-ray wavelengths are larger than Y-ray wavelengths. In comparison with x-rays, UV-rays have weaker photon energy, whereas Y-rays have higher photon energy in relation to x-rays. The wavelength magnitude of x-rays is 1 \AA . XRD is based on the idea that electron transitions occur because of an electron striking a metal. Copper or molybdenum are the target metals used to generate X-rays. Ionization happens when a metal is exposed to radiation because electrons are emitted from its internal shell or because this process knocks electrons out of their orbits. Therefore, the knocking phenomenon causes a void to form in the metal's orbit. An electron in an orbital with a higher energy and position than the orbital of the knocked-out electron will attempt to fill the void. This falling electron will release radiation that can be used to accomplish the goal, specifically X-rays.

A thorough mathematical relationship called Bragg's law is used to effectively explain the diffraction phenomenon. It is frequently used in diffraction of crystals. FWHM and crystallite size are determined with the help of data provided by Bragg's law. Any distinct crystalline material subjected to X-ray diffraction (XRD) will produce a specific characteristic X-ray spectrum.

3.2.3 UV-Vis Spectrophotometry

We use spectroscopic measurement equipment, also known as UV-Vis spectroscopy, to examine the sample's response to the application of the visible and ultraviolet ranges of the electromagnetic spectrum. Every material has a unique molecular configuration, with functional groups that have distinctive UV-visible absorption edges. Information about the material's UV-vis response is displayed when a difference in absorption occurs. Using this method, minute pollutants in a solution are revealed.

Peaks that differ from the material's are providing information about the contaminants. It can be used to monitor the continuous profile of a chemical reaction. For

instance, it is highly suitable for uninterrupted analysis of the photocatalytic removal process's progress. The foundation for the quantitative analysis of solution behavior using UV-VIS is the Beer-Lambert law.

Variations in the specimen's UV-vis behavior during the investigation will reveal the spectrum produced by the UV-Vis spectrometer. This spectrum is compared to previously identified and computed spectrums. Certain wavelength ranges have absorption edges for distinct functional groups. When there is a chance that an atom contains pi or non-binding electrons, electrons are excited to higher orbitals. since UV-Vis light interacts with these electrons. Ultraviolet-visible spectrophotometers have been used in many experiments recently. In comparison with chemical reaction reagents, it offers an easier process. This procedure makes it simple to investigate adsorption experiments. By using this technique, different reactions that arise from the adsorption of both organic and inorganic dye on the adsorbent surface can be studied. Furthermore, photocatalysis reactions are frequently performed using the appropriate technique. The dye and pollutant exhibited a sharp trend by responding differently to the light from the UV-Vis spectrometer.

Using this method, the kinetics of dissolution of various polymers and sand-coated composites were examined. This method can be used to predict both the speed and slowness of a reaction. When examining first order, second order, and pseudo order reactions, this approach is highly helpful. The reaction parameter is easily found by closely plotting the data. UV-vis radiation analysis is a useful tool for chemical engineers looking to design reactors efficiently. Ultimately, this will assist the research student in identifying the weaknesses in reaction monitoring when using chemical reaction engineering in research methodology. Today's modern laboratories are well equipped with this type of technique to qualitative and quadrative investigate the reactor feature. When the difference between HOMO and LUMO is much low. In such scenario low energy is attained form HOMO for transition to happen to higher state which is also called as LUMO. The longer wavelengths of radiation are what cause the excitation because they have a specific energy that allows them to do so. When the gap between the HOMO and LUMO is equivalent to a band gap-sized packet of photons, electrons migrate from the HOMO to the LUMO. The

term " $\sigma - \sigma^*$ " refers to this type of electron transfer (nonbonding sigma to bond sigma molecular orbital). Cuvettes are used in UV-VIS spectroscopy to reveal sample behavior. In this process, two types of cuvettes—quartz and glass cuvettes—are utilized. Economically speaking, quartz is very costly, has very little transmittance loss, and is highly specialized. The UV-vis machine belongs to multiple classes. Both single and double beams are present. There is only one reference point made in a single beam. In contrast, double beam makes use of two standard mixture references and measurements.

3.3 Photocatalytic Experiment

Photocatalytic experiments were conducted to assess pure CdS, ZIF-67 and g-C₃N₄ their nanohybrids' photocatalytic activity using a 100 mg/L tetracycline solution at room temperature. A bottleneck flask was filled with 1000 mL volume deionized water and 100 mg of tetracycline was added, followed by stirring for half an hour to ensure a homogeneous mixture. 100 mg of the corresponding catalyst was added to a beaker containing 100 mL of the solution. To maintain complete darkness, aluminum foil was used to wrap the beaker. After that, the mixture was continuously stirred for 30 minutes while being stored in a wooden box to accomplish the equilibrium between "adsorption and desorption". After 30 minutes, the photocatalytic reactor bulb was turned on to start the photocatalytic process. The overall duration of the degradation experiment was 210 minutes. At 20-minute intervals, samples were collected using a syringe equipped with a nylon filter at the tip. For the degradation analysis of the tetracycline solution, characteristic peaks at 275 nm and 350 nm were monitored using a UV-Visible spectrophotometer. These peaks corresponded to tetracycline.

CHAPTER 4: RESULTS AND DISCUSSION

4.1 XRD Analysis

The STOE θ - θ diffractometer was operated with a 40-mA power supply and 45 kV to analyze crystallography and phases of the samples. The instrument utilized a copper anode to generate fluorescence ($K\alpha$ radiation with $\lambda=1.5406 \text{ \AA}$) for phase analysis. The range of the XRD angle (2θ) was 10 to 80 degrees. XRD patterns for pure g-C₃N₄, pure CdS, and their hybrids are exhibited in the respective figures, while XRD patterns for Pure ZIF-67, pure CdS, and their hybrids are shown in the corresponding figures.

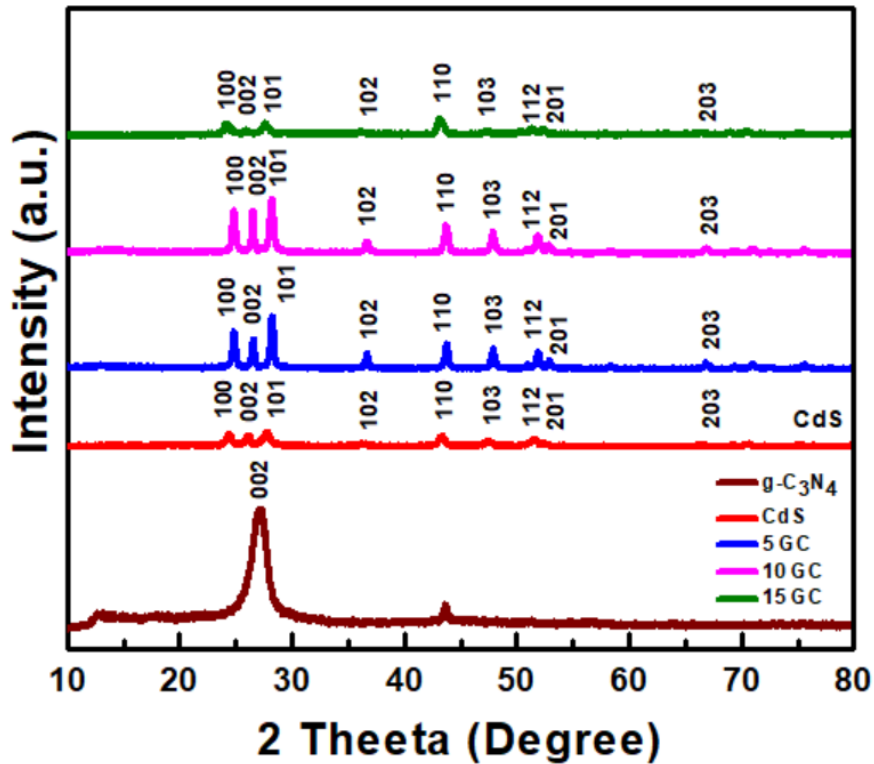

Figure 4.1: XRD pattern of pure CdS, pure g-C₃N₄, and their hybrids (5 mg, 10 mg, and 15 mg) g-C₃N₄@CdS.

Figure 4.2: XRD Pattern of pure ZIF-67, pure CdS, 5 mg CZ, 10 mg CZ & 15 mg CZ.

X-ray Diffraction (XRD) analysis was employed to ascertain the crystalline structure of our synthesized samples and evaluate their degree of crystallinity, whether they exhibited a crystalline or amorphous nature. Figure 10 (i) presents XRD patterns of pure “graphitic carbon nitride” ($g\text{-C}_3\text{N}_4$), pure “cadmium sulfide” (CdS), and their prepared hybrids at various weight percentages. In Figure (a), the XRD pattern of Pure $g\text{-C}_3\text{N}_4$ clearly exhibits characteristic peaks of $g\text{-C}_3\text{N}_4$ at a 2θ value of 27.4, corresponding to the (002) plane. This peak aligns with JCPDS card number 87-1526, as documented in the literature. Figure (b) displays the XRD pattern of pure CdS, revealing peaks on planes (100), (002), (101), (102), (110), (103), (201), and (203) at 2θ positions of 24.7, 26.2, 28.089, 36.33, 43.6, 47.44, 50.8, and 66.4, respectively. These peaks are consistent with

hexagonal cadmium sulfide, as per JCPDS card number 41-1049, which corroborates previous findings in the literature. Figures (c), (d), and (e) represent the XRD patterns of CdS and g-C₃N₄ hybrids. In these hybrid patterns, all the characteristic peaks of pure cadmium sulfide are visible at 2θ values of 24.7, 26.2, 28.089, 36.33, 43.6, 47.44, 50.8, and 66.4, corresponding to planes (100), (002), (101), (102), (110), (103), (201), and (203).

Additionally, the prominent peak of g-C₃N₄ at 2θ value 27.4 on the (002) plane merges with the peak at the same position and plane as cadmium sulfide. This confirms the successful synthesis of the prepared hybrid. Moreover, from these peaks, it is evident that CdS dominates the hybrid, as it completely suppresses the g-C₃N₄ particles, corroborated by SEM images. Figure 3 (ii) illustrates the XRD patterns of ZIF-67 hybrids with CdS. In Figure (f), the XRD pattern of Pure ZIF-67 displays peaks at 2θ values of 7.33, 10.348, and 12.687, corresponding to planes (110), (200), and (211). These peaks align with JCPDS card number 01-089-2803, as also observed in literature. Patterns (h), (i), and (j) show the XRD patterns of the hybrids of ZIF-67 with CdS. In these hybrid patterns, prominent peaks of ZIF-67 are visible on planes (110), (200), and (211).

Importantly, there are no discernible peaks of CdS in these hybrids, indicating that the cadmium sulfide particles have penetrated the pores of ZIF-67. This is further confirmed by SEM images. The crystal sizes of all the fabricated catalysts were calculated using the Scherrer formula and are presented in Table 3. Notably, the hybrid exhibited a smaller crystal size, which contributes to its superior activity compared to all the prepared catalysts.

Table 4.1: Average crystal size of all the prepared samples

Photocatalyst	FWHM	Peak Position	Crystal Size	Average Crystal Size	(nm)

ZIF-67 (Pure)	0.3311, 0.138, 0.661, 0.386	10.183, 12.330, 21.778, 26.234	247,615,124,216	307.25	30.725
CdS (Pure)	0.510, 0.364, 0.665, 0.510	24.352, 26.146, 27.070,43.354	162, 229,126,170	171.75	17.175
10 mg g- C ₃ N ₄ @CdS	0.255, 0.218, 0.255, 0.255	24.352, 26.146, 27.070,43.354	329, 388, 331, 346	348.5	34.85
5 mg g- C ₃ N ₄ @CdS	0.378, 0.378, 0.315, 0.220	24.083, 25.945, 27.536, 43.045	220,220, 266, 403	277.25	27.725
g-C ₃ N ₄ (Pure)	0.756, 0.378, 0.307	12.669, 26.945, 43.635	107, 221, 286	204.67	20.467
	0.146,0.146, 0.109,0.109	7.287, 10.329, 12.665, 17.973	577,578,791,796	685.5	68.55
15 mg g- C ₃ N ₄ @CdS	0.301, 0.167, 0.355, 0.201	24.781,26.500, 28.215,43.722	278, 513, 236, 444	367.75	36.775
5 mg CdS/ZIF-67	0.146,0.146, 0.182, 0.109	0.138, 0.138, 0.174, 0.101	577, 578, 459, 796	602.5	60.25
10 mg CdS/ZIF-67	0.109, 0.146, 0.109,0.109	7.291, 10.303, 12.652, 17.971	788,578, 791, 796	738.25	73.825
15 mg CdS/ZIF-67	0.100,0.100, 0.100, 0.100	7.291, 12.303, 12.652, 17.971	865, 867, 869, 874	868.75	86.875

The average crystallite size of ZIF-67 (Pure), CdS (Pure), 10 mg g-C₃N₄@CdS, 5 mg g-C₃N₄@CdS, g-C₃N₄ (Pure), ZIF-67 (Pure), 15 mg g-C₃N₄@CdS, 5 mg CdS/ZIF-67, 10 mg CdS/ZIF-67, and 15 mg CdS/ZIF-67 is 307.25Å (30.725nm), 171.75Å (17.175nm), 348.5Å (34.85nm), 277.25Å (27.725nm), 204.67Å (20.467nm), 685.5Å (68.55nm), 367.75Å (36.775nm), 602.5Å (60.25nm), 738.25Å (73.825nm), and 868.75Å (86.875nm) respectively.

4.2 Morphological Analysis with Elemental Analysis

Figure 4.3: SEM images of pure CdS, g-C₃N₄ and ZIF-67 respectively.

Morphological characteristics of fabricated catalyst was examined using a scanning electron microscope (SEM) from “JEOL (JSM-64900)”. Before SEM analysis, the samples underwent sputter coating with a thin conductive layer of gold. SEM imaging of “g-C₃N₄, ZIF-67, CdS, g-C₃N₄/CdS, and CdS/ZIF-67” hybrids are presented. In figure (a), CdS-NRs are depicted with a rod-like structure featuring consistent dimensions and a flat surface. On higher resolution Nano rods stacked, against each other are evident. This is possibly because of nucleation and growth of crystals. Moving to Figure (b), the SEM image exhibits morphological structure like flakes/lamellar sheets of pure g-C₃N₄, revealing porous structures with a notably high surface area. These stacking layers suggest similarity of g-C₃N₄ with graphite which is analogous of g-C₃N₄. Figure (c) showcases

well-defined cubic structures of ZIF-67. It shows rhombic dodecahedron crystals of ZIF-67 with smooth surfaces, clear edges and properly defined facets. Nano size crystal of as synthesized ZIF-67 was well separated from each other and there was no agglomeration.

Figure 4.4: SEM images of hybrids composed of g-C₃N₄ and CdS (d-f), and hybrids of CdS and ZIF-67 (g-i)

Scanning electron microscopy (SEM) is used to examine the morphology of CdS-NRs (Cadmium Sulfide Nanorods) and their hybrids with g-C₃N₄ and ZIF-67. Figures (d)-(f) present SEM images of hybrids composed of CdS and g-C₃N₄ and are clear manifestation of morphological characteristics of in situ grown sheets of g-C₃N₄ in CdS nanorods. In all these images, a uniform distribution of CdS nanorods can be observed alongside g-C₃N₄ nanosheets. Graphitic carbon nitride's presence has expanded the surface area, creating more interconnecting layers of g-C₃N₄ and exposing additional active sites of CdS. Similarly, Figures 7(i)-(k) represent SEM images of hybrids formed by combining

CdS with ZIF-67. In these figures, we clearly observe the growth of CdS rods on the cubic structures of ZIF-67, confirming the successful synthesis of these hybrids. The rhombic dodecahedron-shaped crystals of ZIF-67 exhibit a uniform distribution across the surface of CdS nanorods, likely attributed to the sonication process of CdS in a ZIF-67 solution. Additionally, structures resembling rod-like CdS with incorporated ZIF-67 are observed. ZIF-67 effectively envelops the nanorods of CdS from all sides, edges, and surfaces, resulting in a smooth appearance of the CdS rods. Nanorods of CdS can be clearly seen on high resolution. Furthermore, the activity of these hybrids is enhanced because of the resultant particles' larger surface area. As the amount of CdS increases, the cubic structures of ZIF-67 become more extensively covered by rods, leading to a corresponding increase in activity. ZIF-67, g-C₃N₄ and CdS appear under SEM comparable to literature when seen as individual components. However, appearance in hybrid is different.

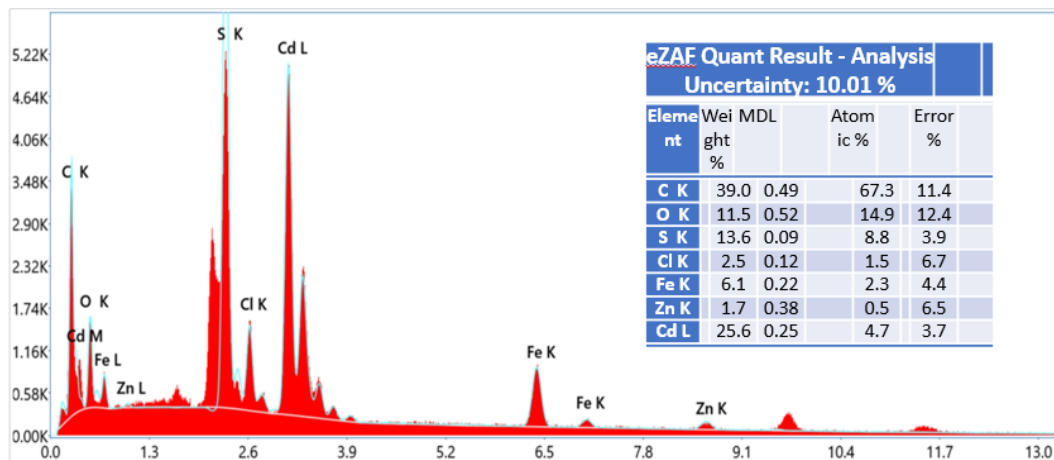

Figure 4.5: EDX of CdS Catalyst

Energy Dispersive X-ray (EDX) is performed to confirm that synthesized catalyst has all the necessary elements.

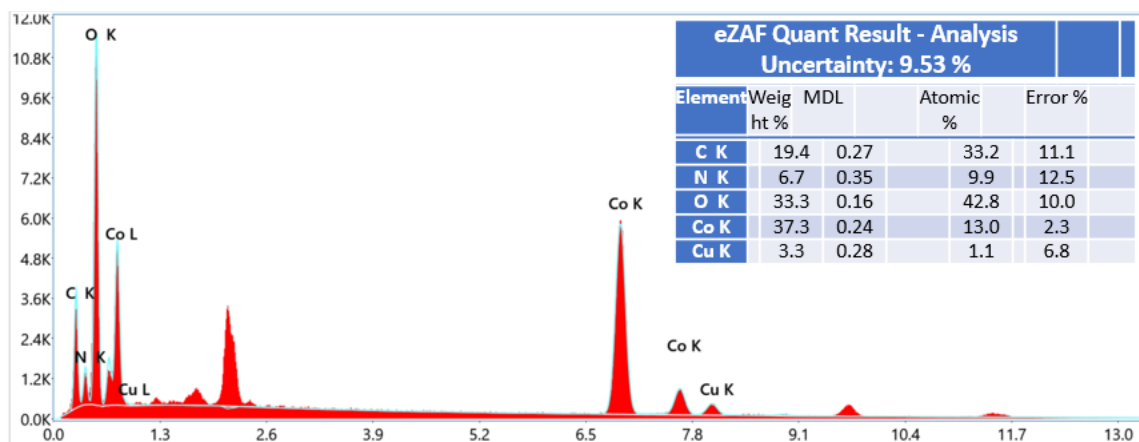

Figure 4.6: EDX of ZIF-67

4.3 Photocatalytic Degradation of Tetracycline

4.3.1 Kinetic Study of Reactions

Figures 15(a-c) display the absorbance spectra of tetracycline over time in the presence of photocatalysts 5CZ, 10CZ, and 15CZ, respectively. The CZ catalyst was synthesized by maintaining a constant ZIF-67 concentration and varying the CdS concentration, resulting in 5 mg, 10 mg, and 15 mg CdS for 5CZ, 10CZ, and 15CZ, respectively. A 100 mg catalyst was introduced into the tetracycline solution. To reach adsorption equilibrium, for thirty minutes, the solution was kept in the dark. Characteristic peaks of tetracycline reached saturation values. Afterward, 2 ml of the solution was taken out of the beaker to measure UV absorbance, and then the lamp was turned on. Among these, 15CZ emerged as the most effective catalyst, exhibiting a remarkable 96.13% removal of tetracycline within 110 minutes using only 100 mg of the nanohybrid.

The degradation of tetracycline is primarily governed by both photocatalysis and adsorption mechanisms. A significant portion of degradation takes place within the first 30 minutes. Following this period, CZ begins to absorb photons of light, leading to a rapid degradation owing to its photoactive properties. In total, CZ effectively eliminates 96.13% of tetracycline, surpassing all other synthesized catalysts. Type 2 heterojunction formed on

ZIF-67 could be the reason for high removal of tetracycline by 15CZ. Adsorption enhancement in initial 30 mins contributes to overall photocatalytic degradation.

High degradation up to 96.13% is due to enhancement in meso-porosity and high number of active sites on the surface of 15CZ for augmented pie-pie interaction between the tetracycline and 15CZ. For 5CZ and 10CZ, the percentage removal was 80.08% and 89.5%, respectively. Notably, 15CZ exhibited a dual role as both a proficient adsorbent and an excellent photocatalyst. It acted as a good adsorbent by removing nearly 40% of tetracycline within the first 30 minutes in the dark. Simultaneously, it proved to be the best photocatalyst, achieving the highest percentage removal of tetracycline in 110 minutes compared to the other catalysts. In the presence of light, CZ nano hybrids demonstrated the highest tetracycline removal efficiency.

Figure 4.7: Photocatalysis by 5mg, 10mg and 15mg CdS@ZIF-67

Peaks at 275nm and 357nm degrade significantly because of possible interaction of A and BCD ring of tetracycline molecule. Saturation of peaks is achieved in both of peaks.

Figure 16(d-f) depicts the absorbance spectra of tetracycline over time in the presence of photocatalysts 5GC, 10GC, and 15GC, respectively. The GC catalyst was synthesized by maintaining a constant CdS concentration while varying the g-C₃N₄ concentration, resulting in 5 mg, 10 mg, and 15 mg of g-C₃N₄ for 5GC, 10GC, and 15GC, respectively. A 100 mg catalyst was introduced into the tetracycline solution. Subsequently, 2 ml of the solution was taken out of the beaker to measure UV absorbance, followed by turning on the lamp. In Figures y(a-c), a noticeable decrease in absorbance can be observed, indicating the ability of the GC catalyst to degrade tetracycline, as absorbance decreases over time.

Among the GC catalysts, 15GC exhibited the highest tetracycline removal rate, achieving a remarkable 90.7% removal within 110 minutes using only 100 mg of the catalyst. The other catalysts, 5GC and 10GC, achieved percentage removals of 82.4% and 89%, respectively. Additionally, 15GC demonstrated proficiency as an adsorbent, removing nearly 35% of tetracycline within the first 30 minutes.

Figure 4.8: Photocatalysis by 5mg, 10mg and 15mg g-C₃N₄@CdS

Shown in Figure, the tetracycline peak at 350nm quickly reaches saturation, indicating that g-C₃N₄ exhibits excellent photocatalytic activity. It indicates that peak at 350nm degradation occurs because of possible interaction of electrons and holes with the BCD rings system of tetracycline molecule.

Possible degradation mechanism does not involve any complex mechanism of heterojunction. Rather GC can be considered photoactive due to presence of narrow band gap semiconductor material g-C₃N₄ onto adsorbent material CdS.

Tetracycline molecules first get adsorbed onto the surface of CdS and then get degraded by hole and electrons generated on surface of g-C₃N₄ due to band gap transition between nitrogen and carbon in heptazine unit of g-C₃N₄. The percentage removal of tetracycline was computed utilizing the formula $[(C_0 - C)/C] * 100$.

$$\text{Percentage Removal of Tetracycline} = \frac{C_0 - C}{C} \times 100 \quad (4.1)$$

Where C is the concentration at the specified time and C₀ represents the initial concentration. As the concentration of g-C₃N₄ in the nanohybrid increased, there was an increase in the percentage removal of tetracycline correspondingly.

g-C₃N₄ is a highly effective photocatalyst with high photostability and minimal charge carrier recombination. As a result, obtaining the required properties in the nanohybrid depends critically on its optimum concentration.

The mesoporous structure of “g-C₃N₄”, “ZIF-67”, and “stacked nanorods of CdS” contributes to the adsorption of TC onto the catalyst surface in all hybrids. The exposure to incident light further enhances the degradation of TC.

During the photocatalysis carried out by hybrids, both peaks are reduced in intensity till saturation is achieved. Maximum percentage removal is shown by 15CZ with a value of 96.13%.

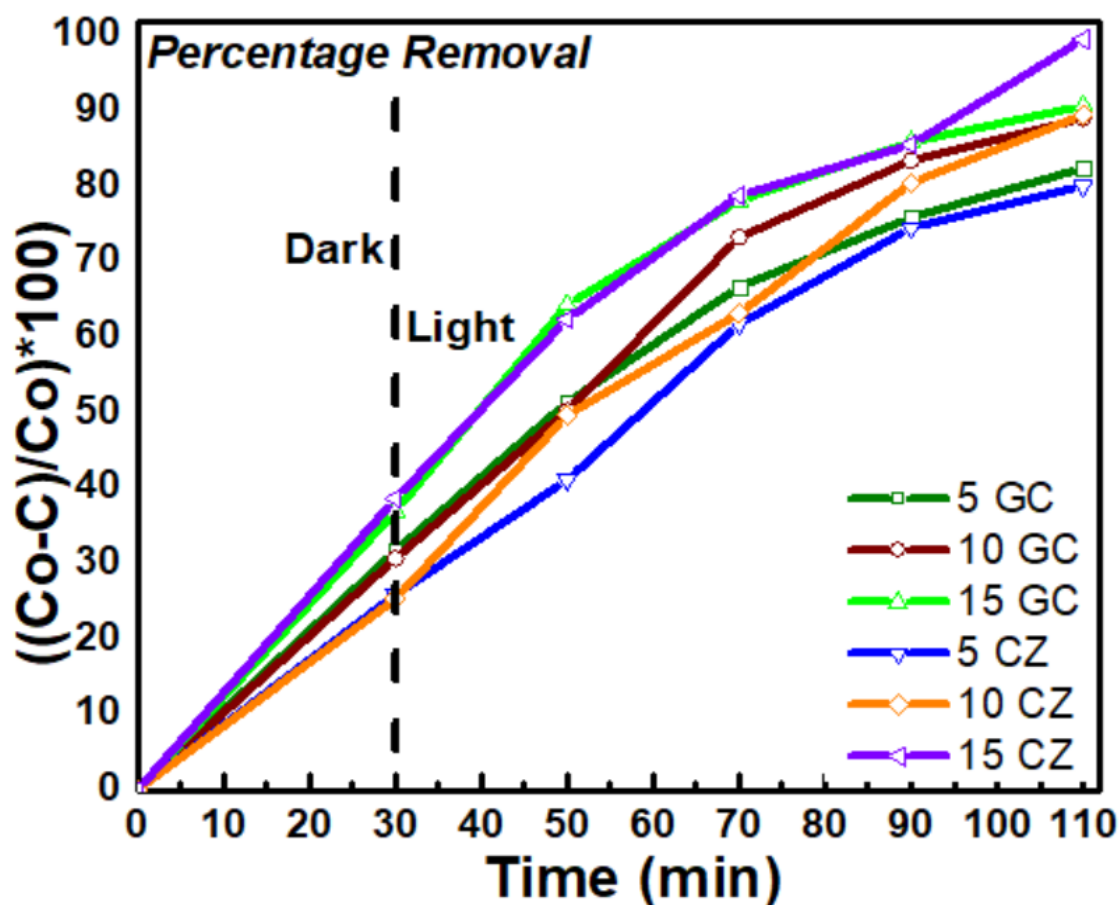

Figure 4.9: Percentage removal of tetracycline by all synthesized hybrids.

The reaction kinetics of catalyst was investigated under fixed temperature as shown in figure. The rate of the reaction exhibited a significant reliance on the adsorption of solute onto the surface of the photocatalyst. Light intensity of reactor has also increased reaction rate due to absorption of photons by photo catalyst.

Reaction kinetics was studied by plotting $\ln(C/C_0)$ versus time as shown. All reactions follow pseudo first order fit with R^2 values greater than 0.90. In Figure 15, the kinetic model of the reaction is presented. The analysis of the kinetics of the tetracycline decomposition reaction involved fitting the kinetic model to determine the reaction kinetics and 1st order rate model. The “rate constant” (k) and order (n) of reaction were determined by plotting the natural logarithm of the ratio (C/C_0) against time. The equation

$$\ln(C/C_0) = -kp.t \quad (4.2)$$

represents the relationship, where “t” represents time in minutes, (C/C₀) denotes the “ratio of concentration” at any time to the initial concentration (mg/L), and “kp” signifies the “photocatalytic rate constant” (min⁻¹).

Figure 4.10: Kinetics of all hybrids.

The figure clearly demonstrates that the kinetics of tetracycline decomposition adhere to a first-order rate model for all photocatalysts, with R² values exceeding 0.90 for each. Approximately 40% of degradation occurs within the first half-hour. In the presence of light, degradation proceeds rapidly due to the photoactive nature of nanohybrids. All things considered, of all the synthesized photocatalysts, 15CZ exhibited the highest tetracycline removal efficiency, removing a maximum of 96%. Since R² values are greater

than 0.90, it indicates that all the synthesized photocatalysts conform to a first order fit and exhibit strong activity in the photocatalytic process. While investigating the reaction kinetics for photo catalysis pseudo first order was fitted. All of catalyst show R^2 values greater than 0.9 which is consistent with the reaction order fit. Rate constant for the 15CZ is higher as compared to all due to presence of heterojunction and high number of electron and hole pair generation. 10CZ shows the second highest removal kinetics because of formation of heterojunction. CZ shows the removal kinetics due to presence of visible light active CdS onto ZIF-67.

Table 4.2: Photocatalytic activity of all synthesized hybrids

Material	“Photocatalyst/ Adsorbent”	R^2	“Removal Efficiency ((Co- C)/Co) *100”	“Rate Constant min^{-1} (photocatalysis) l/min (Adsorption) ”	“Order of reaction (n) ”
5 mg g- C ₃ N ₄ @CdS	Good	0.99557	82.429	-0.0162	n = 1
10 mg g- C ₃ N ₄ @CdS	Better	0.97223	89.04183	-0.02108	n = 1
15 mg g- C ₃ N ₄ @CdS	Better	0.99225	90.69952	-0.02238	n = 1
5 mg CdS@ZIF- 67	Good	0.97414	80.08291	-0.01546	n = 1

10 mg CdS@ZIF-67	Better	0.94148	89.49845	-0.02051	n = 1
15 mg CdS@ZIF-67	Best	0.92258	96.12614	-0.02788	n = 1

The rate constant, measured in min^{-1} through linear fit, reveals an interesting trend. The rate constant having values -0.0162 for 5GC, -0.02108 for 10GC, and -0.02238 for 15GC. For the 5CZ, 10CZ, and 15CZ nano hybrids, the “rate constant values” are -0.01546, -0.02051, and -0.02788, respectively. These rate constant values increase as the concentration of the hybrid materials increases from 5 mg to 15 mg, indicating a substantial dependence on the adsorption of tetracycline on photocatalyst surface.

4.3.2 Possible Mechanism

Possible mechanism of adsorption can be due to fact that moreover there are different ionic forms of tetracycline molecule depending on PH of the solvent. For example, in PH range of 0-5 it exists as positive ion form 5-8 it exists as Zwitter ion and up to PH 11 it is in negative ion. Since stock solution of tetracycline was made in the deionized water having PH value of 7. Thus, tetracycline in this condition will exist as zwitter ion. Electropositive species in these hybrids will also develop interaction with negative poles of zwitter ion.

Hence electrostatic interaction and π - π interaction contribute to enhance adsorption of tetracycline onto the surface of hybrid. Due to enhancement in mesoporosity of g-C₃N₄, CdS adsorption also enhances. This can arise because of increment in active sites of π - π bonding among nitrogen on g-C₃N₄ coupled with CdS rods. Because as in the structure of g-C₃N₄ it is composed of heptazine units which is verified by DFT calculation. And in each heptazine unit beside N₂ there is gap formed due to contribution of these N₂s. This gap serves as propose of adsorption site because of mesoporosity. Increase in adsorption while

increasing the graphitic carbon nitride content in GC hybrids signifies that mesoporosity enhancement in GC leads to increase in adsorption. Flattening of curves of tetracycline removal by adsorption with time is due to attainment of equilibrium concentration by as synthesized GC and CZ series.

The reaction mechanism of photocatalysis has been discussed. In the first phase after attack of electron hole pair hydroxylation of tetracycline molecule takes place. After that tetracycline molecules become dehydrated. At the end demethylation of molecules occurs. Finally, ring opening happens of tetracycline. Ring opening product further oxidized to the CO_2 and H_2O . This process implies that no harmful products are produced, and the process is beneficial to the environment. Trend was such that increase in g- C_3N_4 and CdS content in the GC and CZ series respectively lead to increase in percentage removal because of increase in all dominant factors such as surface area, mesoporosity and large numbers of hole and electron pair generation.

CHAPTER 5: CONCLUSIONS AND FUTURE RECOMMENDATIONS

5.1 Conclusions:

We effectively synthesized the high-efficiency advanced nanohybrid material g-C₃N₄@CdS and CdS@ZIF-67 in this work. Zeolite Imidazole Frameworks (ZIFs) were synthesized in the present research by integrating economical metal salts of zinc and cobalt with chemically designed imidazole organic bridging units of 2-methylimidazole. Once tested under specific conditions, this composite exhibited photocatalysis activity. All the catalysts have been synthesized using a hydrothermal and in-situ process. The nanohybrids were defined by SEM and XRD, confirming that nanohybrids were successfully formed. The band gap of nanohybrid material has been analyzed using UV-VIS. The photocatalytic performance of g-C₃N₄@CdS and CdS@ZIF-67 were examined using varied concentrations of C₃N₄ and CdS respectively. The photocatalyst experiment was completed successfully at PH=7. By using 100 mg of CdS@ZIF-67 hybrid, 96% of tetracycline has been successfully degraded in 110 minutes. The OH radical played an integral part in photocatalysis. Adsorption was caused by electrostatic interactions and the contribution of π - π bonds. Adsorbent mesoporosity and microporosity also influenced the adsorption efficiency trends. It is reasonable to assume that the catalyst worked well for treating wastewater and hospital sludge with high TC concentrations.

Environmental safety is also demonstrated by the formation of a catalyst and photocatalytic activity for removing tetracycline from water. This could pave the way for new processes to replace existing ones, such as the membrane-facilitated activated sludge process. Other processes, such as biological, can also be significantly replaced by photocatalysis using synthesized hybrids. Because such a catalyst does not produce any intermediate or product that is reactive or toxic to the environment. A more complete mineralization of photocatalysis by these hybrids ensures that tetracycline is perfectly oxidized and reduced to CO₂ and H₂O, resulting in environmental safety.

5.2 Future Recommendation

The primary concern is the development of an efficient reactor model that can successfully integrate the synthesized catalyst to perform pollutant degradation such as TC [116]. Various models have been used in the past, such as an immobilized form of catalyst supported on borosilicate glass. A collector with a specific quantum efficacy is provided in this sort of reactor. A photocatalytic reaction occurred when these discs were rotated at specific revolutions per minute because of the concentration of specific intensity light onto the surface of an immobilized catalyst supported on borosilicate glass. A specific inlet and outlet are provided to handle the feed. The problem with these types of reactors is that the catalyst's recovery is very low.

The three-phase fluidized bed, which can be used for manufacturing the catalyst mentioned above, is another apparent type of catalyst reactor. Such a reactor needs to have a separate compartment constructed of solvent-proof borosilicate glass. Through the bottom pipe beneath the compartments', dissolved oxygen is used to circulate the catalyst suspension as it enters the reactor from the inlet feed. Three phases exist as a result of dissolved oxygen acting as a fluidization catalyst. As a result, process effectiveness is raised. The light intensity can be altered in accordance with the reactor's residence time, which is determined by the kinetics of the reaction. For the reactor configuration, steady-state calculations can be performed.

It is possible to conduct active species trapping experiments using various agents. For instance, a variety of radicals, including OH, benzoquinone, and IPA, function as masking agents for certain ROS, such as O₂. Using UV-VIS analysis, these can be seen and identified which can confirm that the species is actively involved in the degradation of tetracycline by means of these experiments.

Future research into CdS based materials should be geared towards enhancing their potential for industrial applications. This can be accomplished by exploring treatment systems capable of removing multiple pollutants instead of focusing solely on individual target compounds. To achieve this, it is advisable to conduct tests using real wastewater samples and investigate the effects influent salt content and PH on the pollutant decomposition procedure. This transition from laboratory-scale experiments to pilot-scale

setups would be a significant advancement. Furthermore, the development of easier and more environmentally friendly methods of synthesis CdS composites and integrating these materials with substrates offers promising avenues for technological advancement.
