APPENDIX 9.1. Measures of Criterion A: Exposure to Stressful Events

ADMINISTERED TO CHILD

Child and Adolescent Psychiatric Assessment (CAPA) Life Events Scale (Angold & Costello, 2000)

Brief Description: This Life Events Scale is part of the PTSD module of the CAPA, a semistructured psychiatric assessment interview (see Appendix 9.3 for a description of the full interview) that assesses both high- and low-magnitude stressors. High-magnitude stressors are assessed for child's whole life; low-magnitude stressors, for past 3 months. Training is required. Interviewer qualifications: Bachelor's degree or higher. Age range: 9–17 years. Languages available: English and Spanish.

Evidence of Reliability: For high-magnitude stressors, the intraclass correlation (ICC) within 2 weeks = .72. For low-magnitude stressors, ICC within 2 weeks = .62 (Costello, Angold, March, & Fairbank, 1998). For seven events that were reported by 4 or more children, the test–retest kappa ranged from .25 for learned about a traumatic event to .88 for diagnosis of a serious illness.

Evidence of Validity: Evidence of validity has yet to be published.

Children's Report of Exposure to Violence (CREV; Cooley, Turner, & Beidel, 1995)

Brief Description: The CREV is a self-report assessment of children's exposure to violence through four modes: media (television or film), reported (people's reports of occurrence), witnessed (directly witnessed), and victim (directly experienced). The CREV includes three categories of victims: the self, strangers, and familiar persons. This report comprises 32 items, 29 of which ask children to indicate the frequency of exposure to violent events in the community during their lifetime. Children rate the frequency of ever being exposed to each type of violence using a 5-point Likert-like scale: *No/Never* (0), *One time* (1), *A few times* (2), *Many times* (3), or *Every day* (4). The final three items, which are open-ended questions that allow children to describe any other kinds of violent experiences not already described, are not scored. Scores are based on the first 29 questions. Age range: 9–15 years.

Evidence of Reliability: In a sample of 228 children (Cooley et al., 1995) ages 9–15 ($M = 11.4$, $SD = 1.37$), attending grades 4 through 7, 50.9% girls, 74.1% African American, 19.7% European American, 1.8% Hispanic, 1.3% Native American, 1.3% Asian, and 1.8% biracial, Cronbach's alpha for the total score was .78, and it was .93 for the Direct Exposure factor (see "Evidence of Validity" below) and .75 for Media Exposure. Test–retest reliability was examined for a sample of 42 children who were retested 2 weeks later. The test–retest reliability Pearson correlation for the total score was .75, and it was .78 for the Direct Exposure and .52 for the Media Exposure factors.

Evidence of Validity: Factor analysis identified two factors on which all but 5 of the items loaded: Direct Exposure (21 items) and Media Exposure (3 items; Cooley et al., 1995). This factor analysis is frequently referred to as evidence of the validity of the CREV. Such "evidence" is incomplete. Although Cooley-Quille, Turner, and Beidel (1995) also are frequently cited as providing evidence for the validity of the CREV, in actuality they provide very little evidence of validity for the scale. This does not necessarily mean the CREV is not a valid instrument; however, the authors chose only to examine correlations between the CREV and general reports of depression, temperament, and internalizing and externalizing behavior, not its association with symptoms of PTSD. Moreover, they examined those correlations separately within two groups: those who scored in the upper and the lower quarters of the CREV. Not only did this reduce their sample sizes drastically but it also reduced the variance associated with exposure to violence within each of the groups, thus limiting the magnitude of any correlation that might be found.

Juvenile Victimization Questionnaire (JVQ)—Child Report (Finkelhor, Hamby, Ormrod, & Turner, 2005)

Brief Description: The JVQ Child Report version (see below for the Caregiver Proxy Report version) asks screening questions about 34 acts of violence against children, related to five general areas: (1) conventional crime, (2) child maltreatment, (3) peer and sibling victimization, (4) sexual victimization, and (5) witnessing and indirect victimization. Questions association with each of the five areas are contained in their own module, each of which was designed for use on their own in stand-alone form. However, Finkelhor and colleagues (2005) note, "For theoretical and practical reasons, however, it is preferable to administer the full instrument" (p. 385). Events that are endorsed are followed up with questions about the number of times the child has been victimized in this manner, who victimized the child, whether or not the child was hurt, and questions specific to the type of victimization reported (e.g., the value of stolen items). The JVQ can be used without the follow-up questions, at the expense of eliciting detailed information about the different experiences. The JVQ asks about the occurrence of events in the previous year, but it can be adapted for asking about lifetime exposure. Early testing of the JVQ included extensive reviews by experts in the field of juvenile victimization. Draft versions were critiqued by focus groups of youth and parents to refine the wording. A series of cognitive interviews with 24 children between the ages of 6 and 15 were conducted to ensure comprehensibility of the questions. Administration time: 20 minutes on average. Age range: As an interview, it can be used with children 8 years and older. It can be administered in a self-report format with juveniles 12 years and older.

Evidence of Reliability: To conduct test–retest evaluation of the JVQ, 100 youth ages 10–17 were recontacted 3–4 weeks after their original telephone interviews and readministered the JVQ. The overall agreement for the total JVQ

was 95%, with a range for the individual screener items of 77–100% (Finkelhor et al., 2005). The mean kappa of the items was .63, with a range of .22–1.0. Small response rates for many items were associated with small kappas. Noting that there are good reasons to question the utility of tests of internal consistency among questions designed to assess actual experiences, the authors reported the values for the total of the 34 JQV items ($\alpha = .80$), as well as for each of the individual summary subscales: .61 for Conventional Crime (8 items), .64 for Physical Assault (10 items), .38 for Property Victimization (3 items), .39 for Child Maltreatment (4 items), .51 for Sexual Victimization (7 items), .35 for Sexual Assault (4 items), .55 for Peer or Sibling Victimization (9 items), and .35 for Peer or Sibling Assault (.35).

Evidence of Validity: Among 992 children and adolescents ages 10–17 who participated in a national telephone survey, most of the single items on the JQV correlated significantly with the Trauma Checklist for Children (TSCC—Briere, 1996b; see Appendix 9.5) subscales of Anxiety, Depression, and Anger, and all of the subscale totals correlated significantly with each of these subscales of the TSCC.

Contact Information: David Finkelhor, PhD, Crimes Against Children Research Center, University of New Hampshire, 126 Horton Social Science Center, Durham, NH 03824. Example items from the questionnaire are available as an appendix to Finkelhor and colleagues (2005).

KID-SAVE (Flowers, Hastings, & Kelley, 2000; Hastings & Kelley, 1997a)

Brief Description: The KID-SAVE measures the frequency of exposure to violence in the home, school, and neighborhood (Hastings & Kelley, 1997a). The scale comprises 34 items with three subscales derived from factor analysis: (1) Traumatic Violence—witnessing a shooting or murder, or being the victim of an assault with a deadly weapon (12 items); (2) Indirect Violence—witnessing less severe interpersonal violence or hearing about violent events (16 items); (3) Physical/Verbal Abuse—hitting among peers, and grownups hitting/screaming at child (6 items). The content of the items is identical to the adolescent version, the Screen for Adolescent Violence Exposure (SAVE; Hastings & Kelley, 1997b; see below, this appendix), although violence in three different settings is not assessed in the KID-SAVE as it is in the SAVE. Each item is rated by the child on frequency of exposure: *Never*, 0; *Sometimes*, 1; or *A lot*, 2. The impact of endorsed incidents—how upsetting they were to the child when they occurred—was rated with the following responses accompanied by faces: *Not at all, with a happy face*, 0; *Somewhat, with a “frowning face,”* 1; and *Very, with a “very upset” face*, 2, for a total possible score of 0–68. Readability was established at the fourth-grade level, so items must be read to children in the third grade. Age range: 8–12 years; grades 3–7. A Caretaker version also is available (P-KID-SAVE—Flowers, Lanclous, & Kelley, 2002; see below, this appendix).

Evidence of Reliability: Among 470 primarily (90%) African American children, 48% boys, ages 7–15 ($M = 10.69$, $SD = 1.71$), who lived in neighborhoods of high crime, Cronbach’s alpha for the Frequency scale was .91 for the total, .86 for the Indirect Violence, .87 for the Traumatic Violence, and .66 for the Physical/Verbal Abuse subscales. The alphas are similar for the Impact totals and subscales: .88 for the total, .85 for Indirect Violence, .77 for Traumatic Violence, and .62 for Physical/Verbal Abuse. The correlation between Impact and Frequency scale scores was .69, and the correlations for subscales were as follows: .84 for Traumatic Violence; .60 for Indirect Violence; and .77 for Physical/Verbal Abuse. A 3-week test–retest reliability was conducted in a subsample of 22 children (55% girls) ages 8–11 ($M = 9.5$, $SD = 0.91$); reliability coefficients for Frequency were .86 for the total, .67 for Indirect Violence, .76 for Traumatic Violence, and .62 for Physical/Verbal Abuse subscales; and for Impact, they were .81 for the total, .73 for Indirect Violence, .82 for Traumatic Violence, and .58 for Physical/Verbal Abuse subscales (Hastings & Kelley, 1997a). Cronbach’s alpha for the Flowers and colleagues (2000) sample was .89 for the Frequency scale. There was insufficient variability in responses on the Impact scale to calculate a Cronbach’s alpha.

Evidence of Validity: Construct validity was established in a subsample of 187 primarily (87%) African American children, 47% boys, ages 7–15 ($M = 10.28$, $SD = 1.72$; Hastings & Kelley, 1997a) by correlating scores on the KID-SAVE with scores on the TSCC (Briere, 1996a, 1996b; see Appendix 9.5). Significant correlations for the frequency scale and subscales ranged from $r = .20$, $p < .05$ to $r = .54$, $p < .001$. Scores on the Impact scale and TSCC also were significantly correlated and ranged from $r = .17$, $p < .05$ to $r = .43$, $p < .001$. In a separate study (Flowers et al., 2002), children in higher grades indicated they experienced greater frequency of exposure to indirect violence, whereas the younger children reported more frequent physical/verbal abuse, and they reported significantly greater impact of their exposure to physical/verbal abuse. Scores on the frequency of exposure to traumatic violence were associated with scores on the Child Behavior Checklist (CBCL; Achenbach, 1991a) Withdrawn, Anxious–Depressed, Delinquent, and Aggression subscales. Frequency of indirect violence was associated with Social Problems on the CBCL. Reports of higher frequency of exposure to indirect violence, physical/verbal abuse, and traumatic violence were associated with higher Anxiety scores on the TSCC. TSCC Depression was associated with child reports of frequency of exposure to physical/verbal abuse and indirect violence. Both the Posttraumatic Stress and Anger scales of the TSCC were associated with frequency of exposure to indirect violence, traumatic violence, and physical/verbal abuse. The Dissociative scale of the TSCC was associated with the frequency of indirect violence and physical/verbal abuse. Total scores on the KID-SAVE were significantly associated with total TSCC scores.

Contact Information: Anise L. Flowers, PhD, Tarrow Center for Self-Management, 1001 West Loop South, #215, Houston, TX 77027. E-mail: doctorflower@email.com. Instructions and items for the child version are included in the original article (Hastings & Kelley, 1997a).

Lifetime Incidence of Traumatic Events (LITE), Student form (Greenwald & Rubin, 1999)

Brief Description: The LITE assesses exposure to 16 potentially traumatic stressors, such as a car accident or the death of someone in the family. It measures the frequency of exposure, age at time of exposure, and how upset the child was at the time of the event and currently on a 3-point scale (*None, Some, Lots*). Age range: 8+. Languages available: English, Spanish, German, Persian, and Swedish.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Sidran Institute, 200 E. Joppa Road, Suite 207, Towson, MD 21286. Telephone: (410) 825-8888. E-mail: sidran@sidran.org. Website: www.sidran.org.

My Exposure to Violence (My ETV; Buka, Selner-O'Hagan, Kindlon, & Earls, 1996; Selner-O'Hagan, Kindlon, Buka, Raudenbush, & Earls, 1998)

Brief Description: My ETV is a highly structured interviewer-administered instrument designed to cover lifetime and past-year exposure to 18 different violent events that have either been witnessed or personally experienced by a child or adolescent. It also ascertains the location of the violence (e.g., school, home, neighborhood), identifies both perpetrators and victims of violence (e.g., family member, stranger), and whether the exposure was gang-related. The instrument measures lifetime exposure ("ever") and prevalence ("in the past year"). Frequency of exposure is measured on a 6-point scale (*Never, Once, 2 or 3 times, 4 to 10 times, 11 to 50 times, and More than 50 times*). Six subscales are defined: (1) Witnessing Violent Events, (2) Victimization, and (3) Total Exposure (witnessing and victimization), obtaining scores for both lifetime and past-year exposure.

Age Range: 9 years and older.

Evidence of Reliability: The ICC test-retest reliability for the six subscales was .88 for the total My ETV Lifetime, .75 for the Victimization Lifetime, .85 for the Witnessing Lifetime, .81 for the Past-Year Total My ETV, .94 for the Past-Year Victimization, and .75 for the Past-Year Witnessing (Selner-O'Hagan et al., 1998). Internal consistency for the scales, as measured by Cronbach's alpha, was .93 for Total Lifetime My ETV, .89 for Total Past-Year My ETV, .79 for Lifetime Victimization, .68 for Past-Year Victimization, .92 for Lifetime Witnessing, and .91 for Past-Year Witnessing subscales.

Evidence of Validity: A theoretical underlying unidimensional latent construct of exposure to violence has been demonstrated using item response theory (IRT; Kindlon, Wright, Raudenbush, & Earls, 1996; Selner-O'Hagan et al., 1998). Neighborhoods with higher rates of crime were associated with significantly higher reports of exposure to past-year violence on the My ETV, but lifetime rates did not differ significantly (Selner-O'Hagan et al., 1998). Children, adolescents, and young adults who reported committing at least one violent event themselves had significantly higher My ETV scores for both the past year and over their lifetime (Selner-O'Hagan et al., 1998). Lifetime My ETV scores were positively correlated with age, with higher scores among older youth. However, there was also a significant quadratic association between age groups, with the two middle ages (15 and 18) reporting more lifetime exposure than the youngest (9–12) and oldest (21–24) age groups. For past-year scores, there was no linear association between age and scores, but there was again a significant quadratic association, with the two middle age groups again reporting more exposure to violence over the past year. African American children and adolescents reported significantly more exposure in the past year than European Americans, but there was no difference in reports of lifetime exposure. Boys reported higher levels of exposure over the lifetime and in the past year than girls, both in terms of witnessing and victimization.

Contact Information: Mary Beth Selner-O'Hagan, PhD, Department of Maternal and Child Health, Harvard School of Public Health, 677 Huntington Ave., Boston, MA 02115. E-mail: mohagan@phdcn.harvard.edu.

Post-Traumatic Stress Disorder Index (Diehl, Zea, & Espino, 1994)

Brief Description: Languages available: Spanish.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: The measure is included as an appendix to Diehl and colleagues (1994).

Screen for Adolescent Violence Exposure (SAVE; Hastings & Kelley, 1997a)

Brief Description: The SAVE is a 32-item, Likert-type scale assessing violence exposure in school, home, and neighborhood on corresponding settings scales. Each setting scale comprises three subscale scores: Traumatic Violence, Indirect Violence, and Physical/Verbal Abuse, for a total of 9 subscales. Response categories for each question included 1, *Never*; 2, *Hardly ever*; 3, *Sometimes*; 4, *A lot*; and 5, *Almost always*. Total setting scores range from 32 to 160, with higher scores indicative of greater violence exposure (Hastings & Kelley, 1997a).

Evidence of Reliability: Coefficient alphas ranged from .58 to .91 for the nine subscales (mean alpha = .78). The lowest alphas were for the Physical/Verbal Abuse subscales (.58 for School Violence, .68 for Home Violence, and .61 for Neighborhood Violence; mean alpha = .62). The highest alphas were for the Indirect Violence subscales (.84 for School Violence, .89 for Home Violence, and .91 for Neighborhood Violence; mean alpha = .88). Alphas for the Trauma Violence subscales were almost as high (.78 for School Violence, .84 for Home Violence, and .85 for Neighborhood Violence; mean alpha = .82). Cronbach's alphas for the three settings (sums of the three subscales within each setting) were .90 for School Violence, .93 for Home Violence, and .94 for Neighborhood Violence. Two-week test-retest correlations varied from .53 to .91 ($M = .76$). The lowest test-retest correlations were again for the Physical/Verbal Abuse subscales (.53 for School Violence, .60 for Home Violence, and .61 for Neighborhood Violence; mean alpha = .58). The highest test-retest correlations were again for the Indirect Violence subscales (.87 for School Violence, .88 for Home Violence, and .91 for Neighborhood Violence; mean alpha = .89). Test-retest correlations for the Trauma Violence subscales were almost as high (.78 for School Violence, .81 for Home Violence, and .82 for Neighborhood Violence; mean alpha = .80). Test-retest coefficients for the three settings were .91 for School Violence, .92 for Home Violence, .92, and .92 for Neighborhood Violence (Hastings & Kelley, 1997b).

Evidence of Validity: Principal components factor analysis with a varimax rotation was conducted separately for each of the three settings in a sample of 1,036 adolescents, 94.2% African American, ages 11 to 19 years ($M = 14.84$, $SD = 1.86$) in grades 6 through 12. Each analysis produced three factor subscales: “(1) Traumatic Violence, relating to severe victimization experiences (12 items), (2) Indirect Violence, relating to the witnessing of or being informed of less severe interpersonal violence (14 items), and (3) Physical/Verbal Abuse, relating to the actual or threatened violent harm directed at the participant (six items)” (Hastings & Kelley, 1997b, p. 515). A separate sample of 214 adolescents, ranging in age from 13 to 18 years ($M = 14.62$, $SD = 1.11$), participated in validity studies of the measure. Confirmatory factor analysis indicated that the three-factor solution provided a reasonable fit for each of the three settings. Known-groups validity was assessed by dividing one group of adolescents according to police zones of low ($n = 262$) and high ($n = 250$) rates of reported violent crime to assess the Neighborhood setting subscales; scores of the upper ($n = 98$) and lower ($n = 98$) quartiles of the Conflict Tactics Scales (CTS; Straus, 1979) to assess the Home setting subscales; and schools reporting low ($n = 238$) and high ($n = 214$) levels of student aggression to assess the School setting subscales. All scales successfully discriminated between high- and low-violence groups. According to these analyses, the Neighborhood scale demonstrated sensitivity of .78 and specificity of .87; the School scale, sensitivity of .76 and specificity of .94; and the Home scale, sensitivity of .68 and specificity of .92. Convergent validity was demonstrated for the Neighborhood subscale, with significant correlations between each of its subscales and violence scores for neighborhoods based on local crime data ($r = .28$ for the Traumatic Violence subscale; $r = .38$ for the Indirect Violence subscale; and $r = .35$ for the Physical/Verbal Abuse subscale of the Neighborhood setting scales). Divergent validity was demonstrated for most of the subscales of the Home and School settings based on nonsignificant correlations between the neighborhood violence scores, except for significant correlations with Indirect Violence for each setting ($r = .24$ and $.27$, respectively). Convergent validity was demonstrated for the Home Traumatic Violence and Physical/Verbal Abuse subscales through significant correlations with parental CTS Verbal Aggression ($r = .43$ for both) and CTS Violence (r 's = .48 and .33, respectively). Divergent validity was demonstrated for the Home subscales, with nonsignificant correlations with the CTS Parent Reasoning scale. Construct validity was demonstrated with significant correlations between the nine SAVE subscales and subscales of the TSCC (Brier, 1996a, 1996b; see Appendix 9.5), the Impact of Event Scale (IES; Horowitz, Wilner, & Alvarez, 1979), and the Youth Self-Report (YSR; Achenbach, 1991b). All nine subscales correlated significantly with the Intrusion and Avoidance subscales of the IES, the Internalizing and Externalizing scales of the YSR, and the Anger subscale of the TSCC (with correlations ranging from .21 to .52). The TSCC Posttraumatic Stress subscale correlated significantly with the Home Indirect Violence subscale (.32), Home Physical/Verbal Abuse subscale (.34), the total Home setting scale (.27), the Neighborhood Physical/Verbal Abuse subscale (.23), the School Physical/Verbal Abuse subscale (.32), and the total School setting scale (.22). The TSCC Dissociation subscale correlated significantly with the Home Indirect Violence subscale (.32), Physical/Verbal Abuse subscale (.38), the total Home setting scale (.33), the Neighborhood Physical/Verbal Abuse subscale (.27), the total Neighborhood scale (.25), the School Physical/Verbal Abuse subscale (.33), and the total School scale (.24). The TSCC Anxiety and Depression subscales correlated significantly with Home Indirect Violence (.22 and .27), Home Physical/Verbal Abuse (.29 and .31), total Home setting scale (.22 and .27), and the School Physical/Verbal Abuse subscale (.32 and .27). The total School setting scale correlated .22 with the TSCC Anxiety subscale (Hastings & Kelley, 1997b).

Contact Information: Teresa L. Hastings, PhD, P.O. Box 95606, Seattle, WA 98145-2606. The items are listed in Hastings and Kelley (1997b).

Stressful Life Events Checklist (SLE; Bean, Eurelings-Bontekoe, Derluyn, & Spinhover, 2004c)

Brief Description: The SLE, a checklist of 12 stressful events “commonly experienced by refugee minors,” includes one open-ended question and a space for comments. The experiences assessed, however, appear to be applicable to other children as well. Responses are yes–no. The SLE was written as a companion assessment tool to the Reactions of Adolescents to Traumatic Stress (RATS—Bean et al., 2004b; see Appendix 9.6). Some questions may require explanation. The manual supplies short answers for those questions that posed problems during the original testing. Age range: 12–18 years. Languages available: Amhars, Albans, Arabic, Bandini, Chinese (Mandarin), Croation, Dari, Dutch, English, French, German, Mongols, Portuguese, Russian, Servo-Croatian, Spanish (presumably European Spanish rather than Central or South American Spanish), Soerani, Somali, and Turkish.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: The SLE correlated significantly with the RATS (Bean et al., 2004b; see Appendix 9.6 for details) in four different large samples: r 's ranged from .45 to .52 for the total RATS, from .43 to .53 for the Intrusion scale, from .36 to .44 for the Numbing/Avoidance scale, and from .38 to .45 for the Hyperarousal scale.

Contact Information: All versions of the SLE, along with the manual, may be downloaded from www.centrum45.nl/research/amaenggz/jukamtool.php. Tammy Bean, PhD, may be contacted via e-mail at t.bean@centrum45.nl.

Stressful Life Events Schedule—Child Version (SLES; Williamson et al., 2003)

Brief Description: To assess stressors in children and adolescents, the SLES comprises 61 potentially stressful events in the life of the child or the child's important others. It also allows for the inclusion of additional events not covered. Events are categorized into domains of education, work, money, housing, crime, health, deaths, romantic relationships, and other relationships. Events are rated on subjective stressfulness on a 4-point scale: *Little or none*, *Some*, *Moderate*, and *High*. Memory aids help the child date the occurrence of each endorsed event. Duration of the event is also recorded. Events also are rated on whether they are behavior-dependent or independent; that is, whether or not the child was actively involved in creating the stressful event. Time required: 15–120 minutes ($M = 35.5 \pm 18.9$, for nonpsychiatrically ill children; $M = 55.5 \pm 26.7$, for psychiatrically ill children—Williamson et al., 2003).

Evidence of Reliability: Ratings for six raters of more than 1,000 events elicited from 60 children and adolescents (half of whom were psychiatrically ill) showed moderate to excellent agreement, with kappas of .67 for exact ratings of objective threat, .84 for behavior-dependence/independence, and .93 for the focus of the event (Williamson et al., 2003). For events labeled severe (rated 3 or 5 on objective threat) agreement was higher (kappa = .70). On an event rated behavior-dependent (3 or 4 on the dependence scale), kappa was .92. Age, gender, and diagnostic status did not significantly impact the reliability estimates. Fifty-nine of the children were reinterviewed approximately 1 week after their initial interview to examine the test–retest reliability of the interview. The ICC for the number of events reported in each interview was .93; for children age 12 or under, ICC was .91, and for those over age 12, it was .94. Normal children had higher intraclass reliability for nonsevere events than did children with psychopathology (.93 vs..83). The test–retest reliability of events with high objective threat was substantially lower, with an ICC of .70. Adolescents had higher test–retest reliability than younger children for severe events (.86 vs..43). The test–retest kappa for any event was .68, and girls had higher kappas (.74) than boys (.62). Test–retest for all events also was higher for adolescents (kappa = .72) than for younger children (.61). For severe events, test–retest reliability was higher, with a kappa of .80. For nonsevere events, kappa was .67, and girls again had higher kappas (.78) for these events than boys (.60).

Evidence of Validity: Children with psychiatric disorders reported more stressful events in the past year than normal children (M 's = 8.1 ± 4.0 vs. 4.9 ± 3.5). Children with psychiatric disorders also reported more behavior-dependent events, more behavior-independent events, more severe events, and higher levels of stressful responses to the events. Adolescents were more likely to report behavior-dependent events and to score higher on the total sum of objective and subjective stress. Total stressful life events assessed with the SLES agreed with those assessed by the Life Events Checklist (Johnson & McCutcheon, 1980), with an ICC of .83 (Williamson et al., 2003).

Survey of Exposure to Community Violence—Self-Report Version (SECV-SR; Richters & Saltzman, 1990)

Brief Description: This self-report measure evaluates children's exposure to 20 forms of severe violence (shootings, stabbings, and rapes), less severe violence (beatings and chases), and moderately severe violence (threats, accidents, drug deals, and arrests). Children report on whether they have been the victim of, witnessed, and simply heard about each kind of event. The frequency of each exposure is assessed on a 9-point scale, ranging from *No exposure* (0) to *Exposed every day* (8). Also known as Survey of Children's Exposure to Community Violence. For the Parent Report Version, see below, this appendix.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Children's reports of exposure to stressors on the SECV-SR (Martinez & Richters, 1993) were significantly correlated with their Checklist of Child Distress Symptoms (CCDS—Richters & Martinez, 1990a; see Appendix 9.5) scores, whether they were themselves victims of community violence ($r_{(37)} = .37$) or witnessed it ($r_{(37)} = .39$), or they witnessed violence in the home ($r_{(37)} = .33$).

Contact Information: John E. Richters, PhD, Department of Human Development and Institute for Child Study, University of Maryland, Benjamin Building, Room 4104, College Park, MD 20742. Telephone: (301) 405-7354. E-mail: jrichter@nih.gov.

Tough Times Checklist (Fletcher, 1996f)

Brief Description: The Tough Times Checklist is a 70-item, paper-and-pencil assessment of lifetime and past-year exposure to low-, moderate-, and high-magnitude stressors, based on the Life Events and Coping Inventory (LECI; Dize-Lewis, 1988) with very minor or general stressors ("You felt angry or upset," "You felt rushed or pressured") excluded. Higher magnitude stressors have been added. Explicit questions about sexual abuse are excluded, although the child is asked whether any peers, adult strangers, or known adults ever made him or her do "something horrible." Assessors are required to inquire as to the nature of that event, if the child endorses it. If a measure that inquires about explicit sexual abuse experience is desired, see the Young Adult Upsetting Times Checklist below, this appendix. Response format is as follows: *Never happened*; *Happened, but the worst time was not upsetting*; *Happened, and the worst time was somewhat upsetting*; and *Happened, and the worst time was very upsetting*. Adolescents are also asked to describe the most upsetting event experienced in the past year, then rate it on how upsetting it was—*A little*, *Very much*, *Totally*. Then the child is asked to describe the most upsetting event experienced prior to last year, and to rate how upsetting it was. Age range: 7 and older. Third-grade reading level required.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Kenneth E. Fletcher, PhD, Department of Psychiatry, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, MA 01655. Telephone: (508) 856-8630. E-mail: kenneth.fletcher@umassmed.edu.

Things I Have Seen or Heard (Richters & Martinez, 1990b)

Brief Description: In this 15-question, simply worded, structured interview designed to assess the frequency of young children's exposure to violence and violence-related themes (Richters & Martinez, 1993), each question is described on a separate page. Response categories are depicted as five stacks of balls, with a different and increasing number of balls in each stack, ranging from none to five, labeled *Never/0 times*, *1 time*, *2 times*, *3 times*, and *Many times*. For the *Never/0 times* response, the ball is empty, and for the others the balls are filled. For times 1 through 3,

an equivalent number of filled balls is shown. For *Many times*, five filled balls are shown. Children are taught to use the proper stack of balls to indicate the frequency of their exposure to each event prior to the interview. Age range: 6–10 years.

Evidence of Reliability: Test–retest correlation for the total score among 21 children over one week is .81, with no significant difference between scores at the two times ($t_{(2)} = 1.34$, ns; Richters & Martinez, 1993).

Evidence of Validity: Among 111 first and second graders (Martinez & Richters, 1993) correlations between experiences of violent victimization in the community, as reported on the Things I Have Seen or Heard, and symptoms of distress, as measured by the Levonn, were significant ($r_{(31)} = .28$, $p < .01$). Children’s reports of witnessing violence in the community also correlated significantly with their total scores on the Levonn ($r_{(81)} = .30$, $p < .01$). Children’s reports of the frequency of seeing guns or drugs also correlated significantly with total distress scores on the Levonn, regardless of where that occurred ($r_{(81)} = .30$).

Contact Information: John E. Richters, PhD, Department of Human Development and Institute for Child Study, University of Maryland, Benjamin Building, Room 4104, College Park, MD 20742. Phone: (301) 405-7354. E-mail: jrichter@nih.gov.

Traumatic Events Screening Inventory for Children (TESI-C; Ford et al., 2002)

Brief Description: On the TESI-C, a 16-item, structured interview regarding high-magnitude stressors, questions are arranged so that the lowest magnitude stressors are asked first and sexual abuse is at the end, to help the child tolerate the potentially stressful nature of the questions. Probes assist the interviewer to determine whether endorsed events meet both parts of criterion A of DSM-IV PTSD diagnosis. If criterion A is met for a particular type of stressor, the interviewer asks for more specifics about the event(s), the child’s age at its occurrence, who else was involved, and whether anyone was hurt and needed medical attention. Age range: 8–17 years. Requires a qualified mental health professional or advanced trainee supervised by a qualified mental health professional.

Evidence of Reliability: Interrater reliability kappas for summary scores ranged from .73 to 1.00 in a sample of pediatric injury patients (Ford & Rogers, 1997). Test–retest reliability kappas for the TESI-C and TESI-P (the parent form; see below) summary scores ranged from .50 to .70 over a 2- to 4-month period. Test–retest kappas for specific events at assessments 1 month or more apart were .83 for sexual abuse, .69 for family arguments, .56 for domestic violence, .51 for physical abuse, .49 for witnessing a death or serious illness, .40 for verbal abuse, .25 for witnessing an accident, and $-.07$ for exposure to a natural disaster. Kappas of parent–child agreement on trauma on specific events ranged from .64 to .79.

Evidence of Validity: Evidence of validity has yet to be published.

Violence Exposure Scale for Children—Preschool Version (VEX; Fox & Leavitt, 1995; Shahinfar, Fox, & Leavitt, 2000)

Brief Description: The VEX, a 23-item, cartoon-based interview to assess children’s self-reports of exposure to violence, is based on the Things I Have Seen and Heard scale designed by Richters and Martinez (1990b; see above, this appendix). The preschool version consists of 15 items. Whereas the violent events are described verbally in the Things I Have Seen and Heard scale, the VEX scale depicts each event in cartoons. Eight of the cartoons show a central character, Chris, witnessing violent events, and 6 cartoons depict Chris as the victim of violent events. “The violent incidents assessed by the preschool version of the VEX scale are beating, chasing, robbery, threat with a weapon, shooting, stabbing, pushing or shoving, and slapping. The children were asked about witnessing all of them, and about victimization by all but shooting or stabbing, partly because of the low probability that preschoolers would be victims of such events, partly out of concern for keeping the traumatic valence of the cartoon depictions at a minimum. Following the interviewer’s explanation of what Chris is witnessing or experiencing in each picture, the children are asked how often they have been exposed to the same incident. Below each cartoon is a picture of four thermometers, each with the mercury at one of four labeled levels: never, once, a few times, and lots of times. For those incidents to which the child responds positively, the interviewer probes for information regarding where the event occurred, who was with the child at the time, and when the event occurred. The probing is intended to assess the veracity of the child’s report on the basis of its relevance to the cartoon depiction. At the same time, the questions are designed to allow comparison between specific parent- and child-reported events” (Shahinfar et al., 2000, p. 117). A revised version was created by Shahinfar and colleagues (2000) based in part on preliminary testing. This resulted in removing several items that lacked clarity and adding new items designed to assess innocuous events to which the child was likely to have been exposed (e.g., watching television or seeing a child sitting on Santa’s lap) to provide a “psychological break” from the more stressful events and to act as a test of a child’s understanding of the questions. Gender-differentiated versions of the full, revised measure were created, wherein the test remained the same in both versions except for the gender of the main character. Shahinfar and colleagues found that children could be divided into three levels of comprehension of the measure: 73 (47.1%) of 155 children appeared to understand the interview; the level of comprehension was either unclear or variable for 56 (36.1%) children; and 26 (16.8%) children were unwilling or unable to complete the interview. Those who understood the VEX scored significantly higher on the Peabody Picture Vocabulary Test—Revised (PPVT-R; Dunn & Dunn, 1981). They also reported significantly lower levels of total violence exposure and symptoms of distress (as measured by a revised, preschool version of the Levonn; see Appendix 9.4), as reported by the children. No group differences were found for parent reports of violence exposure or CBCL behavior problems. In this study of primarily (98.8%) African American children between ages 3.5 and 4.5, the authors carefully debriefed children after administering the revised Levonn (Shahinfar et al., 2000). They reported that very few of

the children indicated, either verbally or behaviorally, that they had been upset by the interview. The authors divided the items into two types: exposure to mild violence (beating, chasing, pushing or shoving, and slapping) and exposure to severe violence (robbery, threats with a weapon, shooting, and stabbing). A Hebrew version is available. It consists of 12 pairs of drawings, one depicting a child witnessing a violent event and the other depicting a child named Nitzan, in this version, as a victim of the same act of violence (Raviv et al., 2001). That version was administered to each child three times in three different settings: home, school, and neighborhood. Responses were depicted as stacks of balls, with *Never* depicted as a white or empty ball, *Once* depicted as a filled or black ball, *2 times* as 2 filled balls, *3 times* as 3 filled balls, and *Many times* as 5 filled balls. Cartoons of extremely violent events were shown only in the witness situation. Age range: Preschool. Languages: English and Hebrew.

Evidence of Reliability: A reliability study of a revised version for school-age children (age 14 and younger) of the VEX-R, used in the National Survey of Child and Adolescent Well-Being (NSCAW; Administration for Children and Families, 2006) reported a Cronbach's alpha of .96 in a sample of 2,738 children whose families had been investigated (but not necessarily supported) for reported maltreatment, and alphas of .86 for a subscale of items related to witnessing mild violence, .88 for items regarding mild violence victimization, and .92 for items related to witnessing severe violence. Among 73 children ages 3.5 to 4.5 who appeared to understand the VEX Preschool Version questions, Cronbach's alphas were .80 for children's reports of exposure to mild violence (8 items) and .86 for exposure to severe violence (6 items; Shahinfar et al., 2000). Parent and child reports showed no significant association with each other in this study. In the Raviv and colleagues (2001) study of Israeli children's exposure to violence, associations between child and parent report versions of the VEX tended to be significant, especially for episodes of mild violence, with correlations of .34 for the total of witnessing items and .47 for the total of victimization items.

Evidence of Validity: Small but significant correlations were found between symptoms of distress (as measured by the preschool version of the Levonn; see Appendix 9.4) and Witnessing Mild Violence ($r = .29, p < .05$), Victimization by Mild Violence ($r = .22, p = .05$), and Witnessing Severe Violence ($r = .25, p < .05$; Shahinfar et al., 2000). No significant association was found between child reports of distress and victimization by severe violence ($r = .14, ns$). Moreover, among the 73 children who appeared to understand the measures, those who reported witnessing mild violence were rated by their parents as displaying more internalizing problems on the CBCL (Achenbach, 1991a) than children who did not report such exposure. Those who reported victimization by mild violence were rated with higher externalizing behavior by their parents. Parents of children reporting exposure to extreme violence did not report any significantly different behavior problems on the CBCL than parents of children who did not report exposure to extreme violence. A factor analysis of the Hebrew version (Raviv et al., 2001) resulted in two factors: Mild Violence (six items: yell, chase, slap, push, beat up, throw something at) and Severe Violence (six items: threaten with a knife or gun, stab, shoot, arrest, deal drugs, rob). In the same study, responses of children from a low-violence neighborhood (LVN) were compared to those of children from a high-violence neighborhood (HVN). Children in the HVN group reported more exposure to violence than children in the LVN. In the same study, the correlations between child and parent reports of severe violence exposure were lower but still significant for the totals of the witnessing (.22) and the victimization items (.37). Mothers of children with more experiences of violent victimization reported that they had more behavior problems, as measured by the CBCL (Achenbach, 1991a). All reports of violent experiences on the VEX also correlated significantly with scores on a revised version of the Levonn (see description of Levonn and the Hebrew version, this appendix).

Contact Information: For revised preschool version: Ariana Shahinfar, PhD, Department of Psychology, University of North Carolina, Charlotte, NC 28223-0001. E-mail: ashahinf@email.unc.edu. For Hebrew version: A. Raviv, PhD, Department of Psychology, Tel Aviv University, Ramat Aviv, Tel Aviv 69978, Israel. Telephone: 972-3-640-8969. E-mail: raviv@post.tau.ac.il.

Young Adult Psychiatric Assessment (YAPA) Life Events Scale (Angold & Costello, 2000)

Brief Description: This Life Events Scale is a module of the full YAPA (Angold & Costello, 2000; see Appendix 9.6). Similar to the CAPA, with which the measure is associated, it assesses both high- and low-magnitude stressors. High-magnitude stressors are assessed for child's whole life; low-magnitude stressors, for past 3 months. Training is required for this semistructured interview. Age range: 18+. Interviewer qualifications: Bachelor's degree or higher. Languages available: English and Spanish.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Developmental Epidemiology Program, Duke University Medical Center, Attention: Juné Rogers, DUMC Box 3454, Durham, NC 27710. Telephone: (919) 687-4686, extension 273. E-mail: jrogers@psych.duhs.duke.edu.

Young Adults Upsetting Times Checklist (Fletcher, 1996; Fletcher & Skidmore, 1997)

Brief Description: The Young Adults Upsetting Times Checklist, a paper-and-pencil assessment of lifetime and past-year exposure to low-, moderate-, and high-magnitude stressors, is based on the Life Events and Coping Inventory (LECI; Dize-Lewis, 1988), with minor stressors ("You felt angry or upset," "You felt rushed or pressured") excluded. Higher magnitude stressors have been added. Unlike the related measures, the Teen Tough Times Checklist, the Tough Times Checklist (both described earlier in this appendix), and the Child's Upsetting Times Checklist (a parent report version is described in this appendix), several explicit questions about sexual and physical abuse have been included. There are many questions about the occurrence of abuse before the age of 18, then again, after the age of 18. To accommodate the extra abuse questions, some of the lowest magnitude stressor questions included on the related stressor checklists have been omitted. Response format is as follows: *Never happened; Happened, but the worst time was not upsetting; Happened, and the worst time was somewhat upsetting; Happened, and the worst time was very*

upsetting; and *Happened, and the worst time was extremely upsetting*. Two additional items ask respondents to describe and rate (1) the worst thing that happened to them in the past year, and (2) the worst thing that ever happened to them prior to the last year, using the same response format. Age range: 13 years and older. Ability of younger adolescents to comprehend the items need to be assessed, and questions referring to occurrences after the age of 18 should be omitted. Number of items: 76, with item 74 rated twice. Languages available: English; Spanish.

Evidence of Reliability: Among 295 undergraduate college students, ages 17–41 ($M = 19.9$, $SD = 2.8$, median = 19), Cronbach's alphas for the total of all stressors prior to the previous year was .96, and for the total of all stressors in the previous year, .97 (reanalysis of data is reported in Fletcher & Skidmore, 1997). Alphas for the six subscales of the lifetime stressors (see below for description of subscales) were .98 for the High-Magnitude Stressors, .78 for the Peer Social Stressors, .85 for the Home Life Stressors, .67 for the Alienation Stressors, .80 for Demoralizing Stressors, and .80 for Home Life Disruptions Stressors. Alphas were .98 for the Major Stressors of the previous year, and .88 for the Minor Stressors of the previous year.

Evidence of Validity: Factor analysis (Fletcher & Skidmore, 1997) of scores on the lifetime stressors prior to the previous year produced seven subscales: High-Magnitude Stressors (e.g., sexual or physical abuse, being shot at or stabbed), Peer Social Stressors (friend in hospital, know someone not family in bad accident, friend died, someone in family died), Home Life Stressors (had to go live with relatives, sibling moved out of house, parent lost job, house robbed), Alienation Stressors (does not like teacher, sent to principal, fight with friend, friend stops hanging out), Demoralizing Stressors (suspended from school, punished, sent back a grade), and Home Life Disruption Stressors (moved, a parent moved out, parents divorced, parent remarried). The total score for lifetime stressors, including the previous year, correlated significantly (.26) with the Impact of Event Scale (Horowitz et al., 1979), as did the total for lifetime prior to the previous year (.28), and total for just the previous year (.13; Fletcher & Skidmore, 1997). Each total also correlated significantly (.28, .25, and .22, respectively; Fletcher & Skidmore, 1997) with a PTSD score based on the Symptom Checklist 90 (SCL-90—Derogatis & Melisaratos, 1983; Saunders, Arata, & Kilpatrick, 1990).

Contact Information: Kenneth E. Fletcher, PhD, Department of Psychiatry, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, MA 01655. Telephone: (508) 856-8630. E-mail: kenneth.fletcher@umassmed.edu.

ADMINISTERED TO CARETAKER OR OTHER ADULTS

Child and Adolescent Psychiatric Assessment (CAPA) Life Events Scale (Angold & Costello, 2000)

Brief Description: This Life Events Scale is a module of the CAPA general psychiatric assessment interview (see Appendix 9.3). It assesses both high- and low-magnitude stressors: High-magnitude stressors for the child's whole life; low-magnitude, for past 3 months. Training is required for this semistructured interview. Age range: 9–17 years. Interviewer qualifications: Bachelor's degree or higher. Languages available: English and Spanish.

Evidence of Reliability: For high-magnitude stressors, ICC within 2 weeks = .83. For low-magnitude stressors, ICC within 2 weeks = .58.

Evidence of Validity: For seven events reported by four or more children, kappas ranged from .16 for a serious accident to .81 for sexual abuse.

Contact Information: Developmental Epidemiology Program, Duke University Medical Center, Attention: Juné Rogers, DUMC Box 3454, Durham, NC 27710. Telephone: (919) 687-4686, extension 273. E-mail: jrogers@psych.duhs.duke.edu.

Child's Upsetting Times Checklist (Fletcher, 1996f)

Brief Description: The Child's Upsetting Times Checklist, a paper-and-pencil assessment of lifetime and past-year exposure to both low- and high-magnitude stressors, is based on the LECI (Dise-Lewis, 1988), with minor stressors ("You felt angry or upset," "You felt rushed or pressured") excluded. Explicit questions about sexual abuse are *excluded*, although the parent is asked if peers, an adult stranger, or a known adult ever made the child do "something horrible." Assessors then inquire as to the nature of that event if the parent endorses it. Response format is as follows: *Never happened*; *Happened, but the worst time was not upsetting*; *Happened, and the worst time was somewhat upsetting*; and *Happened, and the worst time was very upsetting*. The adult is also asked to describe the most upsetting event experienced in the past year, then rate it on how upsetting it was—*A little*, *Very much*, *totally*. Then the adult is asked to describe the most upsetting event experienced prior to last year and rate how upsetting it was. Age range: all ages. Number of items: 70. Languages available: English; Spanish.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Significant correlations were found between the number of stressors endorsed by the parent on the Child's Upsetting Times Checklist and four measures of childhood PTSD (Fletcher, 1996b): the CPTSDI (.40), the Parent's CPTSDI (.47), the Parent's Report of the Child's Reaction to Stress (.50), and the post hoc CBCL PTSD scale (.52).

Contact Information: Kenneth E. Fletcher, PhD, Department of Psychiatry, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, MA 01655. Telephone: (508) 856-8630. E-mail: kenneth.fletcher@umassmed.edu.

The History of Victimization Form (HVF; Wolfe, Gentile, & Bourdeau, 1987)

Brief Description: The History of Victimization Form is an interview with the caretaker or guardians and/or social worker that assesses timing, frequency, duration, time of cessation, number of perpetrators and their relationship to

the child, of physical abuse, sexual abuse, neglect, emotional maltreatment, and family violence. A review of clinical and protective agency records also is considered. Age range: 8–16 years. Format: yes–no.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Vicky Veitch Wolfe, PhD, Child and Adolescent Centre, 346 South Street, London Health Sciences Centre, London, Ontario, Canada, N6A 4G5. Telephone: (519) 685-8500. E-mail: vicky.wolfe@lhsc.on.ca.

Juvenile Victimization Questionnaire—Caregiver Proxy Report Version (JVQ-CPR; Finkelhor, Hamby, Ormrod, & Turner, 2005)

Brief Description: The JVQ-CPR (see above for the self-report version for children 10 and older) comprises screening questions about 34 acts of violence against children related to five general areas: (1) conventional crime, (2) child maltreatment, (3) peer and sibling victimization, (4) sexual victimization, and (5) witnessing and indirect victimization. Questions associated with each of the five areas are contained in their own module, each of which was designed to be used in its own stand-alone form. Finkelhor and colleagues (2005, p. 385) note, “For theoretical and practical reasons, however, it is preferable to administer the full instrument.” Events that are endorsed are followed up with questions about the number of times the child has been victimized in this manner, who victimized the child, whether or not the child was hurt, and questions specific to the type of victimization reported (e.g., the value of stolen items). The JVQ-CPR can be used without the follow-up questions, at the expense of eliciting detailed information about the different experiences. It asks about the occurrence of events in the previous year, but it can be adapted to query about lifetime exposure. Early testing of the JVQ-CPR included extensive reviews by experts in the field of juvenile victimization. Draft versions were critiqued by focus groups of youth and parents to refine the wording. Administration time: 20 minutes on average. Ages: Intended to assess the experiences of children age 2 years and older.

Evidence of Reliability: To conduct test–retest evaluation of the JVQ-CPR, 100 caregivers of children ages 2–9 were recontacted 3–4 weeks after their original telephone interviews and readministered the JVQ-CPR. The overall agreement for the caregiver proxies was 95%, with a range of 80–100% for the individual items (Finkelhor et al., 2005). The mean kappa was .50, with a range of –.03 to 1.0. Most of the small kappas were associated with items that had a low response rate. Noting that there are good reasons to question the utility of tests of internal consistency among questions designed to assess actual experiences, the authors reported the values for the total of the 34 JVQ items ($\alpha = .80$), as well as for each of the individual summary subscales: .61 for Conventional Crime (8 items), .64 for Physical Assault (10 items), .38 for Property Victimization (3 items), .39 for Child Maltreatment (4 items), .51 for Sexual Victimization (7 items), .35 for Sexual Assault (4 items), .55 for Peer or Sibling Victimization (9 items), and .35 for Peer or Sibling Assault (.35).

Evidence of Validity: Among 1,026 caregivers of young children ages 2–9 years who participated in a national telephone survey, most of the single items and all of the subscale totals of their measure of the JVQ-CPR correlated significantly with the Trauma Symptom Checklist for Young Children (TSCYC—Briere, 2000; see Appendix 9.4 below) Anxiety, Depression, and Anger subscales (Finkelhor et al., 2005).

Contact Information: David Finkelhor, PhD, Crimes Against Children Research Center, University of New Hampshire, 126 Horton Social Science Center, Durham, NH 03824. Example items from the questionnaire are available as an appendix to Finkelhor and colleagues (2005).

Lifetime Incidence of Traumatic Events (LITE), Parent Form (Greenwald & Rubin, 1999)

Brief Description: The LITE Parent Form assesses exposure to 16 potentially traumatic stressors, such as a car accident or death of someone in the family. It measures the frequency of exposure, age at time of exposure, and how upset the child was by the event at the time and currently on a 3-point scale (*None, Some, Lots*). Age range: 8+. Languages available: English, Spanish, German, Persian, Swedish.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Sidran Institute, 200 E. Joppa Road, Suite 207, Towson, MD 21286. Telephone: (410) 825-8888. E-mail: sidran@sidran.org. Website: www.sidran.org.

My Exposure to Violence (MyETV)—Parent/Caregiver Report Version (Selner-O’Hagan, Kindlon, Buka, Raudenbush, & Earls, 1998)

Brief Description: MyETV, Parent/Caregiver Report Version is a highly structured interview designed to cover a child’s lifetime and past-year exposure to 18 different violent events that the child has either witnessed or personally experienced. It also ascertains location of violence (e.g., school, home, neighborhood), identifies both perpetrators and victims of violence (e.g., family member, stranger), and whether the exposure was gang-related. MyETV measures lifetime exposure (*Ever*) and annual prevalence (*In the past year*). Frequency of exposure is measured on a 6-point scale (*Never, Once, 2 or 3 times, 4 to 10 times, 11 to 50 times, and More than 50 times*). Six subscales are defined: (1) Witnessing violent events, (2) Victimization, and (3) Total Exposure (witnessing and victimization), obtaining scores for both lifetime and past-year exposure.

Evidence of Reliability: The version of MyETV for children, adolescents, and young adult respondents (see above, this appendix) had high internal consistency ($r = .68-.93$) and test–retest reliability ($r = .75-.94$). But psychometrics for the parent form are not available.

Evidence of Validity: The authors also provide evidence of construct validity for children, adolescents, and young adult respondents.

Contact Information: Mary Beth Selner-O’Hagan, PhD, Department of Maternal and Child Health, Harvard School of Public Health, 677 Huntington Avenue, Boston, MA 02115. E-mail: mohagan@phdcn.harvard.edu.

Parent Version of KID-SAVE (P-KID-SAVE; Flowers, Lanclos, & Kelley, 2002)

Brief Description: The P-KID-SAVE, a reworded version of the KID-SAVE (Hastings & Kelley, 1997a; see above, this appendix), allows administration to caregivers of children. The P-KID-SAVE has yet to be empirically validated.

Evidence of Reliability: Internal consistency among parents of 182 young children (48% girls), in grades 3 through 7 (average age = 9.88 years, $SD = 1.65$), was demonstrated with Cronbach's alphas of .88 for the frequency scale for Indirect Violence, .65 for frequency of Traumatic Violence, and .66 for frequency of Physical/Verbal Abuse; the alphas were .87 for the impact of Indirect Violence scale, .79 for impact of Traumatic Violence, and .69 for impact of Physical/Verbal Abuse. Alphas for the totals of the two domains, frequency and impact, were not reported.

Evidence of Validity: Correlations between parent and child responses to the P-KID-SAVE and the KID-SAVE on five of the six subscales were low (.26 to .30) but significant. The correlation between parent and child ratings on the impact of Indirect Violence were nonsignificant (.15). Paired *t*-tests resulted in only one significant difference between parent and child ratings on the six subscales. Children reported significantly greater frequency of exposure to physical/verbal abuse than did the parents. Parent reports of their children's frequency of physical/verbal abuse was significantly associated with their ratings of their children's Withdrawn, Anxious-Depressed, Social Problems, Attention Problems, Delinquent, and Aggression subscale scores, as well as the Internalizing and Externalizing scores on the CBCL (Achenbach, 1991a). Parent ratings of their children's frequency of traumatic violence also was associated with the Social Problems subscale on the CBCL. Anxiety scores on the Trauma Symptom Checklist for Children (TSCC—Briere, 1996a, 1996b; see Appendix 9.5) were associated with parent's ratings of the frequency of their children's exposure to indirect violence. However, only children's self-reports were associated with the Posttraumatic Stress subscale of the TSCC (see above, this appendix).

Contact Information: Anise Flowers, PhD, Tarnow Center for Self-Management, 1001 West Loop South, No. 215, Houston, Texas 77027. E-mail: doctorflowers@email.com.

Preschool Age Psychiatric Assessment (PAPA) Life Events Scale (Egger & Angold, 2004)

Brief Description: This is the life events form of a module of the full PAPA (Egger & Angold, 2004; see Appendix 9.3). The Life Events Scale is a semistructured interview that assesses stressors affecting this age group. High-magnitude stressors include physical and sexual abuse and death of a parent. Low-magnitude stressors include reduction in standard of living and attending unsafe day care. PAPA includes detailed history of accidents, as well as hospitalization, separation from significant attachment figures for more than 1 week, and becoming homeless. Training is required. Age range: 3–6 years. Interviewer qualifications: Bachelor's degree or higher. Languages available: English and Spanish.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Developmental Epidemiology Program, Duke University Medical Center, Attention: Juné Rogers, DUMC Box 3454, Durham, NC 27710. Telephone: (919) 687-4686, extension 273. E-mail: jrogers@psych.duhs.duke.edu.

Survey of Exposure to Community Violence—Parent Report Version (SECV-P; Richters & Saltzman, 1990)

Brief Description: The SECV-P is a self-report measure that evaluates children's exposure to 20 forms of severe violence (shootings, stabbings, and rapes), less severe violence (beatings and chasings), and moderately severe violence (threats, accidents, drug deals, and arrests). Parents report on whether the child has been the victim of, witnessed, or simply heard about each kind of event. The frequency of each exposure is assessed on a 9-point scale, ranging from *No exposure* (0) to *Exposed every day* (8). "For each positive response, the questionnaire includes context questions about (1) where the violence took place (in or near school versus home), (2) who perpetrated the violence (ranging from stranger to family member), (3) who, if not the child, was victimized (ranging from stranger to family member), and (4) when the incident occurred (ranging from 1 week ago to more than 5 years ago)" (Richters & Martinez, 1993, p. 9). The SECV is also known as the Survey of Children's Exposure to Community Violence. The Child Self-Report Version was presented earlier in this appendix.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Among 53 mothers (Osofsky, Wewers, Hann, & Fick, 1993), their ratings of their children's distress using the CCDS (Richters & Martinez, 1990a; see Appendix 9.5) correlated significantly with the parent's report on the SECV-P child's witnessing community violence ($r = .42$), simply hearing about such violence (.48), minor family conflicts (.39), and severe family conflicts (.61). Moreover, the magnitude of the correlations was associated with the magnitude of the stressor. Thus, the CCDS correlated .35 with moderate types, .29 with the less than severe types of community violence, and .51 with the most severe (a shooting, a stabbing, or rape).

Contact Information: John E. Richters, PhD, Department of Human Development and Institute for Child Study, University of Maryland, Benjamin Building, Room 4104, College Park, MD 20742. Telephone: (301) 405-7354. E-mail: jr Richter@nih.gov.

Traumatic Events Screening Inventory—Parent Report (TESI-P; Ghosh Ippen et al., 2002)

Brief Description: Based on TESI-C (presented earlier in this appendix), the TESI-P is a semistructured interview or self-completion instrument for parents. It is recommended that it be administered as an interview. Two stages are employed to the interview. Stage I comprises only questions about whether the child was exposed to each type of event. In Stage II, detailed follow-up questions, similar to those used in the TESI-C, are asked only for events endorsed positively by the parent. Age range: 0–18 years. Languages available: English, Spanish.

Evidence of Reliability: See TESI-C, this appendix.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Chandra Ghosh Ippen, PhD, Child Trauma Research Project, University of California, San Francisco, CA 94143. Telephone: (415) 206-5312. E-mail: chandra.ghosh@ucsf.edu.

Violence Exposure Scale for Children—Parent Version (VEX-R; Fox & Leavitt, 1995; Shahinfar et al., 2000)

Brief Description: The VEX-R parallels the preschool version (presented earlier in this appendix). For every event to which a caregiver responds positively, the interviewer probes for information regarding the location of the event, the identity of the perpetrators and victims, who was with the child at the time, and how long ago the exposure took place.

Evidence of Reliability: Among 155 parents of children ages 3.5 to 4.5, Cronbach's alpha was .72 for parent reports of their children's exposure to mild violence (8 items; Shahinfar et al., 2000). Too few parents (0.6%) reported that their children had been exposed to severe violence to allow the internal consistency of that set of items to be assessed. Parent and child reports showed no significant association with each other in this study. In the Raviv and colleagues (2001) study of Israeli children's exposure to violence, associations between child and parent reports on respective versions of the VEX tended to be significant, especially for episodes of mild violence, with correlations of .34 for the total of witnessing items, and .47 for the total of victimization items.

Evidence of Validity: No significant associations were found between parent reports of children's exposure to violence and children's distress, as assessed by the CBCL (Achenbach, 1991a). However, when analyses were restricted to children who appeared to understand the measures, parents who reported that their children had witnessed mild violence rated their children as having significantly higher levels of internalizing behavior problem. Parents who reported that their children had been victims of mild violence rated their children as having had higher levels of externalizing behavior problems than did the parents who indicated their children had not had such exposure. No significant association was found between parent reports of children's exposure to severe violence and reports of children's problem behaviors on the CBCL. In a study of the violence experiences of Israeli children (Raviv et al., 2001), the correlations between child and parent reports of severe violence exposure were lower but still significant for the totals of the witnessing items (.22) and the victimization items (.37). Children reporting more experiences of violent victimization were reported by their mothers to have more behavior problems, as measured by the CBCL.

Contact Information: Ariana Shahinfar, Department of Psychology, University of North Carolina, Charlotte, NC 28223-0001. E-mail: ashahinf@email.unc.edu.

APPENDIX 9.2. Assessments of the Level and Quality of Exposure

ADMINISTERED TO CHILD

Children's Peritraumatic Experiences Questionnaire (CPEQ; Wolfe & Birt, 1993)

Brief Description: The CPEQ is a 33-item self-report scale to assess children's emotional reactions during sexual abuse experiences, or for nonabused children, their most negative life experience. Feelings and thoughts related to DSM-IV criterion A2 are assessed, including helplessness, fear, terror, sadness, and anger. Items are divided into five scales derived from a principal components analysis: Extreme Reactions (e.g., thoughts of being killed or killing perpetrator, fear of death and injury, becoming ill, wanting to throw something, terror, or fainting), Fear/Anxiety, Negative Affect, Dissociation, and Guilt. Each question is rated on a 3-point Likert-like response set: *None*, *Some*, and *A lot*. Age range: 8–16 years. The CPEQ is now included with the Children's Impact of Traumatic Events Scale–II (CITES-II; Wolfe, Gentile, Michienzi, Sas, & Wolfe, 1991; see Appendix 9.5).

Evidence of Reliability: Internal consistency alphas are .89 for Extreme Reactions, .86 for Fear/Anxiety, .88 for Negative Affect, .81 for Dissociation, and .54 for Guilt (Wolfe & Birt, 2002a).

Evidence of Validity: Sexual abuse survivors scored significantly higher than both agency-referred and community children on all but the Guilt scale of the CPEQ. The scales correlated significantly with both child and parent ratings of the child's PTSD responses. Frequency of abuse correlated with the Dissociation scale at the .05 level, but not at the Bonferroni-corrected level of .003 (Wolfe & Birt, 2002a).

Contact Information: Vicky Veitch Wolfe, PhD, Child and Adolescent Centre, London Health Sciences Centre, 346 South Street, London, Ontario N6A 4G5. Telephone: (519) 685-8500. E-mail: vicky.wolfe@lhsc.on.ca.

Exposure Questionnaire (EQ; Nader, 1993, 1999)

Brief Description: The EQ assesses aspects of the event(s) that are associated with increased PTSD symptomatology—such as whether there was threat to life, threat of injury, subjective proximity to the events, relationship to victims, worries about others, property damage, and helping efforts—and the child's or adolescent's emotional reactions—such as helplessness, fear, horror, panic, guilt—both during and after the traumatic experience. Inquires are made about frequency and intensity of the reactions. Space is given for a description of the child's experience. Two questionnaires are included, one for Postwar questions and one for Postdisaster or Violence questions. Responses are either yes–no or based on a 5-point Likert-like scale. Age range: 7–17 years. Languages available: English, Croatian, Kuwaiti Arabic.

Evidence of Reliability: Evidence of reliability has not yet been published.

Evidence of Validity: Scores on the EQ have been shown to be associated with exposure and severity levels of children exposed to war (Nader & Fairbanks, 1994; Nader, Pynoos, Fairbanks, Al-Ajeel, & Al-Asfour, 1993).

Contact Information: Kathleen Nader, DSW. Fax: (512) 219-0486. E-mail: measures@twosuns.org.

ADMINISTERED TO CARETAKER OR OTHER ADULTS

Dimensions of Stressful Events (DOSE) Scale (Fletcher, 1996d)

Brief Description: The DOSE scale is designed to assess the characteristics or dimensions of high-magnitude stressor events suggested by the literature to increase the likelihood of a child or adolescent responding with PTSD symptomatology. Items are divided into two sections. The first section contains 25 items that assess things such as the child's proximity to the event, viewing of blood, and whether anyone was injured or died; whether or not the child was separated from caretakers; relationship of the child to any perpetrator and victims; the child's sense of stigmatization; the suddenness and unexpectedness of the event(s); the perceived uncontrollability of the event(s); duration and frequency of exposure to the event(s); whether the source of the event(s) was human rather than nature; whether the adverse consequences of the event(s) are long-lasting, irreversible, liable to recur, or involved moral conflicts for the child; whether the child perceived the event(s) as a threat to family or friends; and whether the event(s) originated within the family. The second section contains 24 items that assess the frequency and degree of child abuse experiences, as well as experiences that may mitigate the child's responses, such as the extent to which the parents support the child's claim. A suggested scoring key accompanies the scale. The measure is in the public domain. The interviewer or clinician completes the measure with information from the child, caretakers, and records. Age range: all ages.

Evidence of Reliability: Internal consistency alpha was .60 among 326 school-age and younger children exposed to domestic violence (Fletcher, Spilsbury, Creedan, & Friedman, 2006).

Evidence of Validity: The DOSE correlated significantly with school-age children's self-reported PTSD symptomatology, as measured by both the When Bad Things Happen scale (.70; Fletcher, 1996g; see Appendix 9.5) and the CPTSDI—Child Form (.77; Fletcher, 1996b, 1996c; see Appendix 9.5). It also correlated significantly with parent reports of the child's PTSD symptomatology, whether measured by the Parent Report of the Child's Reaction to Stress (.54; Fletcher, 1996e; see Appendix 9.5), the CPTSDI—Parent Form (.66; Fletcher, 1996b, 1996c; see Appendix 9.5), or an ad hoc CBCL PTSD scale (.47). When regressing the child's PTSD symptomatology on gender, family income, stressful life experiences, and the DOSE, the DOSE tended to be a significant predictor, whereas stressful life experiences were not (Fletcher, 1996c). Among adolescent psychiatric inpatients, the DOSE correlated significantly with the When Bad Things Happen scale (.45–.54), the CPTSDI—Child Form (.34), and the Child's Reaction to Traumatic Events Scale (CRTES—Jones, 1996; see Appendix 9.5) (.42). The DOSE again tended to predict PTSD symptomatology significantly in statistical regression tests, whereas lifetime stressors did not (Fletcher, Cox, Skidmore, Janssens, & Render, 1997). In a sample of 1,277 children (50.4% female, 44.7% African American, 29.4% European American, 3.1% Hispanic; mean age 7.6 ± 4.4 years) participating in a community-based intervention for children exposed to interpersonal violence, DOSE scores were normally distributed (mean score = 21.2 ± 5.7 , median = 21.0, range 1–38; Fletcher et al., 2006). DOSE scores did not differ by gender. European American children scored slightly higher than African American children [21.9 vs. 21.1, $t(943) = 2.097, p = .030$]. The DOSE correlated significantly with Briere's (1996b) Trauma Symptom Checklist for Children (TSCC; see Appendix 9.5) Posttraumatic Symptom (PTS) scale (.42), Anxiety (.42), Depression (.35), and Dissociation (.26), as well as Saylor, Swenson, Reynolds, and Taylor's (1999) Pediatric Emotional Distress Scale (PEDS; Appendix 9.4) total (.28), and Quay and Peterson's (1996) Revised Behavior Problem Checklist (RBPC) Anxiety (.19) and Conduct Disorder (.20) scales, with TSCC correlations generally higher among girls, and PEDS and RBPC correlations only significant for boys. After adjusting for gender, age, and ethnicity, the DOSE significantly predicted TSCC PTS, Depression, Dissociation, Anxiety, Anger, and Sexual Concerns scales scores (in linear regressions) and clinical cutoffs (in logistic regressions). Receiver operating characteristic (ROC) analysis indicated that a total DOSE score of 22.5 or higher provides the best sensitivity–specificity trade-off when predicting the TSCC PTS scale (area under the curve [AUC] = .74, $p \leq .001$).

Contact Information: Kenneth E. Fletcher, PhD, Department of Psychiatry, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, MA 01655. Telephone: (508) 856-8630. E-mail: kenneth.fletcher@umassmed.edu.

Peritraumatic Response Scale (Pfefferbaum et al., 2002)

Brief Description: The Peritraumatic Response Scale contains 12 items addressing the participant's peritraumatic responses of fear, arousal, and dissociation at the time of the incident.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Betty Pfefferbaum, MD, JD, Department of Psychiatry and Behavioral Sciences, College of Medicine, University of Oklahoma Health Sciences Center, 920 Stanton L. Young Boulevard, WP-3470, Oklahoma City, OK 73104. Telephone: (405) 271-5251. E-mail: betty-pfefferbaum@ouhsc.edu.

APPENDIX 9.3. General Child Psychiatric Assessment Interviews with a PTSD Module

ADMINISTERED TO CHILD

Child and Adolescent Psychiatric Assessment (CAPA) Scale (Angold & Costello, 2000)

Brief Description: The CAPA is a general child and adolescent, glossary-based interview that includes a PTSD module. There are both child and parent report versions. Criteria A1 and A2 are assessed with the Life Events Scale. Other diagnoses covered include disruptive behavior disorders (including attention-deficit/hyperactivity disorder, on the parent version only, and conduct disorder), mood disorders (including depression and mania), anxiety disorders (including generalized anxiety disorder, separation anxiety, panic disorder, and obsessive-compulsive disorder), eating disorders, sleep disorders, elimination disorders, substance use/abuse/dependence, tic disorders, and others (including adjustment disorders, reactive attachment disorder of childhood, and somatization symptoms). Frequency and duration of symptoms are assessed for many symptoms. Psychosocial impairment related to the presence of a symptom is rated in 19 domains related to life at home, school, and elsewhere. There are two alternate forms for different ages: the PAPA for preschool-age children (see below, this appendix) and the YAPA for young adults (see Appendix 9.6). Age range: 9–17 years. Time period covered: Previous 3 months, except for select symptoms involving infrequent acts, such as firesetting or suicide attempts. Interviewer qualifications: bachelor's degree and up. Languages available: English, Spanish.

Evidence of Reliability: Test–retest reliability kappas for DSM-III-R diagnosis using the Child version (CAPA-C) with 77 clinically referred children ages 10–16 years ranged from .50 for conduct disorder to .90 for major depression. ICC for DSM-III-R PTSD symptom scale scores was $>.90$ (Angold & Costello, 1995). The ICC for level of psychosocial impairment by child self-report (on the CAPA-C) was .77 (Angold & Costello, 1995). A kappa coefficient of .64 for interrater reliability on PTSD diagnosis using the CAPA-C was found in another study (Costello et al., 1998). The same study found an ICC for interrater reliability of .94 for the overall CAPA-C. This same study found a kappa of .54 for interrater reliability for PTSD diagnosis using the parent version (CAPA-P), whereas an ICC for interrater reliability on the overall CAPA-P was .99.

Evidence of Validity: The PTSD module of both the Child (CAPA-C) and Parent (CAPA-P) versions differentiated between a clinical sample and a community sample based on PTSD diagnosis (Costello et al., 1998).

Contact Information: Developmental Epidemiology Program, Duke University Medical Center, Attention: Juné Rogers, DUMC Box 3454, Durham, NC 27710. Telephone: (919) 687-4686, extension 273. E-mail: jrogers@psych.duhs.duke.edu.

Children's Interview for Psychiatric Syndromes (ChIPS; Rooney, Fristad, Weller, & Weller, 1999; Weller, Weller, Rooney, & Fristad, 1999, 2000)

Brief Description: The ChIPS is a highly structured interview that screens for 20 DSM-IV Axis I disorders, as well as psychosocial stressors such as emotional, physical, or sexual abuse and neglect. Questions use simple language and short sentence structure to enhance subject comprehension and cooperation. The interview is based on DSM-IV, and results are presented in a concise, easy-to-interpret manner. The Stress Disorders section assesses both ASD and PTSD. Exposure to a high-magnitude stressor is assessed by one question asking whether anything very bad has happened to the child, such as being kidnapped or attacked, and if yes, what? A second question asks whether the child has ever witnessed something bad happening to someone else, but not on TV, and if so, what? If the child does not describe an experience that meets criterion A in one of these questions, no more Stress Disorder questions are asked. Otherwise, five questions attempt to ascertain the child's reactions to the experience(s) and whether or not they satisfy the second half of criterion A. If not, the rest of the Stress Disorder questions are skipped. Otherwise, the child is asked how long ago the event(s) took place. If it happened within 4 weeks of the interview, six questions are asked to assess whether the child reacted with symptoms of dissociation or derealization. If so, children are asked if they have felt as if they were not themselves, as if they were no longer real (depersonalization), and if they have trouble remembering things about the event(s). Then seven questions are asked to assess reexperiencing symptoms, two to assess feeling "upset" by reminders of the experience(s), and one to assess physical reactions to reminders, such as stomachaches or trouble breathing. If none of these symptoms are endorsed, the rest of the Stress Disorder questions are skipped. Otherwise, 10 questions are asked to assess symptoms of avoidance and withdrawal. If none of these are endorsed the rest of the questions are skipped. Otherwise, one question is asked about changes in moods or emotions since the event(s), one about feelings of numbness since the event(s), and two about feelings of foreshortened future. Six questions are then asked about symptoms of overarousal, anger, and difficulty concentrating. If none of these questions are endorsed, one question is asked about a tendency to startle easily. Then the interviewer is given two algorithms to determine whether the child meets criteria for ASD or PTSD, or neither. Next children are asked when the symptoms began and whether they are still troubled by the symptoms, and if not, the interviewer attempts to determine when the symptoms stopped. Children who meet criteria for ASD are asked if the symptoms began within 4 weeks of the event(s), if they lasted more than 2 days, and if they have lasted for less than 4 weeks. Those who meet criteria for PTSD are asked if the symptoms have lasted longer than 1 month. Finally, children are asked whether "these problems cause you trouble" at home, at school, and with other kids. If duration of symptoms can be determined, the interviewer can indicate whether or not the PTSD can be classified as being of acute or chronic duration, and whether symptoms had a regular onset (within 6 months of the event(s) or a delayed onset (more than 6 months after the event(s)). Age range: 6–18 years, with an IQ over 70. Administration time: 49 minutes for inpatients, 30 minutes for outpatients, 21 minutes for a community-based sample (Weller et al., 2000). Training: ChIPS is designed to be administered by people with at least a bachelor's degree in a field associated with mental health. It is recommended that lay interviewers be trained by a clinician familiar with DSM-IV who has undergone similar training on ChIPS.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Among 18 girl and 22 boy psychiatric inpatients (Fristad, Cummings, et al., 1998) agreement between the ChIPS and the Diagnostic Interview for Children and Adolescents—Revised (DICA-R; Kaplan & Reich, 1991; see below, this appendix) for diagnosis of PTSD was .77 for girls (using low-base-rate kappa; Verducci, Mack, & DeGroot, 1988), representing an 89% agreement rate, with the two interviews agreeing that 4 girls had PTSD and 12 did not, while disagreeing on 2 girls' PTSD diagnoses; whereas, the low-base-rate kappa for boys was .49, representing 95% agreement that 21 boys did not have PTSD, while there was disagreement on one boy's PTSD diagnosis. The same data indicated that the two interviews agreed 100% of the time on diagnosis for children ages 6–12 (with 1 yes and 20 no), whereas agreement was 84%, with a low-base-rate kappa of .67 for adolescents ages 13–17 (3 yes and 13 no) and disagreeing on three diagnoses. Among a community sample of 40 children and adolescents ages 6–18, agreement was 100% that none had PTSD (Fristad, Glickman, et al., 1998).

Contact Information: Available from American Psychiatric Publishing Group. Telephone: (800) 368-5777. Website: www.appi.org. Elizabeth Weller, MD, Department of Child Psychiatry, Children's Hospital of Philadelphia, 34th Street and Civic Center Boulevard, Philadelphia, PA 19104; E-mail: weller@email.chop.edu.

Diagnostic Interview for Children and Adolescents—Revised (DICA-R; Kaplan & Reich, 1991; see MAGIC below)

Brief Description: The DICA-R, a semistructured interview, has been replaced by the Missouri Assessment of Genetics Interview for Children (MAGIC—Reich & Todd, 2002; see below). It is included here primarily because so many other measures have used the interview to establish validity. The DICA-R is a modification of the Diagnostic Interview for Children and Adolescents (DICA; Herjanic & Reich, 1983a, 1983b), developed for the assessment of diagnoses in children 6–17 years old. The DICA-R modified the DICA to allow for assessment of DSM-III-R criteria. Questions were rephrased to be more conversational in manner, and questions related to DSM-III-R diagnoses were added (Kaplan & Reich, 1991), including a PTSD module. The DICA-R was revised to allow assessment of DSM-IV diagnoses. The PTSD module included four questions to assess criterion A (exposure to a high magnitude stressor), seven questions for criterion B (reexperiencing), nine for criterion C (denial and numbing), and five questions for criterion D (overarousal). Questions are asked to determine duration (criterion E) and intensity of endorsed symptoms, and to assess changes in social interactions and school behavior (criterion F). Response categories are *No*, *Rarely*, *Sometimes or Somewhat*, and *Yes*. Determination of criterion is accomplished by adding these ratings and meeting specific thresholds. Difficulties have been reported among 7-year-olds in understanding some of the DICA-R questions intended for use with 6- to 12-year-olds (reported in Nader, 1997). Age range: 6–17 years. Available languages: English, Spanish, and Arabic. A computerized version is available. Time required for administration of the full DICA-R is 1½ hours. Training is required. The interview may be administered by research assistants with no more than a bachelor's degree. There are versions for younger children ages 6–12 years, for adolescents, and for parents.

Evidence of Reliability: Cronbach's alphas on the PTSD module among 37 stress-exposed inner-city children were .44, .87, .83, and .87 for criteria A–D, respectively (Yasik et al., 1998). Test–retest reliability for diagnosis of PTSD per the module among 90 children was .79 (reported in Nader, 1997). Interrater reliability averaged .91 among interviewers of adolescents exposed to a residential fire (Jones & Ribbe, 1991).

Evidence of Validity: Agreement between DICA-R PTSD diagnoses and clinical diagnoses was 100% among 86 children; sensitivity was 1.00, and specificity was .86 (reported in Nader, 1997). When Yasik and colleagues (1998) compared DICA-R PTSD diagnoses and clinical diagnoses among 37 stress-exposed and 12 non-stress-exposed inner-city children, 9 of 15 PTSD cases were identified correctly (sensitivity = .60), and 33 of 34 non-PTSD cases were identified correctly (specificity = .97). Overall, the PTSD status of 85.7% of the children was identified correctly. Adolescents exposed to a residential fire reported significantly more symptoms of PTSD when interviewed with the DICA-R PTSD module than did those not exposed to the fire (Jones & Ribbe, 1991). On the other hand, the PTSD module was unable to distinguish between adolescents exposed to wildfires and those not exposed (Jones et al., 1994).

Diagnostic Interview Schedule for Children (DISC; Shaffer et al., 1988, 1993, 2000)

Brief Description: The DISC is a structured interview that assesses more than 30 DSM-IV childhood psychiatric disorders. The PTSD module includes three questions to establish criterion A, exposure to a traumatic event. If none are endorsed, no more questions are asked. Responses are *No* (0), *Sometimes/somewhat* (1), and *Yes* (2). The presence of a symptom in the past month and the past year is assessed. Training recommended for interviewers usually takes 3 days.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Among 671 children and adolescents ages 9–17 years and their parents residing in housing units, only 8 (1.2%) met DSM-III criteria for PTSD per child report using an earlier version of the DISC, and only 4 (0.6%) met PTSD criteria per parent report (Fisher et al., 1993; cited in Nader, 1997). But when the two reports were combined using an algorithm, 21.2% met two or more of the four diagnostic criteria. “There were strong associations between major depression, generalized anxiety disorder, conduct disorder, and substance-use disorders with increased risk of PTSD” (Nader, 1997, p. 321).

Schedule for Affective Disorders and Schizophrenia for School-Age Children (6–18 years)–IV—Revised (K-SADS-IV-R; Ambrosini & Dixon, 2000; Kaufman et al., 1997; Orvaschel, Puig-Antich, Chambers, Tabrizi, & Johnson, 1982)

Brief Description: The K-SADS-IV-R was developed from the adult interview, the Schizophrenia and Affective Disorder Scales. The semistructured versions are the K-SADS-E (Epidemiological version) and the K-SADS-PL (Present and Lifetime versions). This interview is primarily for use in research settings and is to be administered by a clinician trained in its use, so it is rarely used in ordinary clinical settings. It covers a broad spectrum of most child psychiatric diagnoses, with the exception of pervasive development disorders and personality disorders, and is used with children ages 6–18 years. For younger children it is recommended that a single clinician interview the parent(s) first, then repeat the interview with the child. It is recommended that adolescents be interviewed first. The scale includes questions about school performance and other issues relevant to children and adolescents. According to the K-SADS-PL website (see URL in contact information), “The K-SADS-PL was adapted from the K-SADS-P (Present Episode Version), which was developed by William Chambers, M.D., and Joaquim Puig-Antich, M.D., and later revised by Joaquim Puig-Antich, M.D., and Neal Ryan, M.D. The K-SADS-PL was written by Joan Kaufman, Ph.D., Boris Birmaher, M.D., David Brent, M.D., Uma Rao, M.D., and Neal Ryan, M.D. The K-SADS-PL was designed to obtain severity ratings of symptomatology, and assess current and lifetime history of psychiatric disorders, including several disorders not surveyed in the K-SADS-P. The current instrument is greatly indebted to several other existing structured and semi-structured psychiatric instruments, including the K-SADS-E (Orvaschel & Puig-Antich), the SADS-L (Spitzer and Endicott), the SCID ([Structured Clinical Interview for DSM-III-R] Spitzer, Williams, Gibbon, and First), the DIS ([Diagnostic Interview Schedule] Robins and Helzer), the ISC ([Interview Schedule for Children] Kovacs), the DICA (Reich, Shayka, and Taibleson), and the DUSI ([Drug Use Screening Inventory] Tarter, Laird, Bukstein, and Kaminer). . . . The K-SADS-PL is a semi-structured diagnostic interview designed to assess current and past episodes of psychopathology in children and adolescents according to DSM-III-R and DSM-IV criteria. Probes and objective criteria are provided to rate individual symptoms. The primary diagnoses assessed with the K-SADS-PL include: Major Depression, Dysthymia, Mania, Hypomania, Cyclothymia, Bipolar Disorders, Schizoaffective Disorders, Schizophrenia, Schizophreniform Disorder, Brief Reactive Psychosis, Panic Disorder, Agoraphobia, Separation Anxiety Disorder, Avoidant Disorder of Childhood and Adolescence, Simple Phobia, Social Phobia, Overanxious Disorder, Generalized Anxiety, Obsessive Compulsive Disorder, Attention Deficit Hyperactivity Disorder, Conduct Disorder, Oppositional Defiant Disorder, Enuresis, Encopresis, Anorexia Nervosa, Bulimia, Transient Tic Disorder, Tourette’s Disorder, Chronic Motor or Vocal Tic Disorder, Alcohol Abuse, Substance Abuse, Post-Traumatic Stress Disorder, and Adjustment Disorders.” The PTSD module first asks whether the child has ever experienced or witnessed something “very frightening, terrible or upsetting.” If the answer is no, the remainder of the questions in the section are skipped. If yes, the child is asked how it made him or her feel. Again, if the response does not meet DSM-IV criterion A2, the remainder of the questions are skipped. If the answer meets criterion A2, questions are asked to assess the presence or absence of the 17 symptoms of DSM-IV PTSD criteria B through D. The interviewer then rates the overall severity of symptoms on a scale from 1 (*Not at all*) to 6 (*Extreme: almost all the time experience symptomatic trauma. Is impaired daily in all functional areas*). The month, day, and year of the onset and offset of PTSD is then estimated based on reports of the child and parent. Training: A semi-structured interview, the K-SADS-PL requires intensive training relative to the instrument, diagnostic classification, and differential diagnosis. Time required: For normal controls, the child and parent interviews required 35–45 minutes each. With psychiatric patients, they can required 1.5 hours or longer, depending on the range and severity of psychopathology of the child.

Evidence of Reliability: Psychometric properties of the K-SADS-PL were assessed in a sample of 55 psychiatric outpatients and 11 normal controls ages 7–17 years ($M = 12.4$, $SD = 2.6$; Kaufman et al., 1997). Parents and children were both interviewed. Interrater reliability among one Master’s-level and four Bachelor’s-level interviewers in scoring screens and diagnoses for 15 children was high, ranging between 93 and 100%. The test–retest reliability kappa coefficient ($n = 20$) for present PTSD diagnosis over an average of 18 days between administrations was .67. Using an earlier version, K-SADS-E, interrater (parent–child) agreement was 87.5% (McLeer, Deblinger, Henry, & Orvaschel, 1992).

Evidence of Validity: Evidence of validity has yet to be published.

Mini-International Neuropsychiatric Interview for Children and Adolescents (MINI Kids; Amorim et al., 1998; Lecrubier et al., 1997; Sheehan et al., 1997; Sheehan, Lecrubie, Weiller, Hergueta, & Sheehan, et al., 1998)

Brief Description: The MINI Kids is an abbreviated psychiatric interview for children. A parent version is available. Unfortunately, the PTSD module does not assess all of the DSM-IV symptoms. Criteria A1, A2, and B1 are all assessed with one question each. Six questions assess criterion C; five questions assess criterion D; and one question assesses whether the endorsed symptoms have upset the child a lot and caused him or her problems at school, at home, or with friends. All questions are answered yes or no.

Evidence of Reliability: Current psychometrics appear to be restricted to the adult version of the MINI. The interrater reliability kappa for the PTSD module for adults is .95, and the test–retest kappa is .73 (Sheehan et al., 1998).

Evidence of Validity: The psychometrics for the adult version look good, with agreement between the adult clinician rated MINI and the SCID-P (Spitzer, Williams, Gibbon, & First, 1990) diagnosis of PTSD, with a kappa of .78, a sensitivity of .85, specificity of .96, a positive predictive value of .82, and a negative predictive value of .97 (Sheehan et al., 1998).

Contact Information: Free download available online (after free registration) at www.medical-outcomes.com/indexssl.htm.

Missouri Assessment of Genetics Interview for Children (MAGIC; Reich & Todd, 2002)

Brief Description: MAGIC, a semistructured interview with a glossary for interpreting responses, is based on the DSM-IV version of the DICA (Reich, 2000) and DICA-R (discussed earlier, this appendix). Unlike many interviews, most skip patterns have been removed from the different diagnostic modules to allow complete information to be gathered on the number of symptoms per diagnostic category, regardless of whether DSM-IV criteria are met for the diagnostic category. Versions are available for children (MAGIC-C), adolescents (MAGIC-A), and parents about their children (MAGIC-P). The initial question of the PTSD module asks whether the child has ever had something really awful happen to him or her. Many example probes are provided for the interviewer. If the answer is no, the PTSD module is skipped; otherwise, three questions attempt to establish criterion A2 (whether the child's reaction was one of terror, horror, or feeling completely helpless). A further question allows for a description of the child's feelings in his or her own words. Single questions are asked regarding four of the five DSM-IV symptoms of reexperiencing; three questions are asked about feeling as if the event were recurring, flashbacks, and playing games or drawing pictures about the event. Single questions are asked for six of the seven criterion C symptoms, and two questions are asked regarding feelings of detachment and restricted affect. Single questions are asked for four of the five criterion D symptoms, and two questions are asked about increased irritability and loss of temper. If at least one positive response is given to questions regarding criteria B–D, an attempt is made to determine how soon after the traumatic event the symptoms began, how long they lasted, and how much the symptoms have "interfered with her or his life" to assess criteria E and F. Questions are then asked about how much the child had the endorsed symptoms prior to the event, whether or not the child was taken to a doctor or counselor, or other professional because the parent was worried about the child, and if so, who the child saw and whether any medication was prescribed. Then the parent is asked whether he or she was worried about the child because of the event, whether the child stayed in his or her room because of the event, and whether the child ever attempted to "get out of doing things with the family" because of the event. Responses are *No* (0), *Sometimes/somewhat* (1), and *Yes* (2). *Sometimes* is considered an endorsement of a symptom for the PTSD module. Presence of symptoms is assessed for the past year and for the lifetime prior to the previous year. Age range: 9–17 for child and adolescent interviews, and for parents of children ages 7–17.

Evidence of Reliability: Although Todd, Joyner, Heath, Neuman, & Reich (2003) demonstrated good interrater and test–retest reliability for several of the disorders assessed by MAGIC, the reliability of the PTSD module has yet to be examined.

Evidence of Validity: Evidence of the validity of the PTSD module is currently unavailable.

ADMINISTERED TO CARETAKER OR OTHER ADULTS

The Preschool Age Psychiatric Assessment (PAPA; Egger & Angold, 2004; Egger, Ascher, & Angold, 1999; Egger et al., 2004)

Brief Description: The PAPA is a substantial rewrite of the CAPA for preschool-age children, which included changing DSM-IV and ICD-10 criteria to better reflect experiences of younger children; symptoms and diagnoses were included from the *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood, Revised Edition* (CD:0–3R; Zero to Three, 2005); relevant items were added from other preschool measures not covered by the CAPA; appropriate changes were made to the family functioning and relationships sections; and alternative diagnostic criteria for some disorders were used, among other changes. Alternate PTSD and reactive attachment disorder diagnostic criteria were based on criteria suggested by Zeanah, Boris, and Scheeringa (Boris et al., 1998; Scheeringa et al., 1995, 2001; Scheeringa & Zeanah, 1995). In the PTSD module, detailed information is gathered regarding 21 changes in child's behaviors, emotions, or relationships that might have occurred due to the event, such as new fears or anxieties, increased crying, increased aggression, regression of toileting skills or language, and changes in the interactions with others (Egger & Angold, 2004). Each symptom is rated for frequency, intensity, duration, and date of onset. If the caregiver indicates that at least one high-magnitude stressor has occurred in the child's life, and believes that experience is related to at least one symptom (new fears, separation anxiety, etc.), then the interviewer asks the questions in the PTSD section. The PAPA includes the following sections: Family Structure and Function; Play and Peer and Sibling Relationships; Daycare/School Experiences and Behaviors; and Other Food-Related Behaviors; Sleep Behaviors; Elimination Problems; Somatization; Accidents; Oppositional Defiant Disorder/Conduct Disorder; Attention-Deficit/Hyperactivity Disorder; Separation Anxiety; Anxious Affect; Worries; Rituals and Repetitions; Tics; Stereotypes; Reactive Attachment; Depression; Mania; Dysregulation; Life Events; PTSD; Disabilities; Parental Psychopathology; Marital Satisfaction; and Socio-Economic Status. Interviewers must have at least a bachelor's level degree. PAPA training requires 1–2 weeks of classroom work and 1–2 weeks of practice, including at least four practice interviews. Didactic training on the glossary and interview methods is interspersed with role playing, taped and live interviews, and feedback. Certification by a qualified PAPA trainer is required before using the PAPA in the field. Age range: 3–6 years. Respondent: caregiver. Languages available: English and Spanish.

Evidence of Reliability: Test–retest kappa for PTSD diagnosis is .73 (Egger et al., 2004).

Evidence of Validity: Evidence of validity has yet to be published.

APPENDIX 9.4. PTSD-Specific Measures for Children Ages 0–7

ADMINISTERED TO CHILD

Levonn: A Cartoon-Based Structured Interview for Assessing Young Children's Distress Symptoms (Martinez & Richters, 1993; Richters, Martinez, & Valla, 1990). A version for preschool children has been devised by Shahinfar and colleagues (2000; see the VEX scale in Appendix 9.1 for contact information)

Brief Description: Levonn is a 39-item, cartoon-based, structured interview of children's distress symptoms based on an earlier cartoon-based interview of general psychiatric symptoms, Dominique (Valla, 1989). The Dominique interview was revised so that the main character, Levonn, represents an urban child. The new interview includes cartoons of symptoms associated with PTSD, 2–3 sentence scripts are included for each cartoon, and the response format was changed to three thermometers filled to varying degrees of mercury, indicating increasing levels of frequency. The thermometers are labeled *Never*, *Some of the time*, and *A lot of the time*. Before administration of the PTSD interview, children are taught how to use the thermometer response format correctly. Each cartoon is described by the interviewer, after which children circle a thermometer to indicate how often they have felt like Levonn. On one page, for example, the three thermometers take up the top one-third of the page. On the right half of the lower portion of the page are three cartoons, laid out vertically one over the other. In the top cartoon, a frowning young boy, with a white face, is shown in his pajamas walking away from a bed, somewhat slouched over, with his head slightly bent down. The middle cartoon shows the boy, now dressed for school, walking, again slouched over, head bent, and frowning, dragging a book bag along the ground. In the bottom cartoon, Levonn is again in pajamas, standing facing his bed, head bent, and frowning. In the middle of the left bottom half of the page is the following script, which the interviewer reads to the child being interviewed, "Here is Levonn feeling very sad for a whole day. He gets up in the morning feeling sad, he feels sad all day, and he still feels sad at bedtime. How many times have you felt like Levonn?" (Martinez & Richters, 1993, p. 26). The scale comprises four subscales measuring Depression, Anxiety/Recurring Thoughts, Sleep Problems, and Impulsiveness. In the revised version for preschoolers (Shahinfar et al., 2000), the symptoms assessed include sadness, lack of appetite, fear of going outside because of possible violence, intrusive traumatic memories, and having nightmares. In a study of 155, primarily (98.8%) African American children between ages 3.5 and 4.5 years, the authors carefully debriefed children after administering the revised Levonn (Shahinfar et al., 2000). They reported that very few of the children indicated either verbally or behaviorally that they had been upset by the interview. A Hebrew version, with the main character named Sharon, exists (Raviv et al., 2001; see VEX, Appendix 9.1 for contact information).

Evidence of Reliability: Test–retest reliability over a 1-week period of the total was measured with Pearson's correlation, with $r_{(22)} = .81$ among children in first and second grades (Martinez & Richters, 1993). Cronbach's alphas among 111 first and second graders in the same study were .78 for the 10-item Depression subscale, .84 for the 14-item Anxiety/Intrusive Thoughts subscale, and .71 for the 7-item Depression subscale. The number of items in the Impulsiveness subscale was not reported, nor was the subscale's alpha. The alpha was not reported for the full scale.

Evidence of Validity: Among 111 children in the first and second grades (Martinez & Richters, 1993), the total score correlated significantly with parent ratings of their children's distress, as rated by the Checklist of Child Distress Symptoms (CCDS—Richters & Martinez, 1990a; see Appendix 9.5). Correlations among the subscales ranged from .64 to .85, which justified combining them into a total score. Scores on the Levonn correlated significantly ($r_{(76)} = .32$, $p < .01$) with parent reports of their child's distress on the Parent Form of the CCDS (Richters & Martinez, 1990a; see Appendix 9.5). Although parent–child agreement was significant for boys ($r_{(38)} = .41$, $p < .01$), it was not significant for girls ($r_{(38)} = .19$, ns). However, because girls reported significantly more exposure to intrafamilial violence, the agreement was assessed between just mother and daughters within families with levels of intrafamilial violence similar to that reported in the boys' families, and this agreement was significant ($r_{(31)} = .34$, $p < .05$). Correlations between experiences of violent victimization in the community and symptoms of distress as measured by the Levonn were significant ($r_{(31)} = .28$, $p < .01$). Children's reports of witnessing violence in the community also correlated significantly with their total scores on the Levonn ($r_{(81)} = .30$, $p < .01$). Children's reports of the frequency of seeing guns or drugs also correlated significantly with total distress scores on the Levonn, regardless of where that occurred ($r_{(81)} = .30$). In a study of violent experiences among school-age (second- and fourth-grade) Israeli children (Raviv et al., 2001), the Hebrew version of Levonn correlated significantly with the Hebrew version of the VEX (see description in Appendix 9.1) regardless of whether the violence was mild or severe, and whether the experience was as a victim, a witness, or seen on TV, with correlations ranging from .24 (for mild violence on TV) to .46 (for victimization by mild violence). Small but significant correlations were found between symptoms of distress (as measured by the preschool version of the Levonn) and witnessing mild violence ($r = .29$, $p < .05$), victimization by mild violence ($r = .22$, $p = .05$), and witnessing severe violence per reports on the VEX ($r = .25$, $p < .05$; see Appendix 9.1; Shahinfar et al., 2000).

Contact Information: John E. Richters, PhD, Department of Human Development and Institute for Child Study, University of Maryland, Benjamin Building, Room 4104, College Park, MD 20742. Telephone: (301) 405-7354. E-mail: jrichter@nih.gov.

Posttraumatic Symptom Inventory for Children (PT-SIC; Eisen, 1997)

Brief Description: The PT-SIC (Eisen, 1997, cited in Stover & Berkowitz, 2005), a 30-item questionnaire that assesses PTSD symptoms based on DSM-IV criteria, includes a checklist to screen for 11 high-magnitude stressors (e.g., car crashes, sexual abuse, witnessing or being a victim of community violence). Questions are addressed in two stages. A child is first asked whether a symptom ever occurs. If he or she answers affirmatively, the child is asked to indicate the frequency of such occurrences: *A real lot—like everyday* (scored 2) or *Just sometimes* (scored 1). Age range: 4–8 years.

Evidence of Reliability: The full scale had an internal consistency alpha of .91 among 220 children ages 4–17, and a test–retest kappa for diagnosis of .87. It is unclear how many of these children were under 6 years old (reported in Stover & Berkowitz, 2005).

Evidence of Validity: The PT-SIC correlated .64 with the TSCC (Briere, 1996; see Appendix 9.5); however, the TSCC is designed for use only with children age 8 years and older (reported in Stover & Berkowitz, 2005).

Contact Information: M. L. Eisen, PhD, Department of Psychology, California State University, 5151 State University Drive, Los Angeles, CA 90032-8227. Telephone: (323) 343-5006. E-mail: meisen@calstatela.edu.

ADMINISTERED TO CARETAKER OR OTHER ADULTS

Pediatric Emotional Distress Scale (PEDS; Saylor et al., 1999)

Brief Description: Although the 21-item PEDS was designed to assess behaviors theoretically and empirically associated with trauma in children, it does not assess DSM-IV criteria for PTSD. However, it has been used successfully to assess the responses of children ages 2–7 to traumatic events (Saylor et al., 1999; Spilsbury, Drotar, Burant, Flannery, Creeden, & Friedman, 2005; Stokes, Saylor, Swenson, & Daugherty, 1995; Swenson, Saylor, Paige Powell, Stokes, Foster, & Belter, 1996). The scale's first 17 items form three subscales: Anxious/Withdrawn, Fearful, and Acting Out. The sum of these 17 items produces an overall distress score. The additional four items are questions about the child's communication relative to the event or avoidance of reminders of the event. For each item, the frequency of the behavior is rated on a 4-point scale, ranging from *Almost never* to *Very often*. Saylor and colleagues (1999) found that to maximize discrimination between traumatized and nontraumatized children, cutoff scores for the PEDS and its subscales were best adjusted according to the mother's education. Thus, although a PEDS total greater than 27.5 appeared to provide the best sensitivity/specificity trade-off, for mothers with a high school education or less, a PEDS total of 16.5 provided the best cutoff; for mothers with some college or an Associate's degree, the best cutoff was 23.5, and for mothers with a Bachelor's degree or higher, the best cutoff was 36.5. Similar cutoffs for the subscales, overall and adjusted for the mothers' education, are presented in Saylor and colleagues (1999). Overall, the use of such adjusted cutoffs allowed "78% of the cases to be correctly classified, with a false positive rate of 9.5% and a false negative rate of 12.5%" (p. 77). Administration time: 5–8 minutes.

Evidence of Reliability: Among a sample of parents of 475 children ages 2–10, Saylor and colleagues (1999) reported an internal consistency alpha of .85 for the 17-item PEDS total, and alphas of .72 for the Fearful subscale, .74 for the Anxious/Withdrawn subscale, and .78 for the Acting Out subscale. Interrater reliability correlation between mothers' and test–retest fathers' ratings was .65 for the total, .47 for the Fearful subscale, .58 for the Anxious/Withdrawn subscale, and .64 for the Acting Out subscale. Over a 6- to 8-week test–retest period, scores for the two time periods correlated .56 for the total, .55 for the Fearful subscale, .58 Anxious/Withdrawn subscale, and .61 for the Acting Out subscale. In a sample of 383 children ages 2–7 years who received services from the Children Who Witness Violence Program of Cuyahoga County, Ohio, which provides mental health services to children who have witnessed domestic violence, assault, or other violent and traumatic events, exploratory and confirmatory factor analysis suggested the PEDS may actually be better conceived of as having a two-factor structure, with an Act Out factor and an Internalize factor (see discussion in section on validity of evidence for this measure for more detail; Spilsbury et al., 2005). Cronbach's alpha was .80 for the revised total 13-item version, .80 for the Internalize subscale, and .82 for the Act Out subscale.

Evidence of Validity: Children exposed to a Class IV hurricane 14 months earlier scored significantly higher on overall behavioral problems, anxiety, and withdrawal than did children who had no known history of exposure to natural disaster (Swenson et al., 1996). In another study (Stokes et al., 1995), children with a history of negative life events or exposure to high-magnitude stressors scored significantly higher than those with no known trauma on the total PEDS and the Acting Out, Anxious/Withdrawn, and Fearful factors. Moreover, children evaluated due to allegations of sexual abuse scored significantly higher than the other groups on the total and all subscales. Evidence of convergent and discriminant validity in Saylor and colleagues' (1999) study was indicated by significant correlations between the PEDS total (.62) and Acting Out (.86), Anxious/Withdrawn (.42), and Fearful (.32) subscale scores, with scores on the Eyberg Child Behavior Inventory (Eyberg & Ross, 1978). The Reaction Index (Frederick, 1985b) correlated with the total PEDS (.62), and the Anxious/Withdrawn (.62) and Fearful (.59) subscales, but was not significantly correlated with the Acting Out subscale. Spilsbury and colleagues (2005), in a confirmatory factor analysis on 383 children ages 2–7, found that the three-factor solution could not be satisfactorily reproduced. Therefore, the sample was split in half, and an exploratory factor analysis was conducted on half the sample. Four items failed to load on any factor and were removed from further consideration: "Acts younger than used to for age," "Has trouble going to bed/falling asleep," "Clings to adults, doesn't want to be alone," and "Refuses to sleep alone." The final solution comprised two factors, one of which replicated Saylor and colleagues' (1999) Acting Out factor, except for the addition of one item: "Cries without good reason." The second factor, labeled Internalize, combined items from the original two factors of Anxious/Withdrawn and Fearful. A confirmatory factor analysis of the modified two-factor structure on the other half of the sample showed fairly good fit. Convergent and discriminant validity of the two factors was demonstrated by showing that they correlated differently with different subscales of the Revised Behavior Problem Checklist (RBPC; Quay & Peterson, 1996): The PEDS modified Acting Out factor correlated .21 with the RBPC Anxiety/Withdrawal *T*-score, .73 with the Conduct Disorder *T*-score, and .52 with Socialized Aggression, whereas the PEDS modified Internalize factor correlated .57, .18, and .21, respectively, with these RBPC subscales, and no significant correlations were found between either the PEDS modified factor or conceptually unrelated RBPC factors. Small but significant differences were found by gender, ethnicity, and chronicity of the violence in some of the revised PEDS scores. In a subsample of 192 children, both a caregiver and a mental health specialist completed the 17-item PEDS. Correlations between the two ratings were significant, ranging from .46 to .63, indicating good interrater reliability of the measure.

Contact Information: Conway F. Saylor, PhD, Department of Psychology, The Citadel, 171 Moultrie Avenue, Charleston, SC 29409. The items of the PEDS are listed in a table in Saylor and colleagues (1999).

Posttraumatic Stress Disorder Semistructured Interview and Observational Record for Infants and Young Children (PSDSIORYC; Scheeringa & Zeanah, 1994)

Brief Description: The PSDIORYC, a 37-item semistructured interview for the parent or guardian of infants or young children (generally 0–3 years of age) based on the authors' suggested alternate criteria for PTSD in preschool children (Scheeringa et al., 2003), has also been incorporated in both the Research Diagnostic Criteria for Infancy and Preschool (RDC:IP; Task Force on Research Diagnostic Criteria: Infancy and Preschool, 2003) and the Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood: Revised Edition (DC:0–3R; Zero to Three, 2005). Both the RDC:IP and DC:0–3 slightly amend the DSM-IV overall criteria for PTSD, still requiring that both A1 and A2 criteria, one symptom of reexperiencing, but only one or more symptom of avoidance or numbing, and two symptoms of overarousal be met. The interviewer first asks the parent or guardian whether the preschooler or infant has been exposed to one of seven different high-magnitude stressors—an automobile accident or plane crash, an attack by a large animal, other man-made disasters, experiencing or witnessing a natural disaster, witnessing another person being violently abused, physical or sexual abuse—or ever accused someone of physical or sexual abuse. The parent or guardian is given an opportunity to identify an eighth possible high-magnitude stressor. The date of each event described is noted, along with a brief description. For each event, parents or guardians are asked whether the event was traumatic for the preschooler or infant, and whether the child's response was apparent intense fear, helplessness, horror, or disorganized or agitated behavior. Six questions are then asked about symptoms of reexperiencing, seven about symptoms of avoidance or numbing, and five about overarousal. Questions regarding four associated symptoms are asked next: loss of acquired developmental skills, new fears, new separation anxiety, and new aggressive behaviors. The parent or guardian is then asked whether the child has been bothered by most of his or her symptoms for as long as 1 month. Finally, five questions address the child's functioning in the family, among peers, at school, with caregivers, and whether the symptoms upset the child. Possible responses to the questions assessing criteria A–D are *No*, *Possibly*, and *Yes* relative to the symptom's presence. Possible responses for the final five questions on functioning are *A lot of the time*, *Some of the time*, and *Hardly ever or none of the time*. The interview with the caretaker is conducted with the child in the room. Observing the child's behavior during the interview allows the interviewer to include the child's behavior in scoring the interview. Interviewer training required: A high degree of clinical skill is required. Languages available: English, German, Hebrew.

Evidence of Reliability: Mean interrater reliability kappa among four raters of 12 children younger than 48 months for the individual symptoms was .67 (Scheeringa & Zeanah, 2003). Kappas ranged from .81 to 1.00 for the symptom clusters. The mean kappa for PTSD diagnosis was .75.

Evidence of Validity: Scheeringa and Zeanah (2003) compared 62 traumatized children ages 20 months through 6 years with 63 healthy control children of the same age. Mean duration between the traumatic experience and assessment was 11.3 months, with a median of 7.5 months and a 2- to 52-month range. The authors judged that requiring three symptoms of avoidance was too strict a criterion for this age group, and revised this criterion to just one symptom of avoidance to diagnose PTSD. With this revision, 26% (16) of the 62 traumatized children were diagnosed with PTSD, leaving 46 traumatized children with no PTSD. The PTSD group had significantly higher rates of separation anxiety disorder (SAD) and oppositional defiant disorder (ODD) and scored higher on the CBCL Internalizing and total scales compared to the trauma/no-PTSD group. The PTSD group scored higher on 9 of 11 comorbid conditions. Within the traumatized group, regardless of PTSD diagnosis, younger children (1–3 years) exhibited more symptoms of reexperiencing than older children (4–6 years). They also manifested more symptoms of PTSD, SAD, major depressive disorder, and higher Internalizing, Externalizing, and total scores on the CBCL. These children were followed up for at least 2 years (Scheeringa et al., 2005); at the 2-year follow-up assessment, of the 16 children diagnosed with PTSD at time 1 using the PSDSIORYC, 8 (50%) were diagnosed with PTSD 2 years later with the DISC (Shaffer et al., 1988; see Appendix 9.3), whereas 8.7% of the non-PTSD group received a PTSD diagnosis at the 2-year follow-up. Age range: 3–5 years.

PTSD Symptoms in Preschool-Age Children (PTSD-PAC; Levendosky, Huth-Bocks, Semel, & Shapiro, 2002)

Brief Description: The PTSD-PAC is an 18-item questionnaire completed by caregivers, based on the DSM-IV PTSD criteria and with additional, young-child-focused questions based on the PSDSIORYC (Scheeringa & Zeanah, 1994; see this appendix). The first 5 items assess symptoms of DSM-IV criterion B; the next five assess criterion C; and the final eight items assess criterion D. Caregivers indicate the *Presence* or *Absence* of each symptom. The items are listed in Levendosky and colleagues (2002, Table 1).

Evidence of Reliability: Internal consistency alpha was .79 for the full scale (Levendosky et al., 2002).

Evidence of Validity: The PTSD-PAC did not correlate with CBCL post hoc "PTSD" scale (Achenbach, 1991a; the CBCL post hoc "PTSD" scale was created by Wolfe, Gentile, & Wolfe, 1989), perhaps because the so-called "PTSD" scale of the CBCL may actually measure general dysphoria more than PTSD. This possibility is supported by the fact that mothers' kinds of domestic violence experiences were significantly correlated with scores on the PTSD-PAC. Total scores ranged from .38 for "mild violence" experiences to .55 for threats of violence (although they were only .39 with sexual violence). Scores on the Reexperiencing (criterion B) subscale ranged from .45 for exposure to "mild violence" to .61 for exposure to threats of violence (.50 with sexual violence). Scores on the Hyperarousal (criterion D) subscale correlated significantly with three of the four types of domestic violence experiences assessed in the study, with corre-

lations ranging from .27 with experiences of sexual violence to .50 with threats of violence. This subscale was not significantly correlated (.20) with experiences of “severe violence,” although this may have something to do with the small sample size (62 children). On the other hand, the Avoidance (criterion C) subscale did not correlate significantly with any of the four types of the mothers’ domestic violence experiences.

Trauma Symptom Checklist for Young Children (TSCYC; Briere, 2000)

Brief Description: The TSCYC, a 90-item caretaker report, may be used for children ages 3–12. Each symptom is rated on frequency of occurrence in the last month on a 4-point scale, from *Not at all* (1) to *Very often* (4). It contains eight subscales: Posttraumatic Stress–Intrusion (PTS-I), Posttraumatic Stress–Avoidance (PTS-AV), Posttraumatic Stress–Arousal (PTS-AR), Sexual Concerns (SC), Dissociation (DIS), Anxiety (ANX), Depression (DEP), and Anger/Aggression (ANG). A total Posttraumatic Stress scale is created by summing the PTS items. Unlike the Trauma Symptom Checklist for Children (TSCC; Briere, 1996a, 1996b; see Appendix 9.5), the TSCYC is capable of offering a possible diagnosis of PTSD and includes a scale of the validity of the caretaker report response level (RL), a measure of the tendency to endorse very unusual and unrelated behaviors, and atypical response (ATR), a measure of the tendency to deny even normal, minor problematic behavior in one’s child. It also contains an item that asks, “On average, how many hours do you spend in the same place (for example, at home) with him or her each week, not counting when he or she is asleep?” which is rated on a scale from 1 (*0–1 hour*) to 7 (*Over 60 hours*). Examples of items on the TSCYC are looking sad, bad dreams or nightmares, living in a fantasy world, pretending to have sex, drawing pictures about an upsetting thing that happened to him or her, and throwing things at friends or family members. The English version of the scale has recently been tested with 750 children, which allows for the calculation of standard *T*-scores to be computed based on the age and gender of the child. So children’s scores can be compared to normative scores, although the manual states that the normative sample included only 149 children (3- to 4-year-olds), so using the TSCYC to diagnose PTSD with this age group is not appropriate. Languages available: English and Spanish.

Evidence of Reliability: Among a sample of 219 children ages 3–12 ($M = 7.1 \pm 2.6$; 62.8% girls; 38% European American, 27.8% Hispanic, and 25.4% African American) internal consistency alphas were .87 for the total score, and .82 for the PTS-I, .85 for the PTS-AV, .93 for the PTS-AR, .93 for the PTS-Total, .81 for the SC, .86 for the ANX, .84 for the DEP, .91 for the DIS, and .91 for the ANG subscales (Briere, 2000; Briere et al., 2001). For the validity scales, alpha was .73 for the RL but only .36 for the ATR.

Evidence of Validity: Gilbert (2004, as cited in Stover & Berkowitz, 2005) found that the subscales had significant correlations, ranging from .55 to .82 with several other parent reports. The TSCYC ANX and DEP subscales correlated most strongly with the CBCL (Achenbach, 1991a) Anxiety–Depression subscale. The TSCYC ANG subscale correlated most strongly with the CBCL Aggression subscale. The TSCYC SC scale correlated most strongly with Friedrich’s (1998) Child Sexual Behavior Inventory (CSBI). The TSCYC DIS scale was most strongly correlated with the Child Dissociation Checklist (CDC; Putnam, Helmers, & Trickett, 1993). Finkelhor and colleagues (2005) found that among 1,026 parents of young children ages 2–9 years, assessed in a national survey, most of the single items and all of the subscale totals of their measure of victimization in young children, the JVQ-CPR (see Appendix 9.1), correlated significantly with the TSCYC ANX, DEP, and ANG subscales. In a sample of 219 children being seen by therapists for abuse (Briere, 2000; Briere et al., 2001), hierarchical multiple regression analyses, which adjusted for children’s age, gender, and ethnicity, indicated that childhood sexual abuse was associated with ratings of PTS-I, PTS-AV, PTS-Total, and SC on the TSCYC. Childhood physical abuse was related to PTS-I, PTS-AR, PTS-Total, and DIS. Witnessing domestic violence was related to PTS-I, PTS-AV, PTS-AR, PTS-Total, and negatively with SC.

APPENDIX 9.5. PTSD-Specific Measures for Children Ages 7–18

ADMINISTERED TO CHILD

Checklist of Children’s Distress Symptoms, Child Form (CCDS; Martinez & Richters, 1993; Richters & Martinez, 1990a)

Brief Description: The CCDS is a 28-item, self-report scale that asks questions associated with traumatic responses to high-magnitude stressors. Questions examine anxiety, memory problems, sleeping problems, self-esteem, school performance, and feelings of depression, isolation, or hopelessness. Responses are rated on a 1- to 4-point scale, ranging from *Never* (1) to *A lot of the time* (4). The CCDS comprises two subscales measuring Depression and Anxiety, but the two subscales’ high correlation (.64) justifies combining them for the total score. Age range: 10 years and older.

Evidence of Reliability: Among 54 fifth and sixth graders, Cronbach’s alphas for the Depression subscales and Anxiety were .71 and .72, respectively.

Evidence of Validity: Parents reported significantly lower levels of child distress than was reported by their children on both the Depression and Anxiety subscales, as well as on many of the individual items (Martinez & Richters, 1993). Agreement between parents and their daughters was nonsignificant ($r_{(17)} = .06$), whereas agreement between parents and their sons was significant, moderately high, and negative ($r_{(18)} = -.56$), which the authors note was not attributable to outliers (p. 30). They suggest that the negative correlation may be attributable to a tendency of the boys

to deny their symptoms, at least in part. At the same time, children's reports of exposure to stressors were significantly correlated with their CCDS scores, whether they were themselves victims of community violence ($r_{(37)} = .37$) or witnessed it ($r_{(37)} = .39$), or witnessed violence in the home ($r_{(37)} = .33$).

Child and Adolescent Trauma Survey (CATS—March, Amaya-Jackson, Terry, et al., 1997; March et al., 1998)

Brief Description: This 12-item, paper-and-pencil self-report measure is modeled on the CPTS-RI (see below, this appendix) and the Multidimensional Anxiety Scale for Children (MASC; March, Parker, Sullivan, Stallings, & Conners, 1997). It assesses DSM-IV PTSD symptomatology (March, Amaya-Jackson, Terry, et al., 1997; March et al., 1998). This measure has also been referred to as the Kiddie Posttraumatic Symptomatology Scale (March, 1999) and the Self-Reported Posttraumatic Symptomatology scale (SRPTS; March, Amaya-Jackson, Terry, et al., 1997). The CATS is currently undergoing further psychometric testing, and its final form is not yet determined. The CATS first assesses exposure to high-magnitude stressors (13 were included in the original version), which includes witnessing stressful events. Children and adolescent respondents are asked how often they experienced each symptom during the last month, using a 4-point Likert scale—*Never, Rarely, Sometimes, or Often*. Each DSM-IV PTSD criterion variable is represented by at least two questions (March, Amaya-Jackson, Terry, et al., 1997). A total score of 27 or above on the CATS is considered a clinically significant level of PTSD (Suliman, Kammer, Seedat, & Stein, 2005), but PTSD diagnosis is not possible with the CATS (March, Amaya-Jackson, Terry, et al., 1997).

Evidence of Reliability: The CATS reportedly has excellent internal and test-retest reliability, but the actual values have not been published (March et al., 1998). However, Cronbach's alphas among 176 children and adolescents ages 8–17 ($M = 11.8$ years) within 1 month of a recent injury or intensive care unit admission (thus, not yet eligible for a PTSD diagnosis) were .84 at first administration, and then .82 among 146 of the young patients contacted 3 months later (Kassam-Adams, 2006).

Evidence of Validity: Among a sample of 1,327 children and adolescents in the fourth through ninth grades in Hamlet, North Carolina, where an industrial fire at a local chicken-processing plant caused loss of life among family, friends, and/or neighbors, factor analysis supported a three-factor solution ($n = 1,327$), with factors associated with symptoms of reexperiencing, avoidance, and hyperarousal (March, Amaya-Jackson, Terry, et al., 1997). An expected fourth factor, numbing, was highly correlated with the reexperiencing factor (.94), so the two factors were merged. Avoidance and reexperiencing were strongly correlated ($r = .64$), and hyperarousal was weakly correlated with reexperiencing/avoidance (.105). Thus, three subscales emerged from the factor analysis. The items were submitted to an item response theory (IRT)—model analysis, which allowed each item to be weighted optimally to reflect the domain of interest. In the "IRT analyses, information regarding reexperiencing/avoidance clustered at the high or 'symptomatic' end of the distribution of the latent PTS variable. In contrast, hyperarousal followed a bimodal distribution . . . [with] most of the 'information' in the hyperarousal questions [coming] from those with and without hyperarousal (an inverted U-shaped curve). If present, hyperarousal suggested PTS; if absent, it predicted no PTS as marked by reexperiencing/avoidance, but the effect was weak enough to be a distinction without a difference" (p. 1082). The IRT analysis suggested a T -score ≥ 65 on the reexperiencing factor indicative of PTS. Using this analysis, 9.7% of the children met criteria for PTSD, while 11.9% met PTSD DSM-III-R criteria. Agreement between the IRT and DSM-III-R criteria was moderate ($\kappa = .56$), and the difference between the two methods was significant (McNemar's chi-square [1, 1015] = 5.56, $p < .018$). Increasing exposure to victims of the fire strongly predicted increased risk for post-traumatic stress symptomatology as assessed by the CATS. When an IRT-derived T -score > 65 was used to classify children as positive for posttraumatic stress, 3.0% of the children not exposed to the fire, 10.5% of the visually exposed, 15.8% of those with a friend or relative involved, and 30.4% with both visual and friend/relative exposure rose above the cutoff score ($F_{(3,1019)} = 35.15$, $p < .001$; March, Amaya-Jackson, Terry, et al., 1997). The CATS has been demonstrated to be responsive to change (in the total score and in each subscale) over time due to an effective cognitive-behavioral treatment intervention (March et al., 1998). The CATS correlated significantly (.77) with the ASC-Kids (Kassam-Adams, 2006; see Appendix 9.7), a measure of ASD.

Childhood PTSD Interview—Child Form (Fletcher, 1996b, 1996c)

Brief Description: The Childhood PTSD Interview—Child Form is a semistructured interview of the child that allows the interviewer to assess DSM-III-R (APA, 1987) and DSM-IV criteria and to make a diagnosis. It contains items that allow the interviewer to rate the child's willingness to describe the stressor(s), to indicate whether there is evidence that the events did not occur or that the child misperceived or described details inaccurately, and to rate how well the child's description of the event(s) matches that of the caregiver. Fifty-seven questions assess DSM-III-R PTSD criteria A–D. Four questions assess criterion A. Four questions assess the first symptom of criterion B (B1), three assess B2, four assess B3 (two of which ask for clarification of endorsed questions), and three assess B4. Five questions assess C1; three assess C2; one question assesses C3, with a follow-up question, if the first is answered in the negative (both require elaboration for positive responses); three assess C4 (with elaboration required for positive responses); three assess C5, two questions and a rater question regarding possible flat affect of the child assess C6; and 6 questions assess C7 (because C7 concerns a sense of foreshortened future, and few studies support the presence of this symptom in children, the author believes these six questions can be skipped). Two questions, with required elaborations for positive responses, assess D1; two questions, one of which is a follow-up question to establish changed behavior since ex-

posure to the stressor assess D2; four questions assess D3; four questions assess D4; and two questions assess D5. Two questions assess complaint of physiological reactions, which is D6 according to DSM-III-R, and B5 according to DSM-IV. An optional, additional 28 questions assess associated symptoms. Interviewers may choose to ask some, all, or none of these questions. Five questions assess symptoms of anxiety (three require elaboration for positive responses, and one asks the rater to indicate whether breathing problems may be due to asthma). Three questions assess symptoms of depression. Two questions, with required elaboration for positive responses, assess indications of whether the child perceives certain prestressor events as omens. Two questions, with required elaboration for positive responses, assess symptoms of survivor guilt. Two questions, with required elaboration for positive responses, assess symptoms of guilt or self-blame. The interviewer is asked to indicate to what extent the child actually might be considered to have some responsibility for events. Two questions, with required elaboration for positive responses, assess indications of fantasy denial. Three questions, two with required elaboration for positive responses, assess possible self-destructive or suicidal thoughts and behaviors. Four questions assess symptoms of dissociation. Three questions assess antisocial behavior. Two assess risk-taking behavior, and two assess changed eating habits. Age range: 7 or 8+, depending on the child's cognitive abilities. Items are answered *Yes* or *No*. *Don't know*s are allowed on many questions and are scored as *No*.

Evidence of Reliability: Cronbach's alpha = .91 for the full PTSD section of the interview, with alphas = .52 for the four questions of criterion A, .80 for criterion B, .76 for criterion C, and .78 for criterion D (Fletcher, 1996b).

Evidence of Validity: The interview correlated significantly with other measures of childhood PTSD: .87 with the When Bad Things Happen scale (see this appendix), .69 with the Childhood PTSD Interview—Parent Form (see this appendix), .60 with the Parent Report of the Child's Reaction to Stress (see this appendix), and .52 with an ad hoc CBCL PTSD scale. It correlated significantly (.40) with the total number of lifetime stressors the parent indicated the child had experienced, .53 with the parent's ratings of the child's stressful reactions to those events, and .77 with an assessment of the potentially traumatizing dimensions of the immediate stressor(s) for which the child's reactions were being assessed, according to the DOSE scale (see Appendix 9.2). The interview also correlated significantly with the Internalizing score of the CBCL (.40) but not the Externalizing score (.31), and it correlated significantly with the following CBCL subscales: Anxiety (.48), Thought Problems (which include obsessing on certain thoughts, problems concentrating, repetition of certain acts, and staring blankly; $r = .60$), Somatic Complaints (.39), Attention Problems (.39), and Social Problems (.49) (Fletcher, 1996b). The fact that the interview's correlations with other PTSD measures are all higher than its correlations with measures of other problems indicates its discriminant validity. Scores differentiated between traumatized and nontraumatized children (Fletcher, 1996b). Sensitivity in identifying probable cases of traumatized children, as assessed by the DOSE was 75%, and specificity was 90% (Fletcher, 1996b).

Contact Information: Kenneth E. Fletcher, PhD, Department of Psychiatry, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, MA 01655. Telephone: (508) 856-8630. E-mail: kenneth.fletcher@umassmed.edu.

Child Posttraumatic Stress Reaction Index and Additional Questions (CPTS-RI—Frederick, Pynoos, & Nader, 1992; also known as the PTSD—Reaction Index and the Child PTSD—Reaction Index)

Brief Description: The CPTS-RI has been administered in several different forms. However, the primary version is a 20-item scale that assess some, but not all, of the DSM-IV PTSD symptoms from each of the three core criteria B–D and two associated features (guilt and regression). 11 Additional Questions have been added (Nader, 1999). Response format is 5-point, Likert-like frequency ratings for each symptom, from *None* (0) to *Most of the time* (4). DSM diagnosis of PTSD is not possible directly, although several studies have attempted to divide the symptoms into criteria B–D and dichotomize the 5-point response categories to provide provisional information on possible diagnostic caseness. Designed as a semistructured interview, the CPTS-RI has been used as a paper-and-pencil, self-report measure as well. The authors recommend using the three following thresholds: A total score of 12–24 indicates a mild level of PTSD reaction; 25–39 indicates a moderate level; 40–59, a severe level; and 60+, a very severe level. A revised version has been created, the UCLA PTSD Index for DSM-IV (Pynoos et al., 1998; see this appendix). Another revision is being undertaken by Nader and Fletcher. Age range: 7–17 years. Languages available: English, Canadian French, Croatian, Kuwaiti Arabic, Norwegian, Vietnamese. Administration time: 20–45 minutes to administer and score (Ohan et al., 2002).

Evidence of Reliability: Pynoos and colleagues (1987) reported Cronbach's alphas for three subscales of Reexperiencing/Numbing, Fear/Anxiety, and Concentration/Sleep that ranged from .69 to .80. Cronbach's alphas for the total scale = .78 (Nader et al., 1993), .83 (Lonigan et al., 1991), and .89 (Vernberg, La Greca, Silverman, & Prinstein, 1996), respectively. Interrater reliability has been measured at a kappa of .89 (Nader, Pynoos, Fairbanks, & Frederick, 1990). Test–retest reliability over a 1-week period was .93 (Nader et al., 1990).

Evidence of Validity: The CPTS-RI correlated significantly (.51) with the Clinician-Administered PTSD Scale for Children and Adolescents (CAPS-CA; Carrion, Weems, Ray, & Reiss, 2002; see this appendix), .72 with the UCLA PTSD Index for DSM-IV (Pynoos et al., 1998; see this appendix), .84 with the When Bad Things Happen Scale (Fletcher, 1996g) and .80 with the Child PTSD Symptom Scale (CPSS; Foa et al., 2001; see this appendix). Factor analysis revealed three factors: Reexperiencing/Numbing, Fear/Anxiety, and Concentration/Sleep Problems (Pynoos et al., 1987). Level of exposure to or dosage of high-magnitude stressors has been repeatedly demonstrated to be correlated significantly with scores on the CPTS-RI (Nader et al., 1993; Rossman et al., 1997; Thabet & Vostanis, 1999). Levels of exposure to war-related experiences among children in Kuwait (Nader et al., 1993), as measured by the EQ (Nader, 1993, 1999; see Appendix 9.2) were correlated .38 with the total CPTS-RI, .29 with the Reexperiencing subscale, .31 with the Avoidance subscale, and .36 with the Overarousal subscale.

Child PTSD Symptom Scale (CPSS; Foa, Johnson, Feeny, & Treadwell, 2001)

Brief Description: The CPSS is based on the Posttraumatic Diagnostic Scale (Foa et al., 1997), a measure of PTSD in adults. The language of the adult scale was modified to be more appropriate for children. The 26-item scale includes 2 items assessing criterion A, 17 items assessing criteria B–D, and 7 items assessing criterion E, disruption of functioning. Children and adolescents are asked to indicate how often the 17 PTSD symptoms bothered them in the past month, with responses of *Not at all* (0), *Once a week or less* (1), *2 to 4 times a week* (2), and *5 or more times a week* (3). Children indicate whether their symptoms cause them difficulty in each of the following seven areas of functioning: prayers, chores and duties, relationships with friends, fun and hobbies, schoolwork, relationships with family, and general happiness with life. The seven questions about daily functioning are scored as either *Absent* (0) or *Present* (1). Age range: 8–18 years. Administration time: 15 minutes.

Evidence of Reliability: Psychometrics were assessed in a sample of 75 school-age children and adolescents ages 8–15 years ($M = 11.8$ years; 49% girls, 89% European American, in grades 3 through 8) 25 months after the 1994 Northridge, California, earthquake. Children were asked about their reactions to that event (Foa et al., 1997). All children lived within 3 miles of the epicenter of the earthquake and were asleep when it struck at 4:31 in the morning. Their homes sustained moderate to severe earthquake damage, the region was without water or electricity for 3 or more days, 30% of the children were displaced from their homes, and their school was condemned for more than 8 months. The scale and the other measures used in the study were read aloud to groups of 6–8 children. Cronbach's alphas were .89 for the total of the 17 PTSD criterion B–D items, .80 for reexperiencing, .73 for avoidance, and .70 for overarousal. The CPSS was readministered to 65 of the children and adolescents 1–2 weeks after the first administration. The test–retest reliability of PTSD symptom diagnosis according to the CPSS was moderate, with a kappa of .55. Percentage of agreement between the two time points was 84%. It is unclear what kind of reliability coefficients were used to report the test–retest reliability of the PTSD symptom severity scores, but they appear to have been Pearson correlations, with coefficients of .84 for the total score, .85 for reexperiencing, .63 for avoidance, and .76 for overarousal. The internal consistency alpha for the seven functional impairment items was .35, but when one item that was not related to the other items, “general happiness with life,” was removed, the alpha for the remaining six items was .89. The test–retest coefficient for the total functional impairment score was .70. It is unclear whether this included all seven items or only the six that contributed to the internal consistency of this measure.

Evidence of Validity: The CPSS correlated .80 with the CPTSD-RI, demonstrating good convergent validity (Foa et al., 1997). When scored according to DSM-IV PTSD criteria, 24% of the children reported scores consistent with a PTSD diagnosis. Setting a cutoff score of 11 or higher on the CPSS as an indication of extreme distress yielded 95% sensitivity and 96% specificity when compared to the CPTSD-RI high-distress category. Of the children identified as having high PTSD scores on the CPTSD-RI, 70% met criteria for a PTSD diagnosis per the CPSS, and 17% of the children scoring low on the CPTSD-RI met PTSD criteria per the CPSS. The CPSS correlated .58 with the Depression Self-Rating Scale for Children (Birlleson, 1981) and .48 with the MASC (March et al., 1997), demonstrating discriminant validity, because these correlations are substantially smaller than that with the CPTSD-RI. Functional impairment scores correlated .42 with the total of 17 PTSD items, .37 with reexperiencing, .39 with avoidance, and .36 with overarousal. Those children who met DSM-IV PTSD criteria per the CPSS also reported significantly more functional impairment than those who did not. Of those who met DSM-IV PTSD criteria per the CPSS, 70% endorsed at least one functional impairment item, whereas only 14% of those who did not meet PTSD criteria endorsed at least one functional impairment item.

Children's Revised Impact of Event Scale (13 items) (CRIES-13; Children and War Foundation, 1998)

Brief Description: The CRIES-13 is based on one of the first adult measures of PTSD, the Impact of Event Scale (IES; Horowitz et al., 1979), which comprises 13 items that assess symptoms of reexperiencing and avoidance or withdrawal (DSM-IV criteria B and C). Although it was not designed to be used with children, it has been fairly successful in several studies of traumatized children age 8 and older. However, two large studies (the Yule [1992, 1997; Yule, Ten Bruggencate, & Joseph, 1994] study of 334 adolescent survivors of the Jupiter disaster and the Dyregrov, Kuterovac, & Barath [1996] study of traumatized children in Croatia) found that children misinterpreted several of the questions. Two separate factor analyses of children's responses to the IES (Dyregrov et al., 1996; Yule et al., 1994) revealed identical factor structures for the measure. This led to the creation of a shortened, 8-item version, the IES-8, for children. Weiss and Marmar (1997) added items to the IES reflecting symptoms of overarousal (criterion D), which were not represented in the original IES. So five additional items assessing symptoms of overarousal were created and added to the IES-8 to create the current version of the CRIES-13, which comprises four items measuring reexperiencing, four measuring avoidance, and five measuring overarousal. Respondents rate the frequency with which they experienced each of the 13 items during the past 7 days, using a 4-point Likert-like scale: *Not at all* (0), *Rarely* (1), *Sometimes* (3), or *Often* (5). Note that scoring for the last two response categories increases 2 points over the previous response category. The authors note that few studies have used the 13-item version to date; therefore, they recommend that screening be based on the 8-item version, with a score of 17 or greater indicating possible PTSD. Available languages: Arabic, Bosnian, Chinese, Dari, Dutch (Flemish and Dutch Netherlands), and a version for very young children for parents to complete), English, Finnish, German, Norwegian, Pashto, Swedish, and Tamil.

Evidence of Reliability: Psychometric data for the 8-item version reported in Yule (1997) indicated that the total score on the 8-item version correlated .95 with the original 15-item version. The CRIES-13 was used by Smith, Perrin, Dyregrov, and Yule (2003) to assess traumatic reactions of 2,976 children ages 9–14 years who had experienced war

in Mostar, Bosnia. Cronbach's alphas were .70 for the Intrusion subscale, .73 for the Avoidance subscale, .60 for the Overarousal subscale, and .80 for the total.

Evidence of Validity: Yule (1997) reported that the 15-item and the 8-item versions of the IES correlated significantly with a symptom count of DSM-IV PTSD symptoms in adolescents following an acute trauma (15-item = .76, 8-item = .70). Factor analysis of the CRIES-13 (Smith et al., 2003) revealed a three-factor solution corresponding to the three hypothesized subscales.

Contact Information: The measure is available free online at www.childrenandwar.org.

Children's Impact of Traumatic Event Scale-II (CITES-II; Wolfe et al., 1991)

Brief Description: The CITES-II is a 78-item measure, 24 items of which assess DSM-IV PTSD symptoms. The remaining 54 items assess other symptoms, particularly those associated with interpersonal violence or sexual abuse. Questions assessing symptoms associated with DSM-IV PTSD criteria B and C are based on the Impact of Event Scale (IES; Horowitz et al., 1979); questions assessing hyperarousal are included. The remaining 54 items are from the original version of the measure, the CITES (Wolfe, Wolfe, Gentile, & Larose, 1986). Its 11 subscales are divided into four dimensions: PTSD (Intrusive Thoughts, Avoidance, Hyperarousal, and Sexual Anxiety), Abuse Attributions (Self-Blame/Guilt, Empowerment, Distrust, and Dangerous World), Eroticism, and Social Relations (Negative Reactions to Others, Social Support). Originally designed to assess reactions to childhood sexual abuse, the CITES-II can now be used with youth exposed to any kind of potentially traumatic event. Because it was originally used with abused children, the CITES-II assesses many of the symptoms associated with complex PTSD. Many of the items refer to sexual abuse. It can be scored for a DSM-IV diagnosis or as a continuous measure. The measure continues to evolve. Norms are available for adolescent girls, and research is planned to gather norms for adolescent boys. Psychometric analyses suggested that the Personal Vulnerability scale be replaced by a Distrust scale, and the Hyperarousal scale items are being changed, as well. Age range: 8–16 years. Recommended for use as a semistructured interview, the CITES-II can be used as a paper-and-pencil self-report with children with good reading skills. The 3-point scale response categories are *Not true*, *Somewhat true*, or *Very true*.

Evidence of Reliability: Cronbach's alphas are .89 for the full scale, .89 for PTSD, .78 for Abuse Attributions, .57 for Eroticism, and .87 for Social Relations (Wolfe et al., 1991). Alphas greater than .70 were found for the Reexperiencing, Hyperarousal, Sexual Anxiety, Negative Reactions, and Self-Blame/Guilt scales, and alphas less than .60, for the Dangerous World and Personal Vulnerability scales in a sample of 80 sexual abuse survivors ages 8–17 years (Crouch, Smith, Ezzell, & Saunders, 1999). In another study of 158 sexual abuse survivors ages 7–12 (Chaffin & Shultz, 2001), average alpha was .69 for the scales, whereas alphas for subscales were as follows: .79 for Intrusive Thoughts, .56 for Avoidance, .67 for Hyperarousal, .79 for Negative Reactions by Others, .73 for Self-Blame/Guilt, .67 for Empowerment, .66 for Personal Vulnerability, .73 for Social Support, .72 for Sexual Anxiety, .68 for Eroticism, and .57 for Dangerous World.

Evidence of Validity: Significant, though low, correlations were found between the ad hoc CBCL PTSD scale and the scales of the CITES-II: .28 with Intrusive Thoughts scale, .17 with Avoidance, .28 with Hyperarousal, .17 with Sexual Anxiety, .17 with Dangerous World, .18 with Negative Reactions, .24 with Personal Vulnerability, and .22 with Self-Blame/Guilt (Wolfe & Birt, 2002b). The PTSD scale correlated significantly (.72) with the Trauma Symptom Checklist for Children (TSCC; see below, this appendix) PTS scale among 80 survivors of sexual abuse, ages 8–17 years, whereas the Sexual Anxiety score correlated .65 with the Sexual Distress scale, .49 with the Sexual Concerns scale, .50 with the PTS scale, .62 with the Depression scale, and .38 with the Dissociation scale (Crouch et al., 1999). In a different study of the psychometrics of the measure (Chaffin & Schultz, 2001), no aspects of the abuse for which children were being seen, as measured by the Abuse Dimensions Inventory (ADI; Chaffin, Wherry, Newlin, Crutchfield, & Dykman, 1997), predicted any of the CITES-II subscales, though the ADI did correlate significantly with the DICA-R (Kaplan & Reich, 1991; see Appendix 9.3) PTSD scale. CITES-II scores on the Intrusive Thoughts subscale were significantly associated with the child's ($\eta^2 = .50$) but not the parent's DICA-R PTSD reexperiencing symptoms. The Avoidance subscale was associated with the child's ($\eta^2 = .38$) but not the parent's DICA-R avoidance symptoms. The Hyperarousal subscale was associated with the child's ($\eta^2 = .45$) but not the parent's DICA-R hyperarousal symptoms. The Sexual Anxiety subscale was associated with the child's ($\eta^2 = .25$) but not the parent's DICA-R Total Anxiety score, and it was associated with neither parent report on the CBCL Anxiety and Depression scale nor on the Teacher's Report Form Anxiety and Depression scale. Correlations between the CITES-II Personal Vulnerability and Dangerous World scales were small but significant, with similar alternate measures. The CITES-II Social Support scale did not correlate with any child or parent alternate report of social support. The Negative Reactions by Others subscale was significantly correlated with an alternate parent report of similar behaviors ($r = .18$), and the Eroticism subscale was significantly associated with the parent CBCL report of the child's Sexual Problems (.22). The CITES-II was found to be responsive to pre- to postintervention change (Chaffin & Shultz, 2001), although significant changes over time were found only for the Intrusive Thoughts, Avoidance, Hyperarousal, Self-Blame/Guilt, and Eroticism subscales.

Children's PTSD Inventory (CPTSDI; Saigh, 1998a, 1998b)

Brief Description: The CPTSDI is a 47-question interview designed to provide a DSM-IV diagnosis of childhood PTSD. The child is first read a list of sample traumatic events, then is asked four questions intended to examine exposure to high-magnitude stressors, and four questions to assess possible traumatic reactivity to the exposure, per PTSD criterion A in DSM-IV. If this criterion is not met, the interview terminates. Eleven questions examine the presence or absence of symptoms of intrusion (criterion B in DSM-IV). Sixteen questions address criterion C, avoidance and

numbing symptoms. Seven questions address criterion C, symptoms of overarousal. Five questions assess duration of symptoms (criterion E) and significant impairment in functioning (criterion F). Each item is scored as *Present* or *Absent*. Age range: 7–18 years. Training: May be administered by an individual with a bachelor's degree following approximately 2 hours of professionally supervised analogue training with corrective feedback (Saigh et al., 2000). Time: For youth with trauma history, the CPTSDI requires 15–20 minutes; for youths with no trauma history, less than 5 minutes (Saigh et al., 2000).

Evidence of Reliability: In a sample of 51 girls and 53 boys ages 7–18 ($M = 13.8$), with 30% in elementary school, 25% in junior high school, and 46% in high school, 66% Hispanic, 10% European American, 17% African American, and 8% Asian, Cronbach's alphas were .95 for overall diagnosis, .53 for the Situational Reactivity (criterion A) subscale, .89 for the Reexperiencing subscale, .89 for Avoidance and Numbing subscale, .80 for the Overarousal subscale, and .69 for the Significant Impairment subscale (criterion F; Saigh et al., 2000). All children were diagnosed by two examiners to assess interrater reliability. Agreement was 98.1% on overall diagnosis ($\kappa = .96$). Kappas were 1.00 for judgments of meeting the criterion for the Exposure subscale, .66 for Reactivity, .84 for Reexperiencing, .93 for Avoidance/Numbing, and .95 for Significant Impairment. Based on independent administrations (twice for each child), comparisons of the total symptoms endorsed by the two examiners resulted in an ICC of .98 for the total scale, .89 for Exposure, .88 for Reactivity, .95 for Reexperiencing, .96 for Avoidance/Numbing, .96 for Overarousal, and .94 for Significant Impairment. Forty-two children were readministered the scale 2 weeks apart to assess test–retest reliability. Agreement on the total scale was 97.6%. Kappas for overall diagnosis were .91, 1.0 for both Exposure and Situational Reactivity, .81 for Reexperiencing, .86 for Avoidance/Numbing, .78 for Overarousal, and .66 for Significant Impairment. ICCs for the number of symptoms endorsed both times were .88 overall, .94 for Exposure, .93 for Reactivity, .87 for Reexperiencing, .93 for Avoidance/Numbing, .74 for Overarousal, and .66 for Significant Impairment.

Evidence of Validity: Content validity was shown by high levels of correspondence with DSM-IV diagnostic criteria by three child PTSD experts (Saigh et al., 2000). In a sample of 56–62 youth exposed to high-magnitude stressors (Yasik et al., 2001), CPTSDI scores correlated .92 with the number of PTSD items endorsed on the DICA-R (Reich, Leacock, & Shanfeld, 1994) and .91 with the number of items endorsed on the PTSD module of the Structured Clinical Interview for the DSM-IV (SCID; First, Gibbon, Williams, & Spitzer, 1996). The correlations between the CPTSDI and the DICA-R and SCID PTSD module and subscales were .85 and .87 (respectively) for Reexperiencing, .80 and .87 for Avoidance/Numbing, and .84 and .81 for Overarousal. The CPTSDI correlated .70 with the Revised Children's Manifest Anxiety Scale (RCMAS; Reynolds & Richmond, 1978) but not with the Lie Scale of the RCMAS (.08), providing evidence of discriminant validity. It also correlated .59 with the Children's Depression Inventory (CDI; Kovacs, 1992). It correlated significantly (.55) with the CBCL (Achenbach & Edelbrock, 1983) Internalizing subscale but not with the Externalizing subscale (.21), which, the authors contend, provides evidence of discriminant validity. PTSD diagnosis with the CPTSDI has a sensitivity of .87 with clinician-derived diagnosis, 1.00 with DICA-R diagnosis, and .93 with the SCID diagnosis. It has a specificity of .99 with clinician-derived diagnosis, .92 with the DICA-R diagnosis, and .95 with the SCID diagnosis.

Children's Stress Symptom Scale (CSSS; Sharrer, & Ryan-Wenger, 2002)

Brief Description: The CSSS assesses 24 cognitive–emotional and physiological stress symptoms in children 7–12 years of age. Items were generated by children, based on Lazarus's theory that individual appraisal is the most relevant perspective (Sharrer & Ryan-Wenger, 2002). Occurrence of items are rated as *Yes* (1) or *No* (0). Frequency of occurrence of endorsed items is rated as follows: *Once in a while* (0), *A lot* (1), and *Most of the time* (2), for a total possible score of 0 to 48. An impact scale, which assesses “how bad this feeling is for you,” is scored as follows: *Not bad* (0), *Pretty bad* (1), and *Terrible* (2), for a total possible score of 0 to 48 (Sharrer & Ryan-Wenger, 2002).

Evidence of Reliability: Based on the data from a pilot study of 14 inner-city children, Cronbach alphas were .79 for the Occurrence scale, .92 for the Frequency scale, and .91 for the Impact scale (Sharrer & Ryan-Wenger, 2002). Cronbach alphas for another sample of 63 children (32% girls) between ages 7 and 14 years ($M = 9$) were .99 for the Occurrence scale, .99 for the Frequency scale, and .85 for the Impact scale (Skybo, 2005).

Evidence of Validity: The total CSSS score was not significantly correlated (.22) with the total Impact score of the KID-SAVE (Hastings & Kelley, 1997a; Flowers et al., 2000; see Appendix 9.1) or with the total KID-SAVE Frequency score (.15). However, it was significantly correlated (.27) with the total number of violent encounters reported. On the other hand, although the total Impact score of the CSSS was not significantly correlated with the total Frequency score of the KID-SAVE (.25), it was significantly correlated with both the total Impact score of the KID-SAVE (.39) and the total number of violent encounters reported (.29). Similarly, although the total Frequency score of the CSSS was not significantly correlated with the total Frequency score of the KID-SAVE (.27), it also was significantly correlated with both the Impact score of the KID-SAVE (.29) and the total number of violent encounters (.34).

Ryan-Wenger, PhD, RN, CPNP, Ohio State University College of Nursing, 1585 Neil Avenue, Columbus, OH 43210. Telephone: (614) 292-4078. E-mail: ryan-wengen10@osu.edu.

Child Report of Post-Traumatic Symptoms (CROPS—Greenwald, 1997; Greenwald & Rubin, 1999)

Brief Description: The CROPS is a 26-item child interview that includes DSM-IV symptoms of PTSD and additional symptoms. Items are based on DSM-IV (APA, 1994) criteria for PTSD and Fletcher's (1996a, 2003) meta-analysis of the empirical literature on children's responses to high-magnitude stressors. It can be used with or without

an identified stressor. Scores are continuous rather than keyed to diagnostic categories. The child rates how true each statement is on a 3-point scale: *None*, *Some*, and *Lots*. Age range: 5–17 years. Languages available: English, Spanish, Bosnian, Dutch, German, Italian, Persian.

Evidence of Reliability: Cronbach's alpha was .89 in a community sample of 206 children, grades 3–8 (Greenwald & Rubin, 1999). Preliminary results in a study of incarcerated youth ($n = 300$; Greenwald, Satin, Azubuike, Borgen, & Rubin, 2001) indicated an alpha of .92, and a test–retest reliability correlation for a 6-month interval was .70 for 177 of the youth.

Evidence of Validity: The CROPS significantly correlated (.60) with the LITE measure of exposure to stressful events (see Appendix 9.1) in a community sample of 206 children, grades 3–8. Scores increased with increases in traumatic experience and loss (Greenwald & Rubin, 1999). Associations remained strong after controls for age, gender, ethnicity, parent education, and location (urban vs. rural). Preliminary results in a study of incarcerated youth ($n = 300$; Greenwald et al., 2001) indicated that CROPS scores correlated with history of trauma (.48–.52), the TSCC (see below, this appendix), with $r = .53$ –.56 using one scoring system and $r = .63$ –.80 for the subscales (and $r = .83$ for the total scale) and $r = .74$ with the Adolescent Dissociative Experiences Scale (A-DES; Armstrong, Putnam, & Carlson, 1993).

Contact Information: Sidran Institute, 200 E. Joppa Road, Suite 207, Towson, MD 21286. Telephone: (410) 825-8888. Fax: (410) 337-0747 or (888) 825-8249. Website: www.sidran.org. E-mail: sidran@sidran.org.

Child's Reaction to Traumatic Events Scale—Revised (CRTES-R—Jones, 1996; Jones, Fletcher, & Ribbe, 2000)

Brief Description: The CRTES-R (Jones, Fletcher, & Ribbe, 2000) is a 23-item revision of the CRTES (Jones, 1996). The CRTES (originally called the Horowitz Impact of Event Scale for Children) was a 15-item self-report measure based on Horowitz's Impact of Event Scale (IES; Horowitz et al., 1979). As such, it measured symptoms of intrusive thoughts (criterion A), and avoidance and denial (criterion B). The CRTES was revised by the addition of eight items assessing overarousal. Wording used in the IES has been substantially rewritten, making the questions more appropriate for children and adolescents. The CRTES-R is a paper-and-pencil self-report for children and adolescents that can also be administered as a semistructured interview. Respondents indicate how often they have experienced each symptom in the past week, using responses of *Not at all* (0), *Rarely* (1), *Sometimes* (3), and *Often* (5). Note the weighting of the last two responses. Age range: 6–18 years. The CRTES-R must be administered as an interview to younger children and to children with reading disabilities. Scoring the CRTES was based on threshold scores. The CRTES-R allows the use of both thresholds and tentative DSM-IV caseness for PTSD based on criteria B–D. Currently, data are not available for the CRTES-R, but, based on ROC analysis responses of 118 children ages 8–18 who survived residential fires, using DICA PTSD diagnosis as the gold standard, the recommended thresholds for the 15-item CRTES are as follows: Scores of 0–14 indicate low distress; 15–27, moderate distress; and 28+, high distress (Jones, Fletcher, & Ribbe, 2003). Languages available: English and Spanish.

Evidence of Reliability: Psychometrics have yet to be done for the CRTES-R. However, in a sample of African American children living in a low-income, high-crime neighborhood, Cronbach's alphas were .73 for the total 15 items of the original HIES-C, .68 for the Intrusion subscale, and .73 for the Avoidance subscale (Cunningham, Jones, & Yang, 1984). Among children who had experienced a hurricane, alphas were = .85 for the total 15-item HIES-C, .84 for Intrusion, and .72 for Avoidance (Jones et al., 1993). In a sample of 167 children and adolescents ages 4–18, who lived through residential fires, alphas were .86 for the total 15-item CRTES, .85 for Intrusion, and .77 for Avoidance (Jones et al., 2003).

Evidence of Validity: A principle axis factor analysis with a varimax rotation followed by a promax rotation of the CRTES responses of 167 children who had survived residential fires (Jones, Fletcher, & Ribbe, 2003) produced two factors that accounted for 46.54% of the variance: (1) Intrusion (35.49% of the variance) and (2) Avoidance (11.04% of the variance). These results support the theoretical structure of the CRTES, although several items loaded well on both factors and two items did not achieve the .40 threshold on either factor. A higher order factor analysis resulted in a single factor, providing support for the assumption that both factors measure the single underlying dimension of PTSD. Age was associated with neither the total or either of the subscales. Girls and boys did not differ on their total score or on their Avoidance score, but girls scored significantly higher on Intrusion. Among 118 children and adolescents ages 8–18 who survived residential fires, those diagnosed with DSM-IV PTSD per the DICA had significantly higher CRTES scores than those not diagnosed with PTSD (Jones et al., 2003). ROC analysis (Jones et al., 2003) revealed that if children who scored 28 or higher were considered to have PTSD, compared to DSM-IV diagnosis with the DICA (Reich et al., 1994), the sensitivity of this diagnosis would be .83 and the specificity would be .70.

Clinician-Administered PTSD Scale for Children and Adolescents (CAPS-CA; Newman et al., 2004)

Brief Description: The CAPS-CA, a structured interview with the child, comprises approximately 53 items, most of which require additional questions to assess such things as the intensity and duration of the experience. Most of the PTSD-specific items are questions about the occurrence, intensity, and frequency of endorsed symptoms both for the past month and over the lifetime. The interview begins with a script for establishing the meaning of a month's time for younger children who might have trouble with the concept. To establish criterion A, 17 different types of high-magnitude stressors are described one by one, and the child or adolescent is asked to indicate whether each event actually happened to him or her, or whether he or she *Saw it*, *Learned about it*, is *Not sure*, or it *Never happened*. If none of the 17 events is endorsed, four additional prompts are provided to attempt to elicit an experience of a high-magnitude stressor. If three or more events are endorsed, the interviewer tries to determine whether the experience evoked fear or terror, a sense of helplessness, horror, or disorganized agitation. The various means of eliciting this information use

wording that is appropriate for children and adolescents. The interviewer rates whether each event was a life threat, whether a serious injury or threat to physical integrity occurred, and whether each of the four listed emotional reactions occurred. After the interviewer uses a practice question to teach the child or adolescent how to respond to the questions about frequency and intensity of events, questions related to each PTSD symptom listed in DSM-IV are then administered to those who met criterion A. Two questions related to the duration of symptoms (criterion E) are asked, then four questions regarding subjective distress and social, scholastic, and developmental (loss of acquired skill) functioning (criterion F). Three global rating scales are available: one that rates the overall validity of the responses, another that rates the overall severity of PTSD symptoms, and still another that rates global improvement for instances of repeated administration of the interview over time. Six items examine the presence of seven associated features: guilt over acts of commission or omission, survivor guilt when there were multiple victims, shame, reduction of awareness of surroundings, derealization, depersonalization, and changes in attachment. Three open-ended questions determine how the child or adolescent thinks the event has affected his or her life, what has helped him or her to feel better since the event, and coping strategies. Three optional rating sheets provide different graphical representations of the ratings for frequency and intensity of reactions to each symptom. One represents the five categories of frequency as a calendar grid, with increasing numbers of days crossed off, from none to 2, 6, 12, and 24. A second sheet illustrates increasing levels of intensity with a drawing of the top half of a young person who could be either male or female. The facial expression changes from a smile to a slight frown and slightly furrowed eyebrows; to a deeper frown with more deeply furrowed eyebrows; to a partially open mouth, gritted teeth and very furrowed eyebrows, with three drops of sweat flying off the top of the head; to an opened-mouthed gasp with very deeply furrowed eyebrows and five drops of sweat flying off of the head. In addition, although the first illustration indicating "no problem" had no lines across the person's stomach, the illustrations that follow have three increasingly darker, wavy lines across the stomach. The final, optional rating sheet contains two rows of five "smiley" faces; those in the top row illustrate increasing levels of distress, whereas those in the bottom row illustrate increasing levels of pleasure. The interviewer's guide and summary scoring sheet for the CAPS-CA include scoring for ASD, although no algorithms are provided that actually derive a diagnosis of ASD. In addition, because the CAPS-CA assesses the DSM-IV associated symptoms, it should be possible to at least screen for complex PTSD, which might be indicated if the symptoms of ASD last longer than 1 month. In addition to the ability to make a DSM-IV diagnosis, the CAPS-CA also allows the interviewer to make judgments about the level of severity of PTSD, based on the total CAPS-CA scores. Five "rationally derived" categories range from *Minimal PTSD: Asymptomatic or few symptoms* (scores of 0–19) to *Extreme PTSD symptoms* (scores of 80–136). No research supports the use of these categories, however, although empirically derived rules are available for adults assessed with the CAPS. Clinicians should be wary of applications to children until these rules receive empirical support.

Evidence of Reliability: In a study of 50 incarcerated adolescent males (Newman, McMackin, Morrissey, & Erwin, 1997), Cronbach's alpha was found to be .81 for the Reexperiencing subscale, .75 for Numbing and Avoidance, and .79 for Arousal. Among children hospitalized after an injury (Daviss, Mooney, Racusin, Ford, et al., 2000) alphas for these subscales were .78, .73, and .78, respectively. Interrater reliability for 23 hospitalized children was 100% (Daviss, Mooney, Racusin, Ford, et al., 2000), and among 10 children with histories of traumatic stress the interrater kappa reliability was .97 (Carrion et al., 2002). Among a sample of traumatized adolescents, interrater reliability was .54 for the lifetime diagnosis and .84 for current diagnosis (reported in Ohan et al., 2002).

Evidence of Validity: The mean Intensity rating across the 17 diagnostic items correlated .64 with a child self-report measure of PTSD, the Child PTSD Checklist (Amaya-Jackson, McCarthy, Newman, & Cherney, 1995; cited in Weathers, 2004) and .51 with the CPTS-RI (Carrion et al., 2002). The CAPS-CA has been demonstrated to be responsive to change over time due to an effective cognitive behavioral treatment intervention (March et al., 1998).

Kauai Recovery Index (KRI—Hamada, Kameoka, & Yanagida, 1996; Hamada, Kameoka, Yanagida, & Chemtob, 2003)

Brief Description: The KRI, a 24-item, paper-and-pencil self-report measure based on the CPTS-RI (discussed earlier, this appendix), was originally developed to assess children's posttraumatic responses to Hawaii's Hurricane Iniki, a Category 4 storm that affected the islands. It also was used as an outcome measure in a study of the effectiveness of treatment on children affected by Hurricane Iniki (Chemtob, Nakashima, Hamada, & Carlson, 2002). The scale has been used with children as young as second graders. It comprises six reexperiencing items, seven avoidance items, six arousal items, two age-specific items, and three associated features items that do not pertain to PTSD symptoms (Hamada et al., 2003). The KRI was designed as a screening device to help identify children with substantial traumatic reactions to large-scale critical incidents such as natural disasters of large magnitude. Therefore, the guiding principles of its developers were brevity and ease of administration, while preserving reliability and validity. Children rate the frequency of each symptom in the past week by marking each item on a 3-point scale: *No*, *Sometimes*, or *Almost all the time*. The scale is currently suggested for children exposed to Type I (acute) traumas only.

Evidence of Reliability: Ratings of 3,732 children ages 6–15 years ($M = 9.49$, $SD = 1.55$), in grades 2–6 (53% boys, 38% Asian, 28% Hawaiians or part-Hawaiian, 22% white, and 12% from other ethnic backgrounds) were taken about 2 years after the hurricane. When subscales were rationally derived, based on the DSM-IV diagnostic criteria, the Cronbach alphas were .84 for the total scale, .78 for criterion B, .52 for criterion C, and .64 for criterion D (Hamada et al., 2003). Test-retest reliability for 43 students over a 4-week period was .77 for the total score and .44, .29, and .64 for criteria B, C, and D, respectively (Hamada et al., 1996).

Evidence of Validity: Children who thought they would "die or get hurt" during the hurricane had significantly higher scores on the KRI than children who did not think they might die or get hurt. Children who feared for the lives of family members had significantly higher scores than did those who did not. Children whose home suffered greater damage had significantly higher scores than those whose homes had less damage, and those who reported greater fear

during the hurricane had higher scores than those who did not (Hamada et al., 2003). Principal axis factor analysis with promax rotation on the 24 items resulted in a four-factor solution. The first three factors corresponded to reexperiencing, arousal, and avoidance symptoms. The fourth factor comprised two items that could not be labeled, one originally associated with avoidance and the other associated with overarousal.

Kiddie Post-Traumatic Symptomatology Scale (see CATS, this appendix).

My Worst Experience Scale (MWES); My Worst School Experience Scale (MWSES—Hyman, Zelikoff, & Clarke, 1988; National Center for Study of Corporal Punishment and Alternatives in Schools, 1992)

Brief Description: The MWES and the MWSES are self-report scales that assess the reactions of children and adolescents to high-magnitude stressors. Respondents describe their worst experience, answer questions about the experience, then rate the frequency and duration of 105 possible responses. The MWES provides a list of possible high-magnitude stressors. The MWSES provides a list of 39 high-magnitude stressors that might occur at school. Both scales allow DSM-III and DSM-IV diagnoses of PTSD. Factor analysis extracted seven factors that became the seven subscales: Reexperiencing/Intrusive Thoughts, Dissociation/Disturbing Dreams, Depression/Withdrawal, Hopelessness/Suicidal, Avoidance/Hypervigilance, Somatic Symptoms, Oppositional/Defiant, and an overall scale of General Maladjustment. Age range: 9–18 years. No special training is required. Time to administer: 20–30 minutes.

Evidence of Reliability: Internal consistency for the subscales of the MWES ranges from .68 to .91. Test–retest Pearson correlations range from .88 to .95 (Hyman, Snook, Lurkis, Phan, & Britton, 2001).

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Western Psychological Services, 12031 Wilshire Blvd., Los Angeles, CA 90025-1251. Telephone: (800) 646-8857. Fax: (310) 478-7838. E-mail: custsvc@spspublish.com. Website: www.wpspublish.com.

Trauma Symptom Checklist for Children (TSCC; Briere, 1996a, 1996b)

Brief Description: The TSCC is a 54-item scale that “evaluates traumatic symptomatology in children, including the effects of child abuse (sexual, physical, and psychological) and neglect, other interpersonal violence, witnessing trauma to others, major accidents, and disasters” (Briere, 1996a, p. 378). It assess symptoms of posttraumatic stress and associated responses on six subscales: Anger (ANG), Anxiety (ANX), Depression (DEP), Dissociation (DIS), Posttraumatic Stress (PTS), and Sexual Concerns (SC). Dissociation itself has two subscales (Overt and Fantasy). The TSCC also contains eight critical items. The subscales do not provide diagnosis of disorders, including PTSD. Two validity scales are included, one assessing a tendency to underreport and the other assessing a tendency to overreport symptoms. Some symptoms are shared by more than one subscale. The TSCC is available in two versions: the full 54-item test, which includes 10 items tapping sexual symptoms and preoccupation, and a 44-item alternate version (TSCC-A) that makes no reference to sexual issues. The items are written to be understood by children 8 years or older. Each item is rated according to “how often it happens to you,” on a 4-point response scale ranging from *Never to Almost all of the time*. Time required: 15–20 minutes.

Evidence of Reliability: The internal consistency and reliability of the TSCC and subscales have been studied in a large ($n = 3,008$) normative, standardization sample (Briere, 1996b), as well as in several samples of sexually abused children ($n = 105$, Lanktree & Briere, 1995; $n = 399$, Elliot & Briere, 1994; $n = 103$, Nelson-Gardell, 1995). In the normative sample, alpha was .82 for ANX, whereas in the three clinical samples, it ranged from .83 to .86. For ANG, alpha was .89 in the normative sample and ranged from .87 to .89 in the clinical samples. For DEP, the respective alphas were .86 and .85–.89. For PTS alphas were .87 and .85–.87, respectively. For SC, they were .77 and .67–.78, respectively. For DIS, alphas were .83 and .80–.89, respectively, with .81 for the Overt DIS subscale and .58 for the Fantasy DIS subscale, in the normative sample. The two validity subscales were only reported in the normative sample, where alphas were .85 for the Underresponse subscale and .66 for the Hyperresponse subscale.

Evidence of Validity: Convergent and discriminant validity of the scales have been demonstrated through correlations between the TSCC subscales and the relevant scales of the CBCL (Briere & Lanktree, 1995), where similar scales correlated more highly than did dissimilar scales. Evans, Briere, Boggiano, and Barrett (1994) found that TSCC scores correlated significantly with the CDI (Kovacs & Beck, 1977) and the RCMAS: ANX, .45 and .63; DEP, .68 and .63; ANG, .57 and .51; PTS, .51 and .60; DIS, .51 and .56, respectively. In a study of 39 children identified as sexual abuse victims, Smith, Saunders, Swenson, and Crouch (1995) found that the TSCC PTS scale correlated highest with the Intrusive Thoughts of the CITES-II (discussed earlier, this appendix) scale, the TSCC DEP scale correlated highest (positively and negatively respectively) with the CITES-II Self-Blame and Empowerment scales, the TSCC SC scale correlated highest with the CITES-II Sexual Anxiety and Eroticism scales, and the CITES-II Avoidance scale correlated second highest with the TSCC DIS scale, ($r = .60$). Friedrich and Jaworski (1995) found that the TSCC SC was significantly related to CSBI (Friedrich, 1991) but not to CDC scores, whereas the TSCC DIS scale related to CDC scores but not to CSBI scores. Finkelhor and colleagues (2005) found that among 992 children ages 10–17 years in a national telephone survey, most of the single items and all of the subscale totals of their measure of youth victimization, the JVQ (see Appendix 9.1), correlated significantly with the TSCC ANX, DEP, and ANG subscales. Evidence that the TSCC assesses posttraumatic stress was demonstrated by Smith, Swenson, Hanson and Saunders (1994), who found that each of the subscales related to specific aspects of childhood trauma: PTS, DIS, and ANX correlated with stressors involving perceptions of life threat; ANG and DEP correlated negatively with clinician ratings of parental support following abuse disclosure; and sexual assault victims who had experienced penetration had higher SC scores. Briere

and Lanktree (1995) found that sexual penetration correlated most highly with TSCC scales related to trauma and sexual distress: PTS, SC and DIS. The TSCC subscales also discriminated between 81 sexually abused girls and 151 controls (Diaz, 1994). The TSCC has also discriminated between groups of adolescents exposed to violence and controls (Singer, Anglin, Song, & Lunghofer, 1995).

UCLA PTSD Reaction Index for DSM-IV (UPRID Child and Parent report forms—Pynoos, Rodriguez, Steinberg, Stuber, & Frederick, 1998; Steinberg, Brymer, Decker, & Pynoos, 2004)

Brief Description: The UPRID is a 49-item scale purportedly derived from the CPTS-RI (this appendix); however, its provenance appears to be related more to intention than to direct derivation. The DSM PTSD-specific symptoms cover all 17 symptoms, unlike the CPTS-RI, and the items are much better written. The items were written by Rodriguez and Steinberg (Rodriguez, in press). A panel of youth PTSD experts reviewed them for their readability and comprehension by youth, a pilot study led to some refinement of the items, and items reflecting fear of recurrence of the traumatic event and posttraumatic guilt were added given the apparent high incidence of these experience among traumatized youth, as reported by Fletcher (1996a). The first 13 items assess exposure to different high-magnitude stressors for children. Each item is rated either *Present* or *Absent*. Stressors assessed include community violence, natural disaster, medical trauma, and abuse. These are followed by an item that asks children to select the experience that bothers them the most and rate how bothersome it is on a 3-point scale: *A little* (1), *somewhat* (2), or *A lot* (3). The next 13 items assess different responses to the experience that children might have had at the time. These items are intended to establish whether children responded with fear, helplessness, or horror, per DSM-IV criterion A2, but one item also asks about reactions of confusion, one about upset or disorganized behavior, and one about feelings of unreality. These are rated either *Yes* or *No*. Of the final 22 questions, 20 assess the presence of symptoms related to DSM-IV criteria B–D; in addition, fear of recurrence of the trauma and trauma-related guilt are assessed by one item each. These item ratings range from *None of the time* (0) to *Most of the time* (4). The questionnaire is accompanied by a frequency rating sheet that visually assists children in providing accurate responses about how often the reaction has occurred over the past month. Although the instrument was not created to be a diagnostic tool, there also is a score sheet that allows the interviewer to make a preliminary DSM-IV diagnosis. The UPRID has been selected to be the primary PTSD screening measure for the National Child Traumatic Stress Network. Age range: 7–18 years. It is recommended that the instructions and questions be read aloud to children under the age of 12 or to youth with reading comprehension problems. A parent version is available. An original adolescent version (Rodriguez, Steinberg, Saltzman, & Pynoos, 2001a) was eventually merged with the child version (Steinberg et al., 2004). Two shorter versions, one with seven items and one with nine, are available for screening. Training required: Licensed Master's-level clinician, with experience in assessment of trauma exposure and PTSD in children. The measure is designed to be administered three different ways: (1) as a self-report; (2) as a one-on-one "interview," wherein the items are read to the child; and (3) group administration. Time for administration: 20–30 minutes. When criterion A is met, and when sufficient endorsement in each of the B–D criteria categories is made at the top two rating categories (*Much of the time* or *Most of the time*), a likely diagnosis of PTSD is made. When criterion A is met and children meet criteria for only two symptoms of criteria B–D, they are scored as "partial" PTSD. A cutoff of 38 or greater has the greatest sensitivity and specificity for detecting PTSD (Rodriguez et al., 2001a, 2001b).

Evidence of Reliability: In a sample of 46 children, 29 of whom had been exposed to high-magnitude stressors, internal consistency alpha for the child version total score was .87, whereas it was .82 for the Intrusion scale, .72 for the Avoidance scale, and .67 for the Hyperarousal scale (Rodriguez, 2001). The test–retest Pearson correlation for the total was .86, whereas it was .86 for Intrusion, .92 for Avoidance, and .59 for Overarousal. In a sample of 73 adolescents, the internal consistency alpha for the adolescent version total was .92, whereas it was .80 for Intrusion, .84 for Avoidance, and .73 for Hyperarousal. The test–retest correlation among 25 of the adolescents was .84 for the total, .78 for Intrusion, .78 for Avoidance, and .73 for Hyperarousal (Rodriguez et al., 2001a, 2001b). In another sample of 75 youthful clients of school-based trauma clinics (53% boys; 51% Hispanic, 32% African American, and 17% European American [mean age = 13 years, SD = 2.0 years] in grades 5–11), Rodriguez (in press) reported interrater kappas were 1.0 for PTSD diagnosis, reexperiencing (DSM-IV criterion B), and overarousal (criterion D) and .57 for withdrawal and numbing (criterion C). In this study, Cronbach's alphas were .72 for criterion D, .75 for criterion C, .76 for criterion B, and .89 for the total PTSD severity score.

Evidence of Validity: A pilot study (Rodriguez et al., 2001b) indicated that the first 13 trauma exposure questions demonstrated poor validity and high rates of false-negative and false-positive responses when compared with prior information about the youth trauma histories. The UPRID child version correlated .82 with the CAPS-CA intensity scale (this appendix), and traumatized children had significantly higher scores than nontraumatized ones. The adolescent version correlated .70 with the K-SADS PTSD module (Rodriguez, 2001; Rodriguez et al., 2001a, 2001b). The authors report that numerous studies have found consistently higher UPRID scores among traumatized children compared to nontraumatized children, as well as clear "dose–response" relationships of scores across exposure groups (Steinberg et al., 2004). However, because the UPRID was developed from the CPTS-RI (this appendix), it seems that the authors have a tendency to report psychometrics that were actually based on various versions of the CPTS-RI, while implying that those results apply to the UPRID as well. For example, Steinberg and colleagues in the purported psychometric study of the UPRID, reported that in studies after the 1988 earthquake in Armenia (Pynoos et al., 1993), a cutoff of 40 or higher correctly identified 78% of children who met DSM-III-R criteria for PTSD, and 79% of those who did not. Of those who scored 40 or higher, 90% had PTSD. However, the actual measure used to assess PTSD in that study was a version of the CPTS-RI, not the UPRID. Despite the fact that the former was a forerunner of the latter, they are not the same measure. In fact, the two differ very much. Therefore, psychometrics on versions of the

CPTS-RI cannot just be assumed to reflect the psychometrics of the UPRID. In a study of 75 youth receiving services for traumatic responses, Rodriguez (in press) found significant Spearman's rho correlations of .73 between the UPRID subscales reflecting DSM-IV criteria B–D and the total PTSD severity score, and the respective subscales of the K-SADS PTSD module (Kaufman et al., 1997; see Appendix 9.3). Using the K-SADS PTSD diagnosis as the “gold standard” in a ROC analysis, Rodriguez determined that an optimal cutoff score is 37 or greater, which provides a sensitivity of .82 and a specificity of .87. This cutoff score resulted in a positive predictive power of .67, a negative predictive power of .94, and an overall diagnostic efficiency of .86. Rodriguez also suggested that a cutoff score of 27 or greater would be best for purposes of screening for possible PTSD, providing a sensitivity of .94 and a specificity of .66. A cutoff score of 50 or higher leads to a nearly definitive diagnosis of PTSD, with a specificity of .97 and a sensitivity of .65.

When Bad Things Happen Scale (WBTH; Fletcher, 1996g)

Brief Description: The WBTH scale is a 90-item, paper-and-pencil report by the child regarding his or her reactions to exposure to a high-magnitude stressor. The first 58 questions allow the assessment of DSM-IV PTSD criteria A–D. The first four questions assess criterion A; three questions assess recurrent and intrusive recollections of the event(s) (symptom B1); four questions assess distressing dreams (B2); four questions assess acting or feeling as if the event were recurring (B3); three assess intense distress at reminders (B4); two assess psychological reactivity to reminders (B5); five assess avoidance of thoughts, feelings, or conversations that serve as reminders of the event(s) (C1); three assess avoidance of other reminders (C2); two assess the child's inability to recall important aspects of the event (C3); two assess loss of interest in previous activities or loss of recently acquired skills (C4); three assess feelings of estrangement from others (C5); two assess restricted affect (C6); six assess a sense of foreshortened future (C7); two assess sleep problems (D1); three assess increased irritability (D2); four assess difficulties concentrating (D3); four assess hypervigilance (D4); and two questions assess exaggerated startle response (D5). Associated symptoms are assessed by an additional 32 items, five of which assess anxiety; three assess depressive symptoms; two assess superstitious beliefs related to the event(s); two assess survivor guilt; two assess self-blame; two assess fantasy denial; three assess self-destructive behavior, including attempted suicide; four assess symptoms of dissociation; three assess aggressive, antisocial behavior; two assess risk-taking behavior; and four assess changes in eating habits since the occurrence of the event(s). Response to all items is rated on a 3-point scale: *Never*, *Some*, and *Lots*. It is possible with the WBTH to derive DSM-II-R and DSM-IV diagnoses of PTSD and a total PTSD severity score, either for the first 58 DSM PTSD symptoms questions or for the full 90 questions, including the additional 32. Age range: 4 or 5 years to 19 years. Available languages: English and Spanish.

Evidence of Reliability: In a sample of 10 clinically referred children diagnosed with PTSD, 10 community children exposed to high-magnitude stressors, and 10 community children with no reported exposure to high-magnitude stressors (Fletcher, 1996), internal consistency alphas were .92 for the total 58 PTSD items, .70 for the four criterion A items, .89 for the criterion B (reexperiencing) items, .70 for the criterion C (avoidance/numbing) items, and .82 for the criterion D (overarousal) items. Among a sample of 40 adolescent psychiatric inpatients, 24 of whom had a diagnosis of PTSD, the WBTH scale was administered two times, 1–2 weeks apart. The test–retest ICC was .78 (Fletcher et al., 1997). The inpatient adolescents with a diagnosis of PTSD reported significantly higher WBTH total PTSD severity scores than did those without a PTSD diagnosis. Among these adolescents, the WBTH had a sensitivity of 78% and a specificity of 54%. Scores on the WBTH appeared to be associated with IQ in these adolescents.

Evidence of Validity: In the same study referred to earlier (Fletcher, 1996), the WBTH scale correlated .87 with scores on the Childhood PTSD Interview—Child Form (this appendix). It also demonstrated unusually high agreement with parent reports of PTSD. It correlated .60 with the parent's paper-and-pencil self-report on the Parent Report of the Child's Reaction to Stress scale (see below, this appendix), .59 with the Childhood PTSD Interview—Parent Form (see below, this appendix), and .54 with an ad hoc CBCL PTSD scale completed by the parent. The WBTH also correlated .70 with a measure of the potentially stressful characteristics of the child's individual high-magnitude stressor (assessed with the DOSE, see Appendix 9.2), .30 ($p > .05$, ns) with the parent's report of the number of stressors to which the child had been exposed in his or her lifetime, and .42 ($p < .05$) with the parent's ratings of the severity of the child's distress at exposure to each of the stressors on the Child's Upsetting Times Checklist (Fletcher, 1996f; see Appendix 9.1). The WBTH correlated .48 with the CBCL Internalizing and .36 ($p > .05$, ns) with the CBCL Externalizing scales. It correlated .57 with the CBCL Anxiety scale, .43 with the Withdrawn scale, .55 with the Thought Problems scale, .21 ($p > .05$, ns) with the Somatic Complaints scale, .37 with the Attention Problems scale, .49 with the Social Problems scale, .33 ($p > .05$, ns) with the Aggression scale, .36 ($p > .05$, ns) with the Delinquent Behavior scale, and .03 ($p > .05$, ns) with the Sexual Problems scale (none of the children had been sexually abused). The fact that WBTH correlations with other PTSD measures and the DOSE tend to be higher than its correlations with measures of other problems provides evidence of the scale's discriminant validity. Scores differentiated between traumatized and nontraumatized children (Fletcher, 1996b). Sensitivity in identifying probable cases of traumatized children, as assessed by the DOSE scale, was 40%, and specificity was 100% (Fletcher, 1996b). Among a sample of 40 adolescents psychiatric inpatients, 24 of whom had a diagnosis of PTSD, the WBTH scale correlated .78 with the Childhood PTSD Interview—Child Form (this appendix), .79 with the CRTES (this appendix), .38 with scores on the Teen Tough Times Checklist (see Appendix 9.1), .45 with the DOSE (see Appendix 9.1), and .54 with the A-DES (Armstrong, Putnam, & Carlson, 1993), and did not correlate significantly with any of the scales of the Brief Symptom Inventory (Derogatis & Melisaratos, 1983), providing evidence of the convergent and discriminant validity of the scale (Fletcher et al., 1997). Among 15 sexually abused children (Moller-Thau & Fletcher, unpublished), the WBTH scale correlated .84 with the CPTS-RI (this appendix). The kappa for agreement between the two measures for diagnosis of PTSD was .67. The WBTH classified two children with PTSD that the CPTS-RI did not classify.

ADMINISTERED TO CARETAKER OR OTHER ADULTS

Checklist of Child Distress Symptoms, Parent Form (CCDS—Martinez & Richters, 1993; Richters & Martinez, 1990a) ***(also known as the Survey of Children's Distress Symptoms)***

Brief Description: The CCDS Parent Form, is a 28-item, self-report scale that asks questions associated with traumatic responses to high-magnitude stressors. Questions examine anxiety, memory problems, sleeping problems, self-esteem, school performance, and feelings of depression, isolation, or hopelessness. Thus, it does not allow diagnosis of PTSD to be made. Responses are rated on a 4-point scale, ranging from *Never occurs* (1), *Seldom occurs* (2), *Occurs once in a while* (3), or *Occurs a lot of the time* (4). The CCDS comprises two subscales measuring Depression and Anxiety, although the two subscales' very high correlation (.80) justifies combining them for the total score. Age range: 6–10 years.

Evidence of Reliability: Among parents of 54 fifth and sixth graders, Cronbach's alphas were .75 for the Depression subscale, and .70 for the Anxiety subscale.

Evidence of Validity: Parents reported significantly lower levels of their children's distress than were reported by their children on both the Depression and Anxiety subscales, as well as on many of the individual items (Martinez & Richters, 1993). Agreement between parents and their daughters was nonsignificant ($r_{(17)} = .06$), whereas agreement between parents and their sons was significant, moderately high, and negative ($r_{(18)} = -.56$), which the authors note was not attributable to outliers (p. 30). They suggest that the negative correlation may be attributable at least in part to a tendency of the boys to deny their symptoms. Total parent ratings of their children's distress on the CCDS did not correlate significantly with any type of exposure to violence reported by the children, neither for younger children (first and second graders) or older children (fifth and sixth graders). However, another study that examined ratings of 53 children's exposure to potentially traumatizing stressors and ratings on the CCDS by mothers found significant correlations between these ratings (Osofsky et al., 1993). Although the parents' CCDS ratings correlation with the parents' reports of their children's victimization ($r = .21$) was nonsignificant, the parents' CCDS correlations with the child's witnessing community violence ($r = .42$), and the correlations with simply hearing about such violence (.48), minor family conflicts (.39), and severe family conflicts (.61) were all significant. Moreover, the magnitude of the correlations were associated with the magnitude of the stressor. Thus, the CCDS correlated .35 with moderate types, .29 with the less than severe types of community violence, and .51 with the most severe (a shooting, a stabbing, or rape).

Childhood PTSD Interview—Parent Form (Fletcher, 1996b, 1996c)

Brief Description: The Childhood PTSD Interview—Parent Form, a semistructured interview of the caretaker regarding the child's reactions to the stressor(s), allows the interviewer to assess DSM-III-R and DSM-IV criteria and to make a diagnosis. It contains 1 item that allows the interviewer to rate how well the caregiver's description of the event(s) matches the description of the child. Sixty-two questions assess DSM PTSD criteria A–D. Four questions assess criterion A. Of the six questions that assess the first symptom of criterion B (B1), one requires elaboration for positive responses; four assess B2, with a follow-up to a positive response to the first question; four questions assess B3 (two of which ask for clarification of endorsed questions); and three questions assess B4 (with elaboration required for a positive response to the first question). Five questions assess C1, four assess C2, one question assesses C3 with a follow-up question if the first is answered in the negative (both require elaboration for positive responses), three assess C4 (with elaboration required for positive responses), three assess C5, two questions and a rater question regarding possible flat affect of the child assess C6, and six questions assess C7 (because C7 concerns a sense of foreshortened future, and few studies support the presence of this symptom in children, the author believes these six questions can be skipped). Two questions with required elaborations for positive responses assess D1, three questions assess D2, four questions assess D3, four questions assess D4, and two questions assess D5. Two questions assess complaint of physiological reactions, which is D6 according to DSM-III-R, and B5 according to DSM-IV.

An optional additional 26 questions assess associated symptoms. Interviewers may choose to ask some, all, or none of these questions. Five questions assess symptoms of anxiety (two require elaboration for positive responses, and one asks the rater to indicate whether breathing problems may be due to asthma). Three questions assess symptoms of depression. Two questions with required elaboration for positive responses assess indications of whether the child perceives certain prestressor events as omens. Two questions with required elaboration for positive responses assess symptoms of survivor guilt. Two questions, one of which requires elaboration for positive responses, assess symptoms of guilt or self-blame. The interviewer is asked to indicate to what extent the child actually might be considered to have some responsibility for events. Two questions, with required elaboration for positive responses, assess indications of fantasy denial. Three questions, one of which requires elaboration for positive responses, assess possible self-destructive or suicidal thoughts and behaviors. Four questions assess symptoms of dissociation. Three questions assess antisocial behavior. Two questions assess risk-taking behavior, and two assess changed eating habits. Items are answered *Yes* or *No*. *Don't know*s are allowed on many questions and are scored as *No*. Age range: 5–7 years and older.

Evidence of Reliability: Cronbach's alphas were .94 for the full PTSD section of the interview, .60 for the four questions on criterion A, .86 for questions on criteria B and C, and .83 for questions on criterion D (Fletcher, 1996b).

Evidence of Validity: The interview correlated significantly with other measures of childhood PTSD: .59 with the WBTH scale (this appendix), .69 with the Childhood PTSD Interview—Child Form (this appendix), .93 with the Parent Report of the Child's Reaction to Stress (this appendix), and .78 with an ad hoc CBCL PTSD scale. The first two correlations demonstrate unusually high agreement between the parent and child reports. The interview also correlated significantly (.50) with the total number of lifetime stressors the parent indicated the child had experienced, .63 with the parent's ratings of the child's stressful reactions to those events, and .54 with an assessment of the potentially traumatizing dimensions of the immediate stressor(s) for which the child's reactions were being assessed, as measured by the DOSE scale (see Appendix 9.1). The interview also correlated significantly with the Internalizing score (.68) and the Externalizing score (.48) of the CBCL and the following CBCL subscales: Anxiety (.52), Withdrawn (.49), Thought Problems (which include obsessing on certain thoughts, problems concentrating, repetition of certain acts, and staring blankly; $r = .62$), Somatic Complaints (.78), Attention Problems (.45), Social Problems (.63), Aggression (.45), Delinquent Behavior (.40), and Sexual Problems (.41) (Fletcher, 1996b). The fact that the interview's correlations with other PTSD measures are, for the most part, higher than its correlations with measures of other problems indicates its discriminant validity. Scores differentiated between clinically referred traumatized children and traumatized children in the community, and between both of those groups and nontraumatized children (Fletcher, 1996b). Sensitivity in identifying probable cases of traumatized children, as assessed by the DOSE, was 55%, and specificity was 100% (Fletcher, 1996b).

Contact Information: Kenneth E. Fletcher, PhD, Department of Psychiatry, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, MA 01655. Telephone: (508) 856-8630. E-mail: kenneth.fletcher@umassmed.edu.

Childhood Post-Traumatic Stress Reaction—Parent Inventory (CPTSR-PI; Nader, 1984/1995)

Brief Description: The CPTSR-PI is a parent interview that assesses trauma-related responses and additional symptoms in five sections: (1) Pretrauma descriptors of family background, child's behaviors, and personality (e.g., moods, self-confidence, social behaviors) before and after the event; (2) prior trauma history of child and family; (3) parents' description of the child's reported experience of the event and parents' reactions to the child's initial responses; (4) child's reactions after the event, especially in the previous month; and (5) associated symptoms similar to those asked about in the Additional Questions of the CPTS-RI (this appendix). DSM-IV symptoms are assessed. Similarities with the CPTS-RI are identified.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: The CPTSR-RI has been found to differentiate between traumatized and nontraumatized children (Nader, 1991). In a sample of youth exposed to a hurricane, the CPTSR-PI correlated .55 with the RCMAS (Lonigan et al., 1991). In a sample of sexually and/or physically abused adolescents, it correlated .64 with the RCMAS and .70 with the CDI (Kovacs, 1992).

Contact Information: Kathleen Nader, DSW. Fax: (512) 219-0486. E-mail: measures@twosuns.org.

Child Stress Disorders Checklist (CSDC; Saxe, 2001) and Child Stress Disorders Checklist—Screening Form (CSDC-SF; Saxe & Bosquet, 2004)

Brief Description: The CSDC, a 42-item, paper-and-pencil scale, asks parents, guardians, or other observers to report on the child's reaction to high-magnitude stressors. The respondent is first asked to indicate whether and at what age the child has been exposed to eight kinds of high-magnitude stressors (an "Other" category is included). The next five questions ask about the child's emotional reactions to the experience(s). Then, seven items assess symptoms of reexperiencing, five assess avoidance, eight assess numbing and dissociation, six assess increased arousal, and four assess functional impairment. Responses to each questions can be *Not true (as far as you know)*, *Somewhat true*, or *Very true*. The Screening Form (CSDC-SF) includes the same first eight kinds of high-magnitude stressors, followed by just four questions about the child's reactions during the past month: whether the child gets upset at reminders, experiences physical complaints at reminders, does not want to talk about the experience, or startles easily. Unlike most other child PTSD measures to date, the CSDC allows assessment of symptoms of both DSM-IV PTSD and ASD.

Evidence of Reliability: Among a sample of 84 children, which included 43 children with acute burns and 41 who had experienced a traffic crash (Saxe et al., 2003), the internal consistency alpha for the 84 parent respondents was .84. The ICC between total scores reported by the burned children's parents and primary nurse was 0.44 ($n = 37$). For the individual scales of the measure, alpha was .45 for the reexperiencing items, .28 for avoidance, .24 for numbing and dissociation, .36 for arousal, and .27 for functioning. Test-retest reliability (Pearson correlations) over a 2-day period was .84 for the total scale, .89 for reexperiencing, .85 for avoidance, .70 for numbing and dissociation, .74 for arousal, and .63 for functioning. Cronbach's alpha among 176 children and adolescents ages 8–17 ($M = 11.8$ years) on the 30 ASD symptom items within a month of a recent injury or intensive care unit admission was .87 (Kassam-Adams, 2006).

Evidence of Validity: Concurrent, convergent, and discriminant validity were assessed among both parent and nurse reporters for child burn victims ($n = 19$ –43; Saxe et al., 2003). Total body surface area burned was measured and shown to correlate .56 with parent reports and .43 with nurse reports on the total CSDC scores. Parent total scores also correlated significantly (.39) with the children's reports of their own symptomatology on the CPTS-RI (this appendix), but nurse reports did not correlate significantly (.26) with the CPTS-RI scores, although the p -value was $< .10$ for this correlation. The total score correlated .49 with a CBCL post hoc PTSD scale for parent reporters and .33 for nurse reporters. It also correlated with the CDC (Putnam, Helmers, & Trickett, 1993) .49 for parent reports and

.33 for nurse reports. Discriminant validity was demonstrated with nonsignificant correlations between the CSDC and the CBCL Thought Disorder subscale.

Contact Information: Glenn Saxe, MD, Department of Psychiatry, Children's Hospital Boston, Karp Family Research Building, 300 Longwood Avenue, Boston, MA 02115. Telephone: (617) 414-7504. E-mail: glenn.saxe@childrens.harvard.edu.

The CSDC is available online for download at www.nctsn.org/nctsn_assets/acp/hospital/csdc.pdf. The CSDC-SF is available online for download at www.nctsn.org/nctsn_assets/acp/hospital/csdc-Screening%20Form2.pdf.

Parent Report of the Child's Reaction to Stress (PRCRS; Fletcher, 1996e)

Brief Description: The PRCRS is a 78-item, paper-and-pencil parent report about the child's reaction to exposure to a high-magnitude stressor. The first 51 questions allow the assessment of DSM-IV PTSD criteria A–D. The first four questions assess criterion A, then six questions assess recurrent and intrusive recollections of the event(s) (symptom B1); three assess distressing dreams (B2); one assesses acting or feeling as if the event was recurring (B3); three assess intense distress at reminders (B4); two assess psychological reactivity to reminders (B5); four assess avoidance of thoughts, feelings, or conversations that serve as reminders of the event(s) (C1); three assess avoidance of other reminders (C2); one assesses the child's inability to recall important aspects of the event (C3); four assess loss of interest in previous activities or loss of recently acquired skills (C4); three assess feelings of estrangement from others (C5); one assesses restricted affect (C6); five assess a sense of foreshortened future (C7); two assess sleep problems (D1); two assess increased irritability (D2); three assess difficulties concentrating (D3); three assess hypervigilance (D4); and two questions assess exaggerated startle response (D5). Associated symptoms are assessed by an additional 27 items, five of which assess anxiety; two assess depressive symptoms; two assess superstitious beliefs related to the event(s); two assess survivor guilt; two assess self-blame; two assess fantasy denial; two assess self-destructive behavior; three assess symptoms of dissociation; three assess aggressive, antisocial behavior; two assess risk-taking behavior; and two assess changes in eating habits since the occurrence of the event(s). Most items have 6-point Likert-like responses, ranging from *Never to Always*, and a seventh *Don't know* category. Some positive responses are followed by a request for further information. Scorers of the responses are cautioned to consider these explanations carefully before rating the response. For example, parent or guardians are asked to explain what makes them believe their child behaves in new and unusual ways since the event(s). Age range: 4 or 5 years to 19 years. Available languages: English and Spanish.

Evidence of Reliability: In a sample of 10 clinically referred children diagnosed with PTSD, 10 community children exposed to high-magnitude stressors, and 10 community children with no reported exposure to high-magnitude stressors (Fletcher, 1996b), internal consistency alphas were .89 for the total 51 PTSD items, .81 for the four criterion A items, .86 for the criterion B (Reexperiencing) items, .70 for the criterion C (Avoidance/Numbing) items, and .81 for the criterion D (Overarousal) items.

Evidence of Validity: In the same study referred to earlier (Fletcher, 1996b), the PRCRS correlated .93 with scores on the Childhood PTSD Interview—Parent Form (this appendix), .54 with the child's own paper-and-pencil self-report on the WBTH scale (this appendix), .60 with the Childhood PTSD Interview—Child Form (this appendix), and .80 with an ad hoc CBCL PTSD scale completed by the parent. The PRCRS also correlated .54 with a measure of the stressfulness of the experience (the DOSE, see Appendix 9.2), .50 with the parent's report of the number of stressors to which the child had been exposed in his or her lifetime, and .63 with the parent's ratings of the severity of the child's distress at exposure to each of the stressors. The PRCRS correlated .70 with the CBCL Internalizing and .53 with the CBCL Externalizing scales, .56 with the CBCL Anxiety scale, .50 with the Withdrawn scale, .59 with the Thought Problems scale, .77 with the Somatic Complaints scale, .43 with the Attention Problems scale, .63 with the Social Problems scale, .53 with the Aggression scale, .39 with the Delinquent Behavior scale, and .46 with the Sexual Problems scale.

Scores differentiated between traumatized and nontraumatized children (Fletcher, 1996b). Sensitivity in identifying probable cases of traumatized children, as assessed by the DOSE scale was 35%, and specificity was 80% (Fletcher, 1996b).

Contact Information: Kenneth E. Fletcher, PhD, Department of Psychiatry, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, MA 01655. Telephone: (508) 856-8630. E-mail: kenneth.fletcher@umassmed.edu.

Parent Report of Post-Traumatic Symptoms (PROPS; Greenwald, 1997; Greenwald & Rubin, 1999)

Brief Description: The PROPS, a 32-item report based on the CITES (see CITES-II, this appendix) and the CBCL (Achenbach & Edelbrock, 1983), includes items that assess symptoms of DSM-IV PTSD criteria, as well as associated symptoms. Although a companion measure to the child version (CROPS; this appendix), the two measures do not ask parallel questions, but they do share some content. The scale is scored as a continuous measure rather than providing DSM-IV diagnosis. A tentative "clinical" threshold of 16 indicates possible PTSD (Greenwald & Rubin, 1999). The PROPS can be administered as either a paper-and-pencil self-report or a structured telephone interview. Frequency of symptoms during the past week is rated on a 3-point scale: *None, Some, or Lots*.

Evidence of Reliability: Cronbach's alpha was .93 in a community sample of 206 children in grades 3–8 (Greenwald & Rubin, 1999). Test–retest correlation was .79 in the same study.

Evidence of Validity: PROPS correlates significantly with the LITE measure of exposure to stressors (see Appendix 9.1), with $r = .56$.

APPENDIX 9.6. PTSD-Specific Measures for Adolescents and Young Adults

ADMINISTERED TO ADOLESCENT OR YOUNG ADULT

Reactions of Adolescents to Traumatic Stress Questionnaire (RATS; Bean, Eurelings-Bontekoe, Derluyn, & Spinhover, 2004b)

Brief Description: The RATS, a multicultural self-report measure of PTSD for adolescents exposed to high-magnitude stressors, has been translated into 19 languages. The 22 items were derived from the 17 DSM-IV symptoms of criteria B, C, and D of PTSD, with symptoms B3, C1, C5, D1, and D2 divided into two items each. Each of these symptoms has two components, because division into two related questions makes the intent of each question clearer to respondents. Each item is rated by the adolescent or young adult using three response categories: *Not much* (1), *Some* (2), *Much* (3), and *Very much* (4). Each response category is illustrated with a colored circle that increases in size and changes color from *Not much* (small green circle) to *Very much* (large red circle). Items are written to be readable by 12-year-olds. Each question is written both in English and in another language, because the researchers found that many immigrants had limited knowledge of their own written language but had learned their new language (Dutch, in this case) quickly (Bean, Derluyn, Eurelings-Bontekoe, Broekaert, & Spinhoven, 2006). No written back-translations were made, but the “translated questionnaires were reviewed orally with professional interpreters who were regularly involved in treatment sessions of traumatized adult refugees to control the quality of the translations, to ensure that the original meaning was conveyed in the items, and to attempt to achieve semantic equivalence” (Bean et al., 2006, p. 245). Age range: 12–18 years. Languages available: Amhars, Albans, Arabic, Bandini, Chinese (Mandarin), Croatian, Dari, Dutch, English, French, German, Mongols, Portuguese, Russian, Servo-Croatian, Spanish (presumably European Spanish rather than Central or South American Spanish), Soerani, Somali, and Turkish.

Evidence of Reliability: Internal consistency is excellent for all versions of the RATS, with alphas ranging from .81 to .93 for the different versions (Bean et al., 2006). Test–retest reliability was conducted on a sample of 519 adolescents over a 12-month period, which is an exceedingly long time period for assessing test–retest reliability. Nonetheless, the “stability coefficients” (which kind was not specified) were .63 for the total RATS score, .61 for the Intrusion subscale, .44 for the Numbing/Avoidance subscale, and .55 for the Hyperarousal subscale. These low “coefficients” and the extraordinarily long time between first and second assessments make this test of the stability of the RATS over time of little worth.

Evidence of Validity: Validity of the RATS was assessed among 4 separate, large youth samples: 771 unaccompanied refugee minors in the Netherlands, 1,058 Dutch pupils from schools throughout the Netherlands, 939 Belgian immigrant and refugee adolescents, and 617 Belgian schoolchildren (Bean et al., 2006). The RATS correlated significantly with a measure of exposure to high-magnitude stressors created by the authors, the Stressful Life Events Checklist (SLE; Bean et al., 2004c; see Appendix 9.1), among all four samples (r 's ranged from .45 to .52 for the total RATS, from .43 to .53 for the Intrusion scale, from .36 to .44 for the Numbing/Avoidance scale, and from .38 to .45 for the Hyperarousal scale). The RATS consistently demonstrated dose–response relationships. Adolescents who reported exposure to four or more high-magnitude stressors on the SLE were more likely to meet DSM-IV criteria for PTSD according to the RATS (odds ratio [OR] = 8.95, 95% confidence interval [CI] = 7.06–11.35). Those who reported sexual abuse were more likely to meet PTSD criteria (OR = 4.47, 95% CI = 3.57–5.58), as were those who had been separated from their families (OR = 6.18, 95% CI = 5.14–7.42). The RATS was significantly and strongly correlated with the Internalizing scale of the Hopkins Symptom Checklist–37 for Adolescents (HSCL-37A—Bean et al., 2004a; an adaptation of the HSCL-25 of Winokur, Winokur, Rickles, & Cox, 1984) in all four samples (r 's ranged from .66 to .79 for the total RATS, from .56 to .70 for the Intrusion scale, from .55 to .67 for the Numbing/Avoidance scale, and from .58 to .73 for the Hyperarousal scale). At the same time it correlated significantly but far less strongly with the Externalizing scale of the HSCL-37A (r 's ranged from .23 to .33 for the total, from .12 to .23 for the Intrusion scale, from .10 to .27 for the Numbing/Avoidance scale, and from .34 to .40 for the Hyperarousal scale). The authors argue that the lower correlations between the RATS and the Externalizing scale of the HSCL-37A provide evidence of the discriminant validity of the RATS.

Contact Information: Tammy Bean, PhD, Centrum 45, Rijnzichtweg 35, 2342 AX Oegstgeest, Netherlands. Telephone: 071-519-1500. E-mail: t.bean@centrum45.nl. All versions of the RATS, along with the manual, and SPSS code for computing scale scores can be downloaded at www.centrum45.nl/research/amaenggzlukamtool.php.

Young Adult Psychiatric Assessment (YAPA; Angold & Costello, 2000)

Brief Description: The YAPA, a modification of the CAPA, is suitable for use with young adults, providing a focus on diagnoses, living situations, relationships, and areas of functioning relevant to this age group (Angold & Costello, 2000). Age range: 18+.

Evidence of Reliability: Evidence of reliability has yet to be published.

Evidence of Validity: Evidence of validity has yet to be published.

Contact Information: Developmental Epidemiology Program, Duke University Medical Center, Attention: Juné Rogers, DUMC Box 3454, Durham, NC 27710. Telephone: (919) 687-4686, extension 273. E-mail: jrogers@psych.duhs.duke.edu.

APPENDIX 9.7. Measures Appropriate for Assessing Acute PTSD, Complex PTSD, and Other Associated Symptoms and Reactions

ADMINISTERED TO CHILD

Acute Stress Checklist for Children (ASC-Kids; Kassam-Adams, 2006)

Brief Description: The ASC-Kids is a 29-item self-report, with 25 items assessing ASD according to DSM-IV criteria: four items assess whether the experience was horrible, frightening, beyond the child or adolescent's control, or the child feared for his or her life; four assess emotional numbing, derealization, and dissociation; 15 items assess the remaining DSM-IV criteria; one item assesses the degree to which the child or adolescent was emotionally upset by the experience; one assesses disruptions to social interaction with meaningful others; two items assess social functioning at school and with the immediate family; one item assesses social support; and one assesses self-perceived coping skill. Most response categories are rated *Never/Not true* (0), *Sometimes/Somewhat* (1), and *Often/Very true* (2). Items rated 2 can be counted as indicating a DSM-IV symptom is present. Symptom category subscales include Dissociation, Reexperiencing, Avoidance, and Overarousal/Anxiety. Age range: 8–17; items should be read to children 9 years and younger, and to any 10- or 11-year-old who appears to require assistance. Languages: English and Spanish.

Evidence of Reliability: Based on the responses of 176 recently injured children and adolescents (mean age = 11.8; Kassam-Adams, 2006), internal consistency alpha for the 19 ASD items (questions 5–23) was .85, whereas it was .86 for all 29 items, and .64 for the Dissociation, .74 for the Reexperiencing, .73 for the Avoidance, and .73 for the Overarousal/Anxiety subscales. Test–retest correlations among 111 children and adolescents over a 1-week period on the 19 ASC-Kids symptom items were .76, and for total 29 items, .83, whereas it was .72 for the Dissociation, .75 for the Reexperiencing, .59 for the Avoidance, and .68 for the Overarousal/Anxiety subscales.

Evidence of Validity: The ASD-Kids total correlated .77 with the CATS (March, Amaya-Jackson, et al., 1997; see Appendix 9.5) PTSD subscale immediately after the injury occurred and .61 among 147 children and adolescents contacted 3 months later, and .37 with the CSDC (Saxe et al., 2003; see Appendix 9.5) caretaker report of the child's ASD symptoms immediately after the injury. Discriminant validity was demonstrated by lower, though significant, correlations of .49 with the Internalizing *T*-score on the YSR (Achenbach, 1991b) and .30 with the Externalizing *T*-score of the YSR. It correlated even less, but still significantly, with the parent report of Internalizing behavior on the CBCL (.23; Achenbach, 1991a) and of Externalizing behavior (.25). Factor analysis resulted in four factors that “correspond fairly well to the four symptom categories” (p. 136) of DSM-IV ASD.

Contact Information: Nancy Kassam-Adams PhD, Children's Hospital of Philadelphia, TraumaLink 3535 10th Floor, 34th Street and Civic Center Boulevard, Philadelphia, PA 19104. Telephone: (215) 590-1000. E-mail: nlkaphd@mail.med.upenn.edu. A listing of the ASC-Kids items can be found in Kassam-Adams (2006).

Angie/Andy Cartoon Trauma Scales (Praver & Pelcovitz, 1996; Praver, Pelcovitz, & DiGiuseppe, 1998)

Brief Description: Based on the cartoon-based child interview, Levonn: A Cartoon-Based Structured Interview for Assessing Young Children's Distress Symptoms (Richters et al., 1990), this interview is a child version of the Structured Interview for Disorders of Extreme Stress (SIDES; this appendix). It contains 44 full-page cartoons illustrating DSM-IV symptomatic responses to high-magnitude stressors plus the additional symptoms associated with complex PTSD (see Table 9.3). As such, it is primarily a measure of reactions to prolonged, repeated abuse; thus, it is probably more appropriate for assessing complex PTSD among young children. However, it does allow assessment of posttraumatic stress symptomatology. Two summary scores are computed: one for Posttraumatic Stress symptoms and the other for Total Associated symptoms. The associated items are relevant for the assessment of complex PTSD in addition to PTSD. See description of the parallel Angie/Andy Parent Rating Scales below for more detail about which associated symptoms are measured. The child rates how often he or she feels like the child in the drawing by using four separate thermometers filled to levels that correspond to responses of *Never*, *Just a few times*, *Some of the time*, and *A lot of the time*. Age range: 3 or 4 years to adolescence, depending on verbal ability. May be appropriate for children with lower IQs or learning problems as well.

Evidence of Reliability: Cronbach's alphas ranged from .70 to .95 for the scales (Praver & Pelcovitz, 1996).

Evidence of Validity: Among 208 children in three trauma groups—Intrafamilial Violence, Extrafamilial Violence, and Combined Violence—all scored higher than a nontrauma group on the six scales of the interview (Praver & Pelcovitz, 1996). The number of violence and abuse experiences to which a child was exposed correlated with the six subscales, from .44 to .57. The six subscales correlated from .71 to .81 with the Behavioral Assessment System for Children (BASC; Praver & Pelcovitz, 1996). It also significantly correlated with the BASC Parent Report Scale ($r = .55$). The Posttraumatic Stress scale had a sensitivity of .72 and specificity of .94 when differentiating between chronically traumatized and nontraumatized children (Praver, 1996; Praver, DiGiuseppe, Pelcovitz, Mandel, & Gaines, 2000).

Contact Information: Lisa Ayoung, Multi-Health Systems, P.O. Box 950, North Tonawanda, NY 14120-0950. Telephone: (800) 456-3003. Fax: (888) 540-4484. E-mail: r_d@mhs.com. Website: www.mhs.com. Francis Praver, PhD, 5 Marseilles Drive, Locust Valley, NY 11560. Telephone: (516) 671-8531. E-mail: drfranpraver@cs.com.

Structured Interview for Disorders of Extreme Stress Not Otherwise Specified (SIDES; Pelcovitz, van der Kolk, Roth, Mandel, & Kaplan, 1997)

Brief Description: This 48-item interview, which can be administered as a paper-and-pencil self-report measure, assesses the suggested criteria for complex PTSD (also known as disorder of extreme stress not otherwise specified, or

DESNOS). The SIDES was the instrument used to investigate the viability of a separate diagnostic category for complex PTSD during the DSM-IV field trials (Kilpatrick, et al., 1998; van der Kolk et al., 1996). Several questions assess specific symptoms of the domains of complex PTSD. In the domain of alteration in regulation of Affect and Impulses, three questions assess problems with affect regulation in general, four assess problems modulating anger, three assess self-destructive behaviors, one assesses suicidal preoccupation, seven assess difficulty modulating preoccupation with sexual involvement, and one question assesses excessive risk-taking behavior. In the domain of alterations in Attention or Consciousness, one item assesses amnesia and four items assess transient dissociative episodes and depersonalization, and one assesses a sense of ineffectiveness. In the domain of alteration in Self-Perception, one item assesses a sense of ineffectiveness, one assesses a sense of permanent damage to the self, one assesses guilt and responsibility, one assesses shame, one assesses a feeling that nobody can understand, and one item assesses minimizing the traumatic experience(s). In the domain of alterations in Perception of the Perpetrator, one item assesses the adoption of distorted beliefs about the perpetrator, one assesses idealization of the perpetrator, and one assesses preoccupation with hurting the perpetrator. In the domain of alterations in relations with others, three items assess the inability to trust others, one assesses the occurrence of revictimization experiences, and one assesses the tendency to victimize others. In the domain of Somatization, problems with the digestive system and chronic pain are assessed by one question each; cardiopulmonary symptoms are assessed with one item, wherein the respondent can indicate whether any of four different symptoms have been experienced; conversion symptoms are assessed with one item, wherein the respondent can indicate whether any of nine different symptoms have been experienced; and sexual symptoms are assessed with one item, wherein up to four symptoms can be endorsed. In the domain of alterations in Systems of Meaning, three items assess a pessimistic attitude toward the future (also known as a sense of foreshortened future), and two items assess a loss of previously sustaining beliefs. Endorsement of complex PTSD is met when criteria for all scales, except that assessing alterations in perceptions of the perpetrator (see reliability evidence below for details) are met (Pelcovitz et al., 1997).

Evidence of Reliability: In the DSM-IV field trials, a sample of 520 adults was assessed with the SIDES; 395 of the adults were seeking treatment, whereas the rest were from the community; 149 of them had been physically or sexually abused as children; 87 adults were victims of interpersonal abuse as adolescents or adults, 58 witnessed a disaster, and 226 reported on other stressors (Pelcovitz et al., 1997). Cronbach's alphas were .96 for the full scale, .90 for the items assessing alteration in regulation of Affect and Impulses, .76 for alterations in Attention or Consciousness, .77 for alterations in Self-Perception, .53 for alterations in Perception of the Perpetrator, .77 for alterations in Relations with Others, .88 for Somatization, and .78 for alterations in Systems of Meaning. Due to the low internal consistency, the authors did not include the scale intended to assess alterations in Perceptions of the Perpetrator in analyses of validity, and they recommend not requiring evidence for that set of symptoms when assessing complex PTSD. The kappa for interrater reliability for the full scale among 10 raters was .81.

Evidence of Validity: In the DSM-IV field trials (Pelcovitz et al., 1997), endorsement rates were compared between the various abuse groups (see reliability evidence for details). Out of 34 comparisons, differences between the early-onset interpersonal violence group and the disaster group were significant for all but one subscale, Symptoms of Ineffectiveness. Moreover, 23 of 34 differences in endorsement rates between the late-onset interpersonal violence group and the disaster group were significant.

Contact Information: David Pelcovitz, PhD, Azrieli School of Jewish Education, Yeshiva University, 500 West 185th St., New York, NY 10033. Telephone: (212) 960-0196. E-mail: depelcovi@yu.edu.

World View Survey (Fletcher, 1996h; Skidmore & Fletcher, 1997)

Brief Description: The World View Survey, a 50-item paper-and-pencil self-report, assesses important beliefs that may be changed by traumatic experience. The psychometrics of the scale were tested in a sample of 295 college students. Factor analysis (Skidmore & Fletcher, 1997) extracted nine factors, and a secondary factor analysis of these nine factors resulted in two second-order factors. The first factor concerns Trauma Reactive Beliefs and comprises five subscales: (1) Anxious Uncertainty (exemplified by beliefs such as "Life does not seem to make much sense anymore"); (2) Inadequacy (e.g., "I am a jinx"); (3) Dangerous World (e.g., "The world is a dangerous place to live"); (4) Self-Abnegation (e.g., "Sometimes I think I am not a very good person"); and (5) Lack of Control (e.g., "I feel like I have control over my life"—if disagreed with). The second higher-order factor concerns Negative Beliefs and comprises four subscales: (1) Poor Ego-Strength (e.g., "Since I have lived through some bad times, I have a better idea of what is important to me and what is not"); (2) Lack of Personal Empowerment (e.g., "I feel like nothing can keep me from getting what I want out of life anymore"—if disagreed with); (3) Negative Outlook (e.g., "Nowadays I feel like every new day I am alive is a gift"); and (4) Poor Attachment (e.g., "It is easy for me to make friends"—if disagreed with). The total of all items is not used, because the Trauma Reactive scale correlates only moderately with the Negative Beliefs scale ($r = .57$; Skidmore & Fletcher, 1997). Age range: 13 years and older.

Evidence of Reliability: The nine subscales had the following alphas: Anxious Uncertainty, .90; Inadequacy, .85; Dangerous World, .71; Self-Abnegation, .76; Lack of Control, .64; Poor Ego-Strength, .70; Poor Attachment, .74; Lack of Personal Empowerment, .63; and Negative Outlook, .61 (Skidmore & Fletcher, 1997). Alphas were .90 for the Trauma Reactive and .71 for the Negative Beliefs subscales.

Evidence of Validity: Correlations among the five Trauma Reactive subscales with theoretically related measures were all significant, whereas those between the Negative Beliefs scales with these same measures tended to be nonsignificant (Skidmore & Fletcher, 1997), providing further evidence that the two types of scales measure different domains. Thus, the overall Trauma Reactive and Negative Beliefs subscales are correlated .23 ($p < .001$) and .12 ($p < .05$), respectively, with the Young Adults Upsetting Times Checklist (see Appendix 9.1), a measure of exposure to lifetime stress; .34 ($p < .001$) and .02 (*ns*), respectively, with traumatic reactions as assessed by the IES (Horowitz et al., 1979); .61 ($p < .001$) and .27 ($p < .001$), respectively, with another measure of traumatic reactions derived from the Symptom Checklist-90—Revised (SCL-90-R; Derogatis, 1977; Saunders et al., 1990). Comparisons of scores on the

World View Survey of the 295 college students and 40 adolescent psychiatric inpatients, many of whom had diagnoses of PTSD (Skidmore & Fletcher, 1997), demonstrated that the inpatient adolescents scored significantly higher than the college students on the Trauma Reactive subscale ($M = 72.41 \pm 14.22$ vs. 89.18 ± 16.35) and the Negative Beliefs subscale ($M = 38.09 \pm 6.84$ vs. 42.58 ± 9.94). The inpatient adolescents scored significantly higher than the college students on all five subscales of the Trauma Reactive subscale, but on only two of the four subscales of the Negative Beliefs subscale. The two groups did not differ significantly on the Poor Ego-Strength subscale or on the Negative Outlook subscale.

ADMINISTERED TO CARETAKER OR OTHER ADULTS

Angie/Andy Parent Rating Scales (Praver, Pelcovitz, & DiGiuseppe, 1993)

Brief Description: Forty-four items on these scales parallel the Angie/Andy Cartoon Trauma Scales (this appendix), minus the cartoons. As noted in the description for that scale, these two measures were designed to assess reactions to prolonged, repeated abuse; they are therefore more suitable for assessing complex PTSD than simple PTSD in young children. Scales include Attention and Consciousness, Dysregulation of Affect and Impulses, Relations with Others, Self-Perception, Somatization, and Systems of Meaning. Symptoms such as despair, hopelessness, and loss of previously sustained beliefs are included. Two summary scores are also computed: one for Posttraumatic Stress symptoms and one for Total Associated symptoms. Age range: 3 or 4+ years.

Evidence of Reliability: Cronbach's alphas ranged from .75 to .95 for the scales (Praver et al., 1993).

Evidence of Validity: Correlated significantly with the BASC-PRS ($r = .71$ to $.81$; Praver, 1996).

Contact Information: Lisa Ayoung, Multi-Health Systems, P.O. Box 950, North Tonawanda, NY 14120-0950. Telephone: (800) 456-3003. Fax: (888) 540-4484. E-mail: r_d@mhs.com. Website: <http://www.mhs.com>. Frances Praver, PhD, 5 Marseilles Drive, Locust Valley, NY 11560. Telephone: (516) 671-8531. E-mail: drfranpraver@cs.com.

Child Stress Disorders Checklist (CSDC; Saxe, 2004) and Child Stress Disorders Checklist—Screening Form (CSDC-SF; Saxe & Bosquet, 2004)

Brief Description: Unlike most other child PTSD measures to date, the CSDC allows assessment of symptoms of both DSM-IV PTSD and ASD. See full description in Appendix 9.5.

PART V

Developmental Disorders

Autism Spectrum Disorders

Sally Ozonoff
Beth L. Goodlin-Jones
Marjorie Solomon

In this chapter, we review issues and methods relevant to the assessment of autism spectrum disorders (ASDs). We begin with some background about these disorders, including their diagnostic criteria, associated features, developmental course, epidemiology, etiologies, and outcomes. This information is used as a foundation for understanding and evaluating assessment strategies and instruments used with this population of children. Next we provide an overview of the assessment process, common referral questions, and special issues relevant to ASD that must be considered. We then describe the components of a core assessment battery, followed by additional domains that might be considered in a more comprehensive assessment. Domains covered include autism symptomatology, intelligence, language, adaptive behavior, neuropsychological functions, comorbid psychiatric illnesses, and family functioning. Throughout these sections, we discuss the feasibility of particular methods and highlight those that are practical for use in a typical clinical setting. We end with a discussion of the utility of specific instruments for treatment planning and evaluation, outcome assessment, and sensitivity to change.

DIAGNOSTIC CRITERIA

The fourth edition, text revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; American Psychiatric Association [APA], 2000) lists five pervasive developmental disorders (PDDs)¹: autistic disorder, Asperger's disorder, Rett's disorder, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified. Symptoms of autistic disorder fall into three domains (see Table 10.1): social relatedness, communication, and behaviors and interests, with delays or abnormal functioning in at least one of these areas evident in children prior to 3 years of age. In the social domain, symptoms include impaired use of nonverbal behaviors (e.g., eye contact, facial expression, gestures) to regulate social interaction, failure to develop age-appropriate peer relationships, little seeking to share enjoyment or interests with other people, and limited social-emotional reciprocity. Communication deficits include delay in or absence of spoken language,

¹ This term is used synonymously with ASD in this chapter.

TABLE 10.1. DSM-IV-TR Criteria for Autistic Disorder

DSM-IV-TR symptoms	Examples
<u>Deficits in reciprocal social interaction</u>	
(1a) Difficulty using nonverbal behaviors to regulate social interaction	<ul style="list-style-type: none"> • Poor eye contact • Little use of gestures while speaking • Few or unusual facial expressions • Unusual intonation or voice quality
(1b) Failure to develop age-appropriate peer relationships	<ul style="list-style-type: none"> • Lack of interest in peers • Few or no same-age friends • Trouble interacting in groups and following cooperative rules of games
(1c) Little sharing of pleasure, achievements, or interests with others	<ul style="list-style-type: none"> • Delay in or failure to develop joint attention • Does not point to show • Enjoys activities alone, without involving others
(1d) Lack of social or emotional reciprocity	<ul style="list-style-type: none"> • Does not respond to others; appears indifferent • Strongly prefers solitary activities • Does not notice when others are hurt or upset; does not offer comfort
<u>Deficits in communication</u>	
(2a) Delay in or total lack of development of language	<ul style="list-style-type: none"> • No use of words to communicate by age 2 • No simple phrases (e.g., “more milk”) by age 3 • After speech develops, immature grammar
(2b) Difficulty holding conversations	<ul style="list-style-type: none"> • Trouble knowing how to start, maintain, and/or end a conversation • Little back-and-forth; may talk on and on in a monologue • Failure to respond to the comments of others; response only to direct questions • Difficulty talking about topics not of special interest
(2c) Unusual or repetitive language	<ul style="list-style-type: none"> • Repeating what others say to them (echolalia) • Repeating from videos, books, or commercials at inappropriate times or out of context • Using words or phrases that the child has made up or that have special meaning only to him/her • Overly formal, pedantic style of speaking (sounds like “a little professor”)
(2d) Play that is not appropriate for developmental level	<ul style="list-style-type: none"> • Little acting out scenarios with toys • Rarely pretends an object is something else (e.g., a banana is a telephone) • Prefers to use toys in a concrete manner (e.g., building with blocks, arranging dollhouse furniture) rather than pretending with them • When young, little interest in social games like peekaboo, ring-around-the-rosie, etc.
<u>Restricted, repetitive behaviors, interests, or activities</u>	
(3a) Interests that are narrow in focus, overly intense, and/or unusual	<ul style="list-style-type: none"> • Very strong focus on particular topics to the exclusion of other topics • Interest in topics that are unusual for age (sprinkler systems, movie ratings, astrophysics, radio station call letters) • Excellent memory for details of special interests • Interference with other activities (e.g., delays eating or toileting due to focus on activity)
(3b) Unreasonable insistence on sameness and following familiar routines	<ul style="list-style-type: none"> • Wants to perform certain activities in an exact order (e.g., close car doors in specific order) • Need for advanced warning of even minor changes • Becomes highly anxious and upset if routines or rituals not followed

(continued)

TABLE 10.1. (continued)

DSM-IV-TR symptoms	Examples
Restricted, repetitive behaviors, interests, or activities (<i>continued</i>)	
(3c) Repetitive motor mannerisms	<ul style="list-style-type: none"> • Flaps hands when excited or upset • Flicks fingers in front of eyes • Odd hand postures or other hand movements • Spins or rocks for long periods of time
(3d) Preoccupation with parts of objects	<ul style="list-style-type: none"> • Uses objects in unusual ways (e.g., flicks doll's eyes, repeatedly opens and closes doors on toy car), rather than as intended • Interest in sensory qualities of objects (e.g., likes to sniff objects or look at them closely) • Attachment to unusual objects (orange peel, string)
<u>Onset criteria</u>	<ul style="list-style-type: none"> • Delays or abnormal functioning must be present before 3 years of age.

Note. From American Psychiatric Association. Copyright 2000 by the American Psychiatric Association. Adapted by permission.

difficulty with conversational reciprocity, idiosyncratic or repetitive language, and imitation and pretend play deficits. In the behaviors and interests domain, there are often encompassing, unusual interests, inflexible adherence to nonfunctional routines, stereotyped body movements, and preoccupation with parts or sensory qualities of objects (APA, 2000). To meet criteria for autistic disorder, an individual must demonstrate at least 6 of 12 symptoms—at least two from the social domain, and one each from the communication and restricted behaviors/interests categories.

Asperger's disorder (or Asperger syndrome, as it is often called) shares the social disabilities and restricted behaviors and interests of autism, but language abilities are well developed and intellectual functioning is not impaired.² Symptoms of Asperger syndrome are identical to those just listed for autistic disorder except that there is no requirement that the child demonstrate any difficulties in the second category, communication. The main point of differentiation from autistic disorder, especially the higher-functioning subtype, is that those with Asperger syndrome do not exhibit significant delays in the onset or early course of language. As specified in the DSM-IV-TR, nonechoed, communicative use of single words must be demonstrated by age 2 and meaningful phrase speech, by age 3. Most parents of children with

Asperger syndrome are not concerned about early language development and may even report precocious language abilities, such as a large vocabulary and adult-like phrasing from an early age. Autistic disorder must be ruled out before a diagnosis of Asperger syndrome is justified. DSM-IV-TR mandates that the diagnosis of autism always take precedence over that of Asperger syndrome. Thus, if a child meets criteria for autistic disorder, the diagnosis must be autism even if he or she displays excellent language, average or better cognitive skills, and other "typical" features of Asperger syndrome.

Individuals who meet criteria for autistic disorder and are intellectually normal are considered "high functioning." Research comparing Asperger syndrome and high-functioning autism (HFA) provides mixed evidence of their external validity. Early history differences are evident between the disorders, with children with Asperger syndrome showing fewer and less severe symptoms, and better language in the preschool years than children with HFA, but these group differences are likely artifacts of the diagnostic definitions (Ozonoff, South, & Miller, 2000). Follow-up studies demonstrate similar trajectories in outcome (Ozonoff et al., 2000; Szatmari et al., 2000). Neuropsychological research suggests that the two conditions are more similar than different, and consensus has not been achieved on the validity of their distinction (Howlin, 2003; Macintosh & Dissanayake, 2004). Whether the two conditions are different enough to warrant separ-

² Generally defined as IQ scores above 69, although no operational definition exists and other thresholds, such as IQ > 84, are sometimes used.

rate names is of more than academic interest, because resources in many states are provided differentially to children based on the particular autism spectrum diagnosis they receive.

Two other conditions also appear in the DSM-IV-TR PDD category: Rett's disorder and childhood disintegrative disorder. Both involve a period of typical development, followed by a loss of skills and regression in development. The classic symptoms of Rett's disorder, seen primarily in females, include lack of typical social interaction; lack of language; very frequent stereotyped hand movements, including repetitive wringing, "washing," twisting, clapping, or rubbing of the hands in the midline (often leading to lack of functional hand use); unsteady gait; and severe to profound mental retardation. A gene on the X chromosome, *MECP2*, causes most cases of Rett's disorder (Amir et al., 1999).

In childhood disintegrative disorder (CDD), an abrupt and severe regression occurs after at least 2 (and up to 10) years of normal development. After the loss of skills, the child has all the characteristics of severe autism and severe mental retardation. Without taking a history of early development and onset, it is difficult to distinguish between the behavioral phenotype of CDD and autism, and treatments for the two conditions are similar. It is not clear whether the cause(s) of CDD differ from those of autism. There appears to be relatively less improvement over time than occurs in autism, and the condition continues as a chronic, severe, developmental disability throughout life. CDD is a very rare condition, occurring in only 1 in 100,000 individuals (Fombonne, 2002). Given the low incidence of both CDD and Rett's disorder, these conditions are not considered further in this chapter. The interested reader is referred to recent comprehensive reviews for more information (Van Acker, Loncola, & Van Acker, 2005; Volkmar, Koenig, & State, 2005).

The fifth and final condition that falls within the PDD category is pervasive developmental disorder not otherwise specified (PDD NOS). This label is used for children who experience difficulties in at least two of the three autism-related symptom clusters, but who do not meet criteria for any of the other PDDs. The same list of 12 symptoms outlined earlier is used to diagnose PDD NOS, but only one difficulty within the "reciprocal social interaction" domain and one symptom from either the "com-

munication deficits" or "repetitive, restricted behaviors" domains are required. Thus, this is a very heterogeneous category (Walker et al., 2004). Children with PDD NOS demonstrate autistic-like behaviors and difficulties but display either too few symptoms or a different pattern of symptoms than other conditions in the PDD category. For example, a child might be diagnosed with PDD NOS if he displayed only four of the DSM-IV-TR symptoms (ruling out autistic disorder), displayed a delay in language onset (ruling out Asperger syndrome), and showed no regression in development (ruling out both Rett's disorder and CDD). The diagnosis is often misused, with substantial proportions of children carrying this label either meeting full criteria for autism or not meeting criteria for any ASD (Buitelaar, Van der Gaag, Klin, & Volkmar, 1999). Thus, it is always worth reevaluating a child who presents with a diagnosis of PDD NOS made by another clinician or agency, to examine the accuracy of the initial diagnosis.

ASSOCIATED FEATURES

ASDs can co-occur with a variety of other difficulties. Best appreciated is the high comorbidity rate of autism and mental retardation. Most studies have found that the majority of individuals with autism (roughly 75%) are intellectually handicapped, with approximately half of the group functioning in the range of mild to moderate mental retardation, and half in the severe to profound range. However, recent epidemiological investigations focusing on the preschool period found a decrease (down to 25–50%) in the percentage of those with mental retardation (Chakrabarti & Fombonne, 2001; Honda, Shimizu, Misumi, Niimi, & Ohashi, 1996). This trend is consistent with increasing recognition of milder cases. Rising IQ may also reflect the effect of early intervention.

Another commonly associated symptom is seizures. Up to one-third of children with autism develop seizures, although rates tend to be higher in clinic-based studies (e.g., Rossi, Posar, & Parmeggiani, 2000) and may be closer to 10–15% in larger, community-based samples (Tharp, 2004). Seizures are more common in children who have both autism and mental retardation (Danielsson, Gillberg, Billstedt, Gillberg, & Olsson, 2005). Epilepsy onset is often during the preschool years, but there is lack

of consensus on whether there is a second peak onset period for seizures after puberty (Danielsson et al., 2005; Rossi et al., 2000).

Other nonspecific abnormalities have been found in children with autism, including dysregulation of both eating and sleeping patterns. Food sensitivities and selective food intake are widely reported and are a cause of significant concern for many parents, although the nutritional and behavioral impact of these patterns is far from clear at this time. It has been hypothesized that allergies to dairy and wheat by-products may cause or exacerbate symptoms of autism (Erickson et al., 2005), but insufficient empirical study has been conducted to evaluate the validity of such hypotheses. Several studies have found that sleep problems in ASD are approximately double (55%) or higher the prevalence in typically developing children and adolescents (Honomichl, Goodlin-Jones, Burnham, Gaylor, & Anders, 2002; Oyane & Bjorvatn, 2005; Schreck & Mulick, 2000). These findings are consistent across studies that use a variety of methods, including objective measures, such as actigraphy, as well as parental report. However, the impact of the sleep disturbances on daytime functioning in the ASD population is largely unknown (Oyane & Bjorvatn, 2005).

PSYCHIATRIC AND BEHAVIORAL COMORBIDITIES

ASDs can co-occur with a variety of additional psychiatric and behavioral disturbances. Accurate identification of these comorbidities is of great importance for treatment planning and educational interventions. In a study of school-age children who were consecutive cases at an ASD clinic, 85% of those with Asperger syndrome and 65% of those with HFA exhibited clinically significant behavioral and emotional issues (Tonge, Brereton, Gray, & Einfeld, 1999).

Mood and Anxiety Disorders

The most common comorbid conditions in the ASD population are anxiety disorders and depressed mood (Kim, Szatmari, Bryson, Streiner, & Wilson, 2000; Lainhart & Folstein, 1994). There is general agreement that rates are higher than expected (e.g., greater than the 10% lifetime rate in the general population), but epidemiological studies of comorbidity prevalence

have not been done. Risk for anxiety and mood disorders may be especially elevated at the higher functioning end of the autism spectrum (Howlin, Goode, Hutton, & Rutter, 2004; Klin, Pauls, Schultz, & Volkmar, 2005; Towbin, 2005) and may in some cases be secondary to stressful peer interactions and teasing (Howlin et al., 2004; Klin & Volkmar, 1997). In a well-designed study comparing high-functioning children with ASD to a community sample (Kim et al., 2000), individuals with Asperger syndrome and HFA both scored in the clinically concerning range on scales measuring depression (17% of the total sample) and generalized anxiety (13.6% of total). There were no differences between the Asperger syndrome and HFA diagnostic groups in comorbidity rates, but children with higher verbal than nonverbal abilities had more anxiety and mood problems (Kim et al., 2000). Significantly higher rates of phobias and specific fears in children with ASD relative to children with Down syndrome and typical development have also been reported by Evans, Canavera, Kleinpeter, Maccubin, and Taga (2005).

Behavioral Problems

Children with undiagnosed, higher-functioning ASDs are sometimes first identified in a general psychiatry clinic (Towbin, 2005) after referral for nonspecific behavioral problems. Longitudinal studies illustrate that behavior problems are relatively common in children with ASDs, even in higher-functioning individuals. For example, in a large follow-up study of adults with ASD, Ballaban-Gil, Rapin, Tuchman, and Shinnar (1995) found that 69% of participants exhibited behavioral difficulties. Even among individuals with average intelligence, close to half were reported by their families to have behavioral problems. Approximately 25% of individuals with ASD have a history of aggressive outbursts and irritability that bring them to the attention of a mental health clinic (Gillberg & Coleman, 2000). Comorbid mania and bipolar disorder have been described in children with ASD (Frazier, Doyle, Chiu, & Coyle, 2002; Wozniak et al., 1997). Tantum (2003) reported that individuals with Asperger syndrome, like patients with frontal lobe disorders, may experience “catastrophic reactions” or extreme emotional or behavioral responses to apparently ordinary stressors, such as failure or sensory overstimulation. Such reactions can

include screaming, shouting, swearing, and/or running away. Levels of irritability, temper tantrums, and defiance comparable to those seen in conduct disorder have been found in samples of children with Asperger syndrome (Gilmour, Hill, Place, & Skuse, 2004; Green, Gilchrist, Burton, & Cox, 2000).

Despite the apparently elevated rate of behavioral and conduct difficulties just described, the vast majority of individuals with ASDs are not violent toward others (Ghaziuddin, Tsai, & Ghaziuddin, 1991). There have been occasional reports of antisocial acts such as fire setting (e.g., Everall & LeCouteur, 1990), but it appears that such behavior is often driven by social naivete and lack of understanding of consequences or social norms. For example, a child with ASD may not realize the necessity of paying for things in a store or appreciate that interest in a member of the opposite sex is unreciprocated.

Attention and Activity Level

Tsai (2000) reported that 60% of individuals with ASD have poor attention and concentration and that 40% are hyperactive. Similarly, Goldstein and Schwabach (2004) completed a retrospective chart review of 27 children with ASD and found that almost 60% met criteria for attention-deficit/hyperactivity disorder (ADHD). In this sample, 26% met the criteria for ADHD combined type and 33% met criteria for ADHD inattentive type. Ghaziuddin, Weidmer-Mikhail, and Ghaziuddin (1998) reported that approximately 30% of individuals with Asperger syndrome meet diagnostic criteria for ADHD. Despite these research reports and the clinical experience of many practitioners, DSM-IV-TR criteria do not permit the diagnosis of ADHD in individuals with ASD. It has been suggested that this exclusion should change in future DSM versions, and many clinicians do diagnose both conditions in the same individual (Frazier et al., 2001; Ghaziuddin, Tsai, & Alessi, 1992), particularly when symptoms that are not part of the autism spectrum, such as hyperactivity, are evident. It is more challenging to distinguish between ASD and the inattentive subtype of ADHD, and the validity of this differential diagnosis has not been adequately studied.

It has been suggested that attention problems in the context of ASD differ qualitatively from those found in ADHD. "Overfocus" of

attention and internal distractibility are said to be more characteristic of ASDs, whereas under-focused attention and distractibility by external events and stimuli are the hallmarks of ADHD (Hendren, 2003; Jensen, Larrieu, & Mack, 1997). It has also been suggested that hyperactivity may be more prominent in children with ASD at younger ages but diminish with age, so that only inattention and distractibility remain in adulthood (Klin, Sparrow, Marans, Carter, & Volkmar, 2000; Tatum, 2003). Others have found that occasionally children present with ASD in preschool but appear to "grow out" of their social symptoms and present later in childhood very much like children with primary ADHD (Fein, Dixon, Paul, & Levin, 2005).

Psychosis

Another psychiatric condition important in the differential diagnosis of ASD is schizophrenia (see McDonell & McClellan, Chapter 11, on early-onset schizophrenia, this volume). For many years, the prevailing belief was that autism and schizophrenia shared a common etiology (Volkmar & Cohen, 1991); in fact, the terms "autism" and "childhood schizophrenia" were used interchangeably for the first several decades after Kanner's (1943) description of the syndrome. More recent research has, however, established clear diagnostic boundaries for autism and schizophrenia, and suggests that they do not co-occur more often than expected by chance. One well-known, large study found only one individual with schizophrenia and autism in a sample of 163 adolescents and adults (Volkmar & Cohen, 1991). In another 22-year prospective follow-up study of 38 individuals with autism, none went on to develop schizophrenia as adults (Mouridsen, Rich, & Isager, 1999).

The differentiation between ASD and psychosis is less clear, however, when considering symptoms that exist on the diagnostic boundaries of both the autism and schizophrenia spectrums. Clinically, it can occasionally be quite challenging to disentangle the ritualistic behaviors, unusual verbalizations, and social withdrawal that are part of autism from signs of psychosis, such as formal thought disorder, delusional beliefs, and affective flattening. Studies have documented signs of formal thought disorder (e.g., illogical statements, loose associations, disorganized thinking) and

other negative symptoms of schizophrenia in individuals with ASD (Dykens, Volkmar, & Glick, 1991; Ghaziuddin, Leininger, & Tsai, 1995; Konstantareas & Hewitt, 2001; Van der Gaag, Caplan, van Engeland, Loman, & Buitelaar, 2005). It is not clear whether these are just superficial similarities in presentation or whether a subgroup of individuals with ASD also shows signs of psychosis (Clark, Baxter, Perry, & Prasher, 1999). Several groups have described complicated clinical cases in which symptoms of ASD, such as gross impairments in peer relationships, circumscribed interests, and deficits in conversational reciprocity, exist alongside delusions, paranoia, formal thought disorder, poor attention and impulse control, and affective instability (Kumra et al., 1998; Towbin, Dykens, Pearson, & Cohen; 1993; Van der Gaag et al., 1995). Consistent with this, a National Institute of Mental Health study of 75 children with childhood-onset schizophrenia found that 25% had a lifetime diagnosis of ASD (mostly PDD NOS; Sporn et al., 2004).

DEVELOPMENTAL COURSE

The onset of autistic disorder always occurs before age 3, at two peak periods. The majority of children (approximately two-thirds) display developmental abnormalities within the first 2 years of life. A smaller group of children with autism display a period of normal or mostly normal development, followed by a loss of communication and social skills, and onset of autism (Kurita, 1985). Onset, parental recognition, and clinical diagnosis do not always (or even usually) coincide. The average age of diagnosis of autism is currently right around the third birthday (Lingam et al., 2003; Mandell, Novak, & Zubritsky, 2005). For example, in a large epidemiological study in the United Kingdom, the child's age at the time of first symptom recognition by parents was 18.6 months, age at referral was 32.4 months, and age at diagnosis was 37.8 months (Chakrabarti & Fombonne, 2005). Parents often begin to be concerned when language fails to develop as expected (De Giacomo & Fombonne, 1998). However, several other behavioral differences, particularly social ones, appear to predate the child's language abnormalities that parents report at the time of recognition, including less looking at faces, responding to his or her name,

pointing, and sharing enjoyment and interests with others (Baron-Cohen et al., 1996; Lord, 1995; Osterling & Dawson, 1994; Trevarthen & Daniel, 2005; Wetherby et al., 2004; Wimpory, Hobson, Williams, & Nash, 2000; Zwaigenbaum et al., 2005).

In the regressive pattern of onset, there is a period of normal development, followed by a change in or loss of previously acquired behavior and the onset of autistic symptoms (Kurita, 1985). The average onset of regression is consistently described across studies as between 14 and 24 months of age (Fombonne & Chakrabarti, 2001; Hoshino et al., 1987; Kurita, 1985; Shinnar et al., 2001). Regression typically progresses gradually, although onset can be sudden in a minority of cases. It is important to distinguish between regression and a developmental plateau, in which children fail to progress as expected and do not gain new skills. This form of onset is not considered a regression, because there is no loss of previously acquired skills. Loss of language is the most commonly described and perhaps most salient manifestation of regression (Goldberg et al., 2003; Siperstein & Volkmar, 2004), but even within the communication domain, the nature and extent of loss is heterogeneous. Some children stop talking altogether, whereas others lose only some words and retain others; still others lose only nonverbal means of communication. Virtually all children who lose language lose social behaviors as well, such as eye contact, interest and engagement with others, and social games such as peekaboo (Lord, Shulman, & DiLavore, 2004; Ozonoff, Williams, & Landa, 2005). By definition, the regression that occurs in approximately one-third of children with autistic disorder occurs earlier than that in children with CDD. It is not yet known whether autism and CDD are on a continuum, or whether they differ in important ways other than onset.

The onset of Asperger syndrome and PDD NOS is less well understood. Children with these disorders usually present at older ages (Mandell et al., 2005), and parent report of early development may not be as accurate when more time has passed. Additionally, the symptoms of Asperger syndrome and PDD NOS may be far subtler in preschool than those of autism and difficult to detect even by professionals. In a large sample of children with ASD identified at 2–3 years of age, less than 3% met criteria for Asperger syndrome (McConachie,

Le Couteur, & Honey, 2005). This may reflect that one of the most common symptoms to bring children to early clinical attention is language delay (Mandell et al., 2005), which is an exclusion for the diagnosis of Asperger syndrome. Many parents of children with Asperger syndrome and PDD NOS do retrospectively report social symptoms before age 3, but this criterion is not required by the DSM-IV-TR for a diagnosis of Asperger syndrome or PDD NOS, as it is for autistic disorder. No prospective studies of these higher-functioning forms of ASD have addressed this question, but at present it is assumed that onset is usually early in life for these conditions, too.

ASDs are considered lifelong, chronic conditions. There may be periods of waxing or waning of particular symptoms, and improvement with age and development, however. Some studies suggest that improvement is most marked in preschool and early childhood, with functioning levels remaining stable and sometimes even worsening in adolescence and adulthood (Eaves & Ho, 1996; Sigman & McGovern, 2005). Once diagnosed with an ASD, the vast majority of children retain this diagnosis into adulthood (Gonzalez, Murray, Shay, Campbell, & Small, 1993; Piven, Harper, Palmer, & Arndt, 1996) and present with functional impairment throughout life (Billstedt, Gillberg, & Gillberg, 2005; Howlin, 2003; Seltzer et al., 2003). In a very small proportion of cases, children appear to “grow out of” an ASD diagnosis (Lovaas, 1987; Perry, Cohen, & DeCarlo, 1995), although some do retain difficulties in other areas (Fein et al., 2005). Diagnosis at age 2 is remarkably reliable and stable, with 85–90% of children diagnosed at this age retaining the diagnosis over time (Lord, 1995; Moore & Goodson, 2003; Stone et al., 1999).

There have been several large longitudinal studies of individuals with autism. As summarized by Howlin (2005), outcomes for adults with ASD have improved over the last 25 years. Results of studies conducted after 1980 (e.g., Ballaban-Gil et al., 1995; Howlin, 2003; Kobayashi, Murata, & Yashinaga, 1992; Venter, Lord, & Schopler, 1992) suggest that approximately 20% of adults have good outcomes. Although highly variable across studies, the average percentage of individuals with ASD attending college in these studies was 12%. Enrollment ranged from 0 to 50%, with the highest rates found among those with the highest cognitive abilities. In these same studies, ap-

proximately 24% of individuals with ASD were employed. Most of their jobs were relatively menial and included food service, unskilled factory, and warehouse work. Employment stability also was low. Again, individuals with higher cognitive abilities fared better. Some of these individuals secured jobs in the computer and electronics industries. Howlin (2005) also points out that there also has been a drop in individuals with poor outcomes over time, from 65% prior to 1980 to 46% after 1980.

In contrast to the relatively optimistic portrait painted by Howlin's (2005) review, a recent Scandinavian study published the results of a prospective, population-based, follow-up study of 120 individuals diagnosed with autism in childhood (Billstedt et al., 2005). This sample of largely mentally retarded and/or nonverbal individuals was followed 13–22 years after initial contact. The mortality rate was unexpectedly high (5%). The rate of epilepsy was over 40%. Approximately 80% of the sample had poor or very poor outcomes, defined as displaying obvious, severe handicaps, without the possibility of independent living or satisfying social relationships.

Several inferences may be drawn from these studies. First, outcome is highly related to overall cognitive ability. Across all studies conducted to date, the most powerful predictors of outcome continue to be two factors identified over 20 years ago: IQ scores and verbal ability at age 5 (Lotter, 1974; Rutter, 1984). Howlin and colleagues (2004) found that a minimum IQ of 70 was required for a positive outcome. Even above this IQ cutoff, however, outcomes were mixed, with over 40% of individuals having poor or very poor outcomes. Educational, vocational, community, and family supports appear to play an important role in promoting positive adaptation and may be important factors in explaining variability in outcome. For example, the strength of the local economy and availability of vocational assistance programs may impact the employment outlook for persons with autism (Shea & Mesibov, 2005). Finally, it is important to remember that longitudinal studies of the least severely impaired individuals on the autism spectrum have not yet been undertaken. Given their lack of language delay, these individuals may be diagnosed later in life, and not in time to be included in longitudinal studies. Additionally, the availability of high-quality, intensive early intervention has

increased in the last decade, and children who were provided such treatment have not yet reached adulthood. For these reasons, we really do not yet know what “best outcomes” for ASD may be and how often they might be achieved. It is important for clinicians to represent accurately our current state of knowledge about outcome as they counsel families over time, and not inadvertently dampen their hopes, aspirations, and enthusiasm for interventions.

EPIDEMIOLOGY

Early research suggested that autism (strictly defined, meeting full criteria for the disorder) occurred at the rate of 4–6 affected individuals per 10,000 (Lotter, 1966; Wing & Gould, 1979). An influential study in the mid-1980s broadened diagnostic criteria somewhat, and found a rate of 10 per 10,000 in a total population screening of a circumscribed geographical region in Canada (Bryson, Clark, & Smith, 1988). Newer studies that have utilized standardized diagnostic measures of established reliability and validity employed active ascertainment techniques. These surveys have given prevalence estimates of 60–70 per 10,000 or approximately 1 in 150 across the spectrum of autism, and 1 in 500 for children with the full syndrome of autistic disorder (Chakrabarti & Fombonne, 2001). One obvious reason for the rise in rates is that more recent research has examined all ASDs, whereas early surveys looked only at rates of strictly defined autism. However, in studies that have broken down the rates by specific PDD subtypes, it is clear that the prevalence of classic autism itself is higher. Chakrabarti and Fombonne (2001) reported a rate of 16.8 per 10,000 for autistic disorder, which is three to four times higher than the rate suggested in the 1960s and 1970s, and over 1.5 times the rate reported in the 1980s and 1990s. Thus, ASDs are no longer rare conditions, and it is likely that many or most practitioners will encounter individuals with suspected ASD in their practices.

Several reasons for the rising prevalence rates have been proposed, from methodological artifacts to newly emerging environmental and biological risk factors. The first category includes increased awareness among clinicians and the general public, better identification and referral practices, more sensitive diagnostic

tools, broader classification systems, and more active methods of case ascertainment in epidemiological studies. No doubt, the ability of clinicians to identify more subtle manifestations of ASD and to discriminate between autism and mental retardation has improved; it is also clear that the DSM-IV-TR diagnostic system casts a broader net than previous classification systems. Diagnostic criteria and methods of ascertainment (e.g., active case finding vs. registry screening) have also influenced estimates of prevalence (Kielinen, Linna, & Moilanen, 2000). Whether changes in referral, case ascertainment, and diagnostic criteria alone can account for the large increase is uncertain, and hypotheses abound about environmental factors that may have emerged in the last few decades to put infants and young children at greater risk for developing autism. These are covered, along with other etiological factors, in the next section.

Very few studies have examined the prevalence of autism as a function of race and ethnic group. It has occasionally been suggested that the rate of ASD is higher in immigrant than in native populations (Gillberg, Steffenburg, & Schaumann, 1991). For example, one study observed an elevated rate of autism in immigrants from Pakistan to the United Kingdom (Morton, Sharma, Nicholson, Broderick, & Poyser, 2002), suggesting that the increase was due to high (60%) rates of consanguinity. However, a large California study with a similar database analysis of the prevalence rate of autism across race and ethnic groups (white, Hispanic, black, Asian, or other) described the rates as very similar during an 8-year period (Croen, Grether, Hoogstrate, & Selvin, 2002). Fombonne (2005) suggests that there is no relationship between ethnicity or race and ASD in large studies with adequate sampling and statistical control.

Kanner (1943), who provided the first description of autism, was the first to identify the much greater preponderance of affected boys. A meta-analysis suggests that the widely reported 4:1 ratio of boys to girls is quite consistent across studies, geographical regions, ethnicities, and time (Fombonne, 2003). Sex differences in autism have received little attention except for the purpose of examining differences in prevalence. Of the few studies, most describe greater severity in females. For example, studies of intelligence consistently report lower IQ (Kurita, Osada, & Miyake, 2004;

Tsai, Stewart, & August, 1981; Volkmar, Szatmari, & Sparrow, 1993) and mental age (Pilowsky, Yirmiya, Shulman, & Dover, 1998) in females than in males with autism. Other studies have reported more pronounced behavioral abnormalities in females with autism (Steinhausen & Metzke, 2004). Some investigators have suggested that females with autism have a different phenotype and present with different referral issues than boys (Gillberg & Rastam, 1992; Kopp & Gillberg, 1992), but this position is controversial and has not been studied enough. More attention to the area of gender differences in prevalence, presentation, functioning, treatment needs, and outcome is clearly needed (Koenig & Tsatsanis, 2005; Thompson, Caruso, & Ellerbeck, 2003).

ETIOLOGIES

Kanner suggested that children with autism are born with “an innate inability to form the usual, biologically provided affective contacts with people” (Kanner, 1943, p. 250). Later, however, his thinking came into line with that of his contemporaries trained in the psychoanalytic tradition that was predominant at the time. He and others suggested (incorrectly) that autism was the result of inadequate nurturance by emotionally cold, rejecting parents (Bettelheim, 1967), a theory that prevailed until the late 1960s. Rimland (1964) did a tremendous service to the field when he provided powerful arguments that autism had an organic etiology. It is now clear that biological mechanisms produce brain changes that lead to the symptoms of autism. There are no viable social–environmental hypotheses of autism etiology.

Genetic factors play a strong role in the development of autism (Bailey et al., 1995; Veenstra-Vanderweele, Christian, & Cook, 2004). The recurrence risk for autism after the birth of one child with the disorder is at least 3–6% (Bailey, Palferman, Heavey, & LeCouteur, 1998) and perhaps as high as 10–15% (Zwaigenbaum et al., 2005), far exceeding that of the general population rate. The concordance rate for autism in monozygotic (MZ) twins is greatly elevated relative to that for dizygotic (DZ) twins. The most recent twin studies, which used standardized diagnostic measures and total population screening, found concordance rates for strictly defined au-

tistic disorder of 60% in MZ pairs (up to 90% concordance for broader ASD symptoms), but only 5% in DZ pairs (Bailey et al., 1998). These figures yield a heritability estimate greater than .90 for ASD (Bailey et al., 1995; Le Couteur et al., 1996). There is also evidence of familial transmission of an extended set of cognitive and social anomalies that are milder than, but qualitatively similar to, autism (the so-called “broader autism phenotype”; Bailey et al., 1998). Family members also have higher than average rates of anxiety and affective disorders, and learning disabilities. Collectively, these features of the broader autism phenotype have been found in 15–45% of family members of people with ASD (Bailey et al., 1998).

Advances in the molecular genetics of autism have been rapid, but the results so far are inconclusive. One reason is that the inheritance pattern appears far from simple, with statistical models suggesting that several, and perhaps as many as 10, genes are involved in conferring susceptibility (Pickles et al., 1995; Risch et al., 1999). Case reports have demonstrated a link between autism and a wide variety of chromosomal anomalies, with one review (Gillberg, 1998) reporting associations with all but three chromosomes. It is not yet clear which associations are random and which may provide clues about etiology. The one cytogenetic abnormality that has been consistently replicated in a small proportion of children with autism is a duplication of material on chromosome 15 (Rutter, 2000).

Twin studies also make it clear that autism is not a purely genetic disorder, since the concordance rate for identical twins falls short of 100%, and there can be tremendous phenotypic variability even among MZ twins. The search for nongenetic factors that influence the development and severity of autism is intense and has received much media attention. It has been suggested that environmental factors, including immunizations, heavy metal or pesticide exposures, viral agents, and food products, may interact with genetic susceptibility to trigger autism, to cause it alone, or to mediate the expression and severity of the disorder (Hornig & Lipkin, 2001). The potential environmental etiological agent that has received the most attention is immunization. Wakefield and colleagues (1998) described a case series of 12 children with gastrointestinal disturbances that were reported to begin around the time that autistic behaviors became evident. He pos-

tulated that these children had a new subtype of “regressive autism” induced by the measles–mumps–rubella (MMR) vaccination. The postulated mechanism was a persistent measles virus infection resulting in damage to the intestinal lining, increased permeability, and absorption of toxic peptides that caused central nervous system dysfunction and behavioral regression. Recent studies do not support this hypothesis, however. Taylor and colleagues (1999, 2002) identified 498 children with autism, born since 1979, and linked clinical records to independently recorded immunization data. No evidence of a change in trend in incidence or age at diagnosis was associated with the introduction of the MMR vaccine in 1988. Other recent studies that have examined large cohorts of children born in Japan and Denmark failed to find any increase in vaccinated relative to unvaccinated children, and any temporal clustering of autism cases after immunization (Honda, Shimizu, & Rutter, 2005; Madsen et al., 2002).

A related hypothesis about environmental risks for autism concerns mercury exposure, through either environmental exposures or thimerosal, an ethyl-mercury-based preservative included in some vaccines to prevent bacterial contamination. MMR, polio, and varicella vaccines have never contained thimerosal, but it was included in other, multiple-use vaccines since the 1930s. Concerns have been raised recently that the cumulative exposure to ethyl-mercury, via thimerosal, is far greater now than in the past, due to the increased number of vaccines given to children before age 2. This controversial theory has provoked strong reactions on both sides, but current scientific evidence does not clearly support a link between autism and thimerosal exposure (Madsen et al., 2003).

Several decades of research have demonstrated conclusively that the brains of people with autism are both structurally and functionally different from normal. Kanner’s original description (1943) noted unusually large head size in a proportion of children, and macrocephaly (head circumference > 97th percentile) has been confirmed in approximately 20% of individuals with autism (Fombonne, Roge, Claverie, Courty, & Fremolle, 1999; Lainhart et al., 1997). The increase in head volume reflects an increase in brain volume, which is not apparent at birth but is present by the first birthday (Courchesne, Carper, & Akshoomoff, 2003) and is hypothesized to be due to both

overgrowth and the failure of normal pruning mechanisms (Piven et al., 1996). Recent studies have suggested that excessive growth may be followed by a period of abnormally slow or arrested growth later in childhood (Courchesne, 2004), although not all studies support this conclusion.

Aside from macrocephaly, structural neuroimaging studies have yielded inconsistent results, possibly stemming from methodological issues: small samples, inappropriate or no control groups, and inconsistent use of covariates, such as gender, IQ, and total brain volume, in statistical analyses. Studies have demonstrated decreased volume of the cerebellar vermis, particularly lobules VI and VII (Courchesne, Yeung-Courchesne, Press, Hesselink, & Jernigan, 1988), but this finding has not always been replicated by other research teams (Hardan, Minshew, Harenski, & Keshavan, 2001; Piven, Bailey, Ranson, & Arndt, 1997). Bauman and Kemper (1985, 1988) published seminal findings of normal volume but smaller neuron size and increased cell density in the amygdala and several other brain regions of autopsied brains of people with autism. More studies have found abnormalities of amygdala volume, including both increased (Howard et al., 2000; Sparks et al., 2002) and decreased size (Abell et al., 1999; Aylward et al., 1999; Pierce, Mueller, Ambrose, Allen, & Courchesne, 2001). More recently, Schumann and colleagues (2004) reported that group differences in amygdala volume may be related to age. They found larger volume in children under age 12.5 years with autism than in controls, but no difference in amygdala volume between adolescents over age 12.5 with autism and typical controls.

Structural magnetic resonance imaging (MRI) results are variable across studies and do not point to any signature abnormality characteristic of ASD. Because regional volumetric changes do not directly measure brain function, they are not the most sensitive index of the brain-level mechanisms operative in ASD. Functional brain imaging studies have more consistently demonstrated differences in samples of children with autism. In activation studies that examine brain regions used during performance of specific tasks, several research groups have found that individuals with autism show reduced or different patterns of brain activity than do controls. In one study in which participants had to identify facial expressions

of emotion, those with autism activated the fusiform gyrus (part of the temporal lobes), the left amygdala, and the left cerebellum significantly less than did controls (Critchley et al., 2000). Other researchers have found reduced or absent activation of similar brain regions in children with autism during social reasoning tasks (Baron-Cohen et al., 1999; Schultz et al., 2000).

In summary, it is now abundantly clear that early psychogenic theories of etiology have no merit and that ASDs have biological underpinnings. There is ample evidence that the disorder is genetically influenced and that the brain is both structurally and functionally different, but specific causes (e.g., particular genes or brain defects) are not yet clear, and there is likely to be substantial etiological heterogeneity among affected individuals. In the remainder of the chapter, we examine concepts and methods relevant to the evaluation of individuals with ASD.

ASSESSMENT OF ASDs

Specific practice parameters for the assessment of ASD have been published by the American Academy of Neurology (Filipek et al., 2000), the American Academy of Child and Adolescent Psychiatry (Volkmar, Cook, Pomeroy, Realmuto, & Tanguay, 1999), and a consensus panel with representation from multiple professional societies (Filipek et al., 1999). These practice parameters describe two levels of screening/evaluation. Level 1 screening involves routine developmental surveillance by providers of general services for young children, such as pediatricians. Level 2 evaluation involves a comprehensive diagnostic assessment by experienced clinicians for children who fail the initial screening (Filipek et al., 1999, 2000; Volkmar et al., 1999). These publications have been significant milestones in the field of autism, because they provide, for the first time, consensus guidelines for ASD assessment. We cover Level 2 evaluation in this chapter.

Special Issues in Assessment of ASDs

Several important considerations should inform the assessment process. First, a developmental perspective must be maintained (Burack, Iarocci, Bowler, & Mottron, 2002). Autism is a lifelong disorder. It is first diag-

nosed in early childhood and continues to be apparent throughout a person's life. It is characterized by unevenness in development that differs over the lifespan of the individual. Studying a child within a developmental framework provides a benchmark for understanding the severity and quality of delays and/or deficits. Delays in one developmental achievement can significantly impact the acquisition of later developmental milestones, such as when early levels of joint attention (i.e., focus on an object shared with another person) predict later language acquisition (Mundy, Sigman, & Kasari, 1990) and theory of mind abilities (Baron-Cohen, 1991). Autism symptoms are usually at their worst in preschool and may substantially improve over time. Children who have very poor eye contact and make few social initiations at this age may have quite different social symptoms when they are teenagers. They may be somewhat more interested in social engagement by this later stage and may have acquired some more advanced social skills. Their social difficulties may now be manifest as awkwardness or inappropriateness rather than the lack of interest seen in young childhood. Thus, the form and quality of symptoms change with age. There are also characteristic patterns of delays in ASD that differ across domain and developmental levels. For example, a child with autism may have meaningful expressive language, a large vocabulary, and adequate syntactic abilities but not be able to participate in a conversation or even adequately answer questions.

A second important consideration is that the evaluation of a child with ASD should include information from multiple sources and contexts, because symptoms of ASD may be dependent on characteristics of the environment. For example, children with HFA and Asperger syndrome may present as charming, precocious, and highly intelligent when provided with one-on-one attention and conversational scaffolding from a well-meaning adult professional. The same child may look much more symptomatic with peers on a playground or in a distracting classroom situation, where individual adult attention is unavailable. Conversely, children with severe learning and behavioral deficits may seem much more competent in a known environment, such as the classroom, than in an evaluation room without familiar, well-practiced routines. Thus, parent and teacher reports; child observation across settings; cognitive and adaptive behavior as-

assessments; and clinical judgments may all be part of the most comprehensive ASD assessment (Filipek et al., 1999).

Third, it is recommended that assessments of ASD be multidisciplinary whenever possible, including professionals from psychology, speech–language pathology, and medical specialties as needed (e.g., pediatrics, psychiatry, neurology). On interdisciplinary teams, it is important that one member act as the evaluation coordinator. The person in this role communicates with parents and referring professionals before the evaluation to understand the referral questions, organizes appropriate team members, plans the components of the assessment, establishes contact with the service providers in the community who will implement the recommendations from the evaluation, and perhaps monitors later treatment. This type of coordination is critical for the successful outcome of an evaluation.

Common Referral Questions

As one might expect, the types of concerns that prompt clinical referrals depend on both the age and cognitive abilities of the child. Concerns about language development in toddlers constitute the most common reason for referral (DeGiacomo & Fombonne, 1998). Parental concerns about a toddler’s hearing and lack of response to his or her name or verbal commands are also frequent reasons for referral for assessment of ASD. In school-age children, the most frequent reasons for referral revolve around unexpected academic and social problems.

Children with ASD frequently present with academic underperformance. Although some of them may be quite bright, their cognitive profiles are usually uneven (Stewart, 2002). They tend to have spared rote memory, mechanical, and visual–spatial processes and deficient higher-order conceptual processes such as abstract reasoning (Minshew, Goldstein, & Siegel, 1997). Children with ASD who have average cognitive ability may do well in early elementary grades, when success relies largely on vocabulary, reading decoding, simple reading comprehension, and rote memorization. Some children, especially those who possess a great deal of knowledge about specific topics and who display adult-like language with advanced vocabulary, may be perceived as intellectually gifted; only some of these children will actually perform in the superior range of intelligence on

an IQ test, however. When abstract reasoning becomes a more important part of academic work (approximately in fourth grade), children with ASD exhibit greater than anticipated problems with reading comprehension, understanding the “gist” of written and verbally presented material, math concepts that rely on abstract principles, and organizational skills. At this juncture, their academic performance decline may confuse parents and teachers. The children may present with internalizing or externalizing problems symptomatic of stress due to increased academic challenges (Goodlin-Jones & Solomon, 2003). Referral to a psychologist or neuropsychologist can help to illuminate the exact nature of the child’s strengths and weaknesses, and assist those working with the child to adjust their expectations and the academic program accordingly. Suggestions for educational accommodations and other considerations related to school environments may be found in Ozonoff, Dawson, and McPartland (2002).

Impairments in reciprocal social interaction are among the defining features of ASD; thus, social issues and peer problems comprise another common set of presenting problems. Everyday social interactions that require “give and take” (i.e., maintaining friendships, solving social problems, responding to others empathically, and having mutually enjoyable conversations) are challenging for children with ASD. As discussed earlier in the section “Behavioral Problems,” these children also may have difficulty managing frustration and anger, creating additional obstacles to interpersonal relationships.

A third type of referral question revolves around differential diagnosis. As discussed earlier, there is both overlap between the symptoms of ASD and the symptoms of other conditions (e.g., social withdrawal that is a part of autism, some anxiety disorders, and schizophrenia), and comorbidity between ASD and other psychiatric disorders. Thus, referral questions are sometimes explicitly related to differential diagnosis (e.g., Is it ASD or ADHD or both?), whereas at other times, the need to distinguish conditions is inherent in the referral (e.g., What is the appropriate diagnosis for this child?). Differential diagnosis within the autism spectrum is another common referral question (Is it HFA or Asperger syndrome?).

Another reason for referral is to determine appropriate treatments given a child’s unique combination of strengths and weaknesses, both

for symptoms of autism and for the associated problems that often co-occur, such as eating, sleeping, behavior, and discipline problems. Related to this is the referral to evaluate progress and response to treatment.

In the sections below, we discuss assessment approaches that address these common referral questions. First, we describe the components of a “core” assessment battery necessary for almost any referral concern (diagnosis, treatment planning, annual or other regularly scheduled assessment, evaluation of treatment progress, program admission or discharge, eligibility for entitlements, etc.). Then we discuss other domains that might be part of a more comprehensive assessment and/or necessary for a particular individual, depending on the referral question and/or evaluation goals.

A Core Autism Assessment Battery

The first step of the core assessment process is to review with parents the child’s early developmental history and their current concerns. The critical aspects of this history taking are reviews of communication, social, and behavioral development; additionally, brief screening of potential medical and psychiatric issues, such as anxiety and depression, should be conducted at this stage to determine the need for more detailed evaluation (possibly including referral to specialists). A review of available records (e.g., medical, school, previous testing, intervention reports) rounds out the history-taking aspect of the evaluation. Combined with this review is direct observation of and interaction with the child. Whenever feasible, teachers should be consulted to provide their observations about the child’s functioning in the less structured, socially challenging school setting.

Autism Diagnostic Measurement

There is general agreement in North America and Europe on the primary characteristics of autism, as evidenced by close overlap of the diagnostic criteria laid out in DSM-IV-TR and the 10th edition of the International Classification of Diseases (ICD-10) (Sponheim, 1996). All professional practice parameters state the necessity of collecting data from both parents (i.e., interviews) and the child (i.e., observation and direct testing; Filipek et al., 1999, 2000; Volkmar et al., 1999), ideally using the types of standardized instruments we review below. In the relatively short observation of the child that

is feasible in most clinical settings, the full range of difficulties he or she experiences will likely not be evident, so parent report is vital. Parents, however, do not have the professional expertise and experience to recognize or interpret all difficulties, so observation and testing by informed practitioners in a controlled setting are also necessary. The information gained from these sources can then be integrated into a diagnosis. We describe the parent report, then the direct assessment tools available for use in the diagnosis of ASD.

Clinical impression, oral traditions, and subjective observations dominated the assessment process of ASD until fairly recently (Klinger & Renner, 2000). Use of standard diagnostic criteria, and recognition and interpretation of symptoms differed across settings (university clinics, private practice settings, research projects). The publication of two standardized assessment tools—the parent interview, Autism Diagnostic Interview—Revised (Lord, Rutter, & LeCouteur, 1994; Rutter, LeCouteur, & Lord, 2003) and the performance-based Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000)—have ended many of these disparities and are currently considered “gold standards” for diagnosis of ASD. Use of these and other tools described below has advanced scientific progress and improved the accuracy and reliability of diagnostic assessment (Filipek et al., 1999).

PARENT INTERVIEWS AND QUESTIONNAIRES

The Autism Diagnostic Interview—Revised (ADI-R; Lord et al., 1994; Rutter et al., 2003) is a comprehensive parent interview that probes for symptoms of autism. It is administered by a trained clinician using a semi-structured interview format. The “long” version of the ADI-R requires approximately 3 hours for administration and scoring, and is used primarily for research purposes. A short form of the ADI-R, which includes only the items on the diagnostic algorithm, may be used for clinical assessment and takes less time, approximately 90 minutes (Lord et al., 1994). The use of the ADI-R for research purposes requires attending a 3-day training seminar by a certified trainer and completion of reliability testing with the developers of the instrument. Training to use the ADI-R as a clinical tool is also available; it is helpful, but not required, for routine use by practitioners who do not participate in research protocols.

The ADI-R elicits information from the parent on current behavior and developmental history. It is closely linked to the diagnostic criteria set forth in the DSM-IV-TR and ICD-10. The significant developmental time point on the ADI-R is age 4 to 5 years for most behaviors. The rationale for the focus on this age period is that children are old enough to provide an adequate range of behavior but young enough not to have undergone major changes that may occur with age (Lord et al., 1994). The items that empirically distinguish between children with autism and those with other developmental delays are summed into three algorithm scores measuring social difficulties, communication deficits, and repetitive behaviors. The algorithm scores discriminate well between autism and other developmental disorders, such as severe receptive language disorders (Mildenberger, Sitter, Noterdaeme, & Amorosa, 2001) and general developmental delays (Cox et al., 1999; Lord et al., 1994). There are no thresholds yet established for other autism spectrum disorders (e.g., Asperger syndrome or PDD NOS).

The ADI-R is a very helpful tool, but it does have some limitations. Because it is not sensitive to differences among children with mental ages below 20 months or IQs below 20 (Cox et al., 1999; Lord, 1995), it is not advised for use with such children. Its sensitivity to the milder ASDs in children (Asperger syndrome and PDD NOS) is low early in the preschool period (McConachie et al., 2005) but improves by age 4. It is not designed to assess change through repeated administrations and is best suited to confirm the initial diagnosis of autism (Arnold et al., 2000). Finally, and perhaps most importantly, it is labor intensive and requires more administration time than most practitioners can spend. The Social Communication Questionnaire (SCQ, formerly known as the Autism Screening Questionnaire or ASQ; Berument, Rutter, Lord, Pickles, & Bailey, 1999; Rutter, Bailey, & Lord, 2003) is a short parent report questionnaire based on the ADI-R. It contains the same questions included on the ADI-R algorithm, presented in a briefer, yes–no format that parents can complete on their own in 10 minutes or less. Its agreement with the more labor-intensive ADI-R on diagnostic categorization is high (Bishop & Norbury, 2002); thus, it is an efficient way to obtain information from parents about autism symptoms. Two versions are available—one for current behavior and the other for lifetime behavior. The life-

time version is recommended for diagnostic purposes, whereas the current version is more appropriate for assessment of change over time in an individual. A cutoff score of 15 differentiates between ASD and other diagnoses for children age 4 years and older, whereas a cutoff of 22 discriminates between children with autistic disorder and those with other ASDs (PDD NOS or Asperger syndrome). Using these cutoffs, sensitivity of .85 and specificity of .75 have been reported in a large sample of children and adults with autism and other developmental disorders (Berument et al., 1999). In summary, this measure, which has excellent psychometric properties, is useful for treatment monitoring, is feasible for use in general clinical settings, and is highly recommended.

The Autism Behavior Checklist (ABC; Krug, Arick, & Almond, 1988), an informant report questionnaire, was once widely used in both clinics and schools, but is based on conceptualizations of ASD that are no longer current (e.g., emphasizing sensory dysfunction and motor stereotypies). Several studies have demonstrated that the rate of both false positives and false negatives produced by the ABC is quite high and that most children with HFA or Asperger syndrome are not identified by the cutoff of 67 (Sevin, Matson, Coe, Fee, & Sevin, 1991; Sponheim & Spurkland, 1996; Volkmar et al., 1988; Wadden, Bryson, & Rodger, 1991). Therefore, it is not recommended for use.

The Modified Checklist for Autism in Toddlers (M-CHAT; Dumont-Mathieu & Fein, 2005; Robins, Fein, Barton, & Green, 2001) is a 23-item parent checklist designed to be used at well-baby 24-month visits to screen quickly for symptoms of autism. There are six critical items on the M-CHAT (pointing, following a point, response to name, showing, interest in other children, imitation); any child who fails two or more requires a more comprehensive evaluation. The sensitivity (.87) and specificity (.99) of this instrument are quite impressive, but the original population-based sample has not been followed long enough to gauge the false-negative rate. As discussed in a later section, the M-CHAT's predecessor, the CHAT, appeared to be an excellent screening measure in initial studies with short follow-up periods, only to demonstrate a high rate of failed identification once the population was rescreened in middle childhood. Thus, it is not yet possible to evaluate fully the utility of this measure. In particular, low scores that are not consistent with

parent concerns or clinical judgment may represent false negatives. Therefore, this instrument should not be used as the sole measure of parent report about autism symptoms.

The Gilliam Autism Rating Scale (GARS; Gilliam, 1995), another informant-report instrument that has rapidly come into wide use in schools and diagnostic clinics, is appropriate for rating the behavior of children and young adults ages 3–22 years. It consists of four subscales measuring Social Interaction, Communication, Stereotyped Behaviors, and Developmental Disturbances. Ratings made on a 4-point scale are summed and converted to standard scores based on the reference sample (but not broken down by age or gender). The primary score of interest is the Autism Quotient, which is intended to measure “the likelihood that a child has autism” (Gilliam, 1995). Reference data are from over 1,000 North American children with informant-reported (but not verified) diagnoses of autism. Enthusiasm for the GARS stems from its ease of use, its recent norms, and its explicit relationship to DSM-IV-TR symptoms. However, the only two reports of the psychometric properties of the GARS both raise significant questions about its utility. In a sample of children with autism, verified by ADI-R, ADOS, and expert clinical consensus, over half were rated as having below average or very low likelihood of autism by the GARS in one study (sensitivity of .48; South et al., 2002). This high false-negative rate was replicated in the second study (Lecavalier, 2005) and is seriously troubling, because it may result in many missed diagnoses when used by practitioners with little ASD expertise. Therefore, the GARS, in its current form, is not recommended for routine clinical use.

The Parent Interview for Autism (PIA; Stone, Coonrod, Pozdol, & Turner, 2003) is an instrument developed specifically for the purpose of measuring change in autistic symptomatology over time. It is appropriate for preschool children ages 2–6. It has good internal consistency and is able to differentiate between autism and nonautism developmental delays (Stone et al., 2003). Change in PIA scores after 2 years of intervention correlated highly with clinical ratings of behavioral and diagnostic improvement (Stone et al., 2003). Another informant report instrument developed to measure behavioral change in response to treatment is the PDD Behavior Inventory (Cohen & Sudhalter, 2005). Norms exist for children ages 1.5

12.5 years. The questionnaire covers both autism symptoms and adaptive and maladaptive behaviors that might be altered by treatment. It demonstrates a high degree of internal consistency, provides adequate test–retest reliability (Cohen, Schmidt-Lackner, Romanczyk, & Sudhalter, 2003), and correlates highly with both the ADI-R and the Childhood Autism Rating Scale (CARS; Cohen, 2003). These measures appear both feasible and useful for practitioners who wish to track the progress of patients enrolled in treatment programs.

ASPERGER SYNDROME DIAGNOSTIC TOOLS

The differential diagnosis of HFA and Asperger syndrome is both difficult and of questionable nosological validity (Miller & Ozonoff, 2000; Prior, 2000). While at one time it was proposed that individuals with Asperger syndrome differed from those with autism in several meaningful ways (Klin, Volkmar, Sparrow, Cicchetti, & Rourke, 1995; Ozonoff, Rogers, & Pennington, 1991), research has largely failed to confirm this, and most studies conclude that the two are more similar than different (Howlin, 2003). Differences, when present, are most distinct in early childhood (Ozonoff et al., 2000), and the two conditions appear to converge phenomenologically at older ages (Howlin, 2003; Starr, Szatmari, Bryson, & Zwaigenbaum, 2003). This conclusion has not yet been incorporated into clinical practice, however, and many clinicians are convinced that the two are distinct conditions.

Asperger syndrome was included for the first time in DSM-IV (APA, 1994). As described at the beginning of the chapter, Asperger syndrome is differentiated from autism in DSM-IV-TR primarily by age of onset of speech. Precedence is given to the diagnosis of autism, so if an individual meets criteria for both conditions, autistic disorder is the diagnosis that must be made. Prior to DSM-IV, clinical and research diagnoses were made according to a variety of different proposed criteria. Diagnostic assignment (HFA vs. Asperger syndrome) was highly dependent on which diagnostic criteria were used (Ghaziuddin, Tsai, & Ghaziuddin, 1992; Klin, Pauls, Schultz, & Volkmar, 2005), complicating significantly the interpretation of research conducted before DSM-IV. Despite the appeal of the standardized criteria for Asperger syndrome outlined in DSM-IV-TR, there has been dissatisfaction with it on several grounds,

particularly the narrowness of the criteria that lead to even Asperger's original cases meeting criteria for autism when applied rigorously (Miller & Ozonoff, 2000; see also Woodbury-Smith, Klin, & Volkmar, 2005 for a different perspective). In clinical practice, it appears that DSM-IV-TR criteria are often ignored, with Asperger syndrome used synonymously with autism without mental retardation or autism without language delay (Klin et al., 2005; Mayes, Calhoun, & Crites, 2001).

In recent years, several parent report measures have been developed to assist with the Asperger syndrome diagnosis, but all suffer from the current lack of consensus in the field about the definition and boundaries of the condition. As summarized recently in an excellent review by Campbell (2005), three commercially available instruments with published psychometric data have been developed to diagnose Asperger syndrome. The Gilliam Asperger Disorder Scale (GADS; Gilliam, 2001), a 32-item, informant report rating scale based on DSM-IV-TR criteria, is widely used in some settings, such as schools. It was standardized on a large, multicultural sample with unverified diagnoses of Asperger syndrome. Internal consistency reliability is somewhat lower than desirable standards. The Asperger Syndrome Diagnostic Scale (ASDS; Myles, Bock, & Simpson, 2001) is a 50-item, informant report rating scale appropriate for children and adolescents ages 5–18. The standardization sample recruited through mailings and conferences was not evaluated by the test authors for independent diagnostic verification. Reliability is below a .90 criterion for internal consistency considered by Campbell (2005) to be adequate (see also Goldstein, 2002). The *Krug Asperger's Disorder Index* (KADI; Krug & Arick, 2003), a 32-item rating scale, can be completed by anyone in daily contact with the individual being rated. Two forms, an elementary and a secondary version, are available and may be used for individuals from ages 6–21. The KADI has the strongest psychometric properties of the published Asperger syndrome measures. However, as with the GADS and ASDS, the diagnoses of individuals in the standardization sample were not confirmed by the test developers.

As Campbell (2005) states succinctly, "Any instrument that claims to diagnose [Asperger syndrome] must be able to discriminate between [Asperger syndrome] and HFA, given the considerable overlap of diagnostic features"

(p. 34). However, none of the three commercially available measures verified the Asperger syndrome diagnoses of individuals in the standardization sample, examined classification accuracy in samples with HFA, or examined directly the ability to differentiate between the two conditions. Thus, these measures should never be used for differential diagnosis of Asperger syndrome versus HFA. In summary, at the time this volume went to press, no parent report measures alone should be used to diagnose Asperger syndrome. The best the field currently has to offer is measures, such as the SCQ, that can differentiate between ASDs as a group (e.g., Asperger syndrome, HFA, PDD NOS) and non-ASD conditions.

DIRECT TESTING AND OBSERVATIONAL DIAGNOSTIC INSTRUMENTS

In the ADOS (Lord et al., 2000; Lord, Rutter, DiLavore, & Risi, 2002), a semistructured interactive assessment of ASD symptoms, four different modules, graded according to language and developmental level, make possible administration to a wide range of patients, from very young children with no language to verbal, high-functioning adults. Most diagnostic observation instruments are hampered by the short time period of assessment. One cannot always be sure that a behavior is deficient after only an hour of observation, but this is often all the time a professional has with a patient. The ADOS minimizes this problem by including multiple opportunities or "presses" for social interaction and communication that elicit spontaneous behaviors in standardized contexts. There are, for example, a number of different activities and situations during administration of the ADOS that, in a typical child, consistently elicit eye contact. Once a child misses several chances to display this typical social behavior, a clinician can be reasonably certain that the behavior in question is difficult for the child being assessed. The algorithm for the ADOS includes only social and communication symptoms; because there are no "presses" for repetitive and stereotyped behaviors, their presence or absence cannot be reliably assessed. Two empirically defined cutoff scores, one for autistic disorder and the other for broader ASDs (e.g., PDD NOS or Asperger syndrome), are provided.

For children with younger mental and chronological ages, items from Modules 1 and 2 of

the ADOS assess social interest, joint attention, communicative behaviors, symbolic play, and atypical behaviors (e.g., excessive sensory interest, motor stereotypies). For older and more capable individuals, Modules 3 and 4 of the ADOS focus on conversational reciprocity, empathy, insight into social relationships, and special interests. Until recently, there was a gap in coverage of the ADOS for older, lower-functioning individuals. Specifically, the materials and activities of the first two modules, such as bubbles and dolls, may be appropriate for the mental age of older children, teens, and adults with severe-to-profound mental retardation, but were experienced by clinicians, parents, and sometimes even the individuals themselves as inappropriate for their chronological age. Recently, activities in ADOS Modules 1 and 2 have been adapted to make them more developmentally appropriate for older individuals (Berument et al., 2005). As with the ADI-R, use of the ADOS for research purposes requires attending a training workshop and establishing reliability with a certified trainer. Shorter clinical training available for clinicians not involved in research, like that for the ADI-R, is very helpful but not required for routine clinical use of the instrument.

Lord and colleagues (2000) published a study of the psychometric properties of the four modules of the ADOS. Excellent interrater reliability, internal consistency, and test-retest reliability were reported for each module. Diagnostic validity (sensitivity and specificity) for autism versus nonspectrum disorders was also excellent. The ADOS is used widely in empirical studies of autism and as an outcome measure in several treatment studies (e.g., Owley et al., 2001). In summary, the ADOS is highly recommended. It is considered a "gold standard" method of assessment in both research and clinical practice, and is feasible for use in typical clinical settings provided that appropriate training has taken place.

The Childhood Autism Rating Scale (CARS; Schopler, Reichler, & Renner, 1988), a 15-item structured observation instrument, is appropriate for children over 24 months of age. Items are scored on a 7-point scale (from *Typical* to *Severely deviant*) and summed into a composite score that ranges from 0 to 60. Scores above 30 are consistent with a diagnosis of autism, although slightly lower cutoffs have been recommended for adolescents (Garfin, McCallon, & Cox, 1988). Several studies report high internal

consistency, interrater and test-retest reliability, and criterion-related validity (DiLalla & Rogers, 1994; Eaves & Milner, 1993; Sevin et al., 1991), even when used by raters with little training on the measure or sophistication about ASD (Schopler et al., 1988). The CARS total score correlates highly with the ADI-R ($r = .81$; Saemundsen, Magnusson, Smari, & Sigurdardottir, 2003) but overidentifies autism relative to the ADI-R, occasionally classifying children with mental retardation as having autism (Lord, 1997; Saemundsen et al., 2003). It was developed as a tool to rate behavior observed during developmental evaluation, but it has also been adapted for use as a parent questionnaire (Tobing & Glenwick, 2002). The CARS is a frequently used measure (Luiselli et al., 2001), but it is based on pre-DSM-IV conceptualizations of autism (Van Bourgondien, Marcus, & Schopler, 1992) and does not measure some constructs now considered important to autism diagnosis and/or to have prognostic significance (e.g., joint attention). Therefore, it is not as highly recommended as the ADOS.

The Checklist for Autism in Toddlers (CHAT; Baron-Cohen, Allen, & Gillberg, 1992; Baron-Cohen et al., 1996, 2000) was developed for use in primary care settings to screen children for possible autism before their second birthday. There are two sections: a brief (nine-question) parent interview and a set of five items administered by a clinician to the child. It appears to work best for children who meet full criteria for autism and to be less sensitive to those with milder presentations. Although initially this instrument appeared very promising for use in general clinical settings, sensitivity was quite low (.38) when the initial screened population was followed to age 7 years, with a high false-negative rate (Baird et al., 2000). Thus, this instrument is not recommended for routine clinical use. It is currently undergoing revision by the authors.

The Screening Tool for Autism in Two-Year-Olds (STAT; Stone Coonrod, & Ousley, 2000) is an interactive measure for children between ages 24 and 36 months. Similar in purpose and scope to the ADOS Module 1 but slightly briefer to administer, the STAT consists of a 20-minute play session in which several different activities are presented to the child to assess symbolic play, reciprocal social behavior, joint attention, imitation, and communication. The STAT differentiates well between autism and

other forms of developmental delay. This promising instrument, because of its relatively recent development, is not yet used as routinely as the ADOS.

SUMMARY

Several measures are available to collect information from parents and directly assess children suspected of ASD, each with its own strengths and weaknesses. Few studies compare these instruments; thus, there are few em-

pirical data to guide clinicians in choosing among them. In many cases, practical constraints dictate choices. Table 10.2 lists all measures recommended for use, with information on dimensions such as format, administration time, training requirements, and applicable age ranges to assist examiners in choosing among them. One limitation of all diagnostic observational measures for autism is their reliance on current behavior. Deviancies and delays typical of autism are most apparent in early childhood and occasionally may be missed or not recog-

TABLE 10.2. Recommended Measures of a Core Assessment Battery for ASDs

Measure	Format	Age range ^a	Administration/ completion time	Training need ^b
<u>Autism diagnosis: Parent report</u>				
ADI-R	Interview	18 months–adult	1.5–3 hours	Intensive
SCQ	Questionnaire	4 years–adult	10 minutes	Minimal
M-CHAT	Questionnaire	18–30 months	10 minutes	Minimal
PIA	Questionnaire	2–6 years	20–30 minutes	Minimal
PDDBI	Questionnaire	1–17 years	10–15 minutes	Minimal
<u>Autism diagnosis: Direct observation</u>				
ADOS	Direct testing	2 years–adult	30–50 minutes	Intensive
CARS	Observation	2 years–adult	5–10 minutes	Moderate
<u>Intelligence</u>				
MSEL	Direct testing	Birth–68 months	15–60 minutes	Moderate
DAS	Direct testing	2.5–17 years	25–65 minutes	Moderate
WISC-IV	Direct testing	6–16 years	50–70 minutes	Moderate
Stanford–Binet V	Direct testing	2–85 years	45–75 minutes	Moderate
Leiter—Revised	Direct testing	2–20 years	25–90 minutes	Moderate
<u>Language</u>				
CELF	Direct testing	3–21 years	30–45 minutes	Moderate
PPVT	Direct testing	2.5–90+	10–15 minutes	Moderate
EOWPVT-2000	Direct testing	2–18 years	10–15 minutes	Moderate
TLC	Direct testing	5–18 years	< 60 minutes	Moderate
CCC	Questionnaire	5–17 years	10–15 minutes	Minimal
<u>Adaptive behavior</u>				
Vineland	Interview	Birth–18 years	20–60 minutes	Moderate

Note. ADI-R, Autism Diagnostic Interview—Revised; ADOS, Autism Diagnostic Observation Schedule; CARS, Childhood Autism Rating Scale; CCC, Children’s Communication Checklist; CELF, Clinical Evaluation of Language Fundamentals; DAS, Differential Abilities Scale; EOWPVT, Expressive One-Word Picture Vocabulary Test–2000; M-CHAT, Modified Checklist for Autism in Toddlers; MSEL, Mullen Scales of Early Learning; PDDBI, Pervasive Developmental Disorders Behavior Inventory; PIA, Parent Interview for Autism; PPVT, Peabody Picture Vocabulary Test; SCQ, Social Communication Questionnaire; TLC, Test of Language Competence; WISC-IV, Wechsler Intelligence Scale for Children, 4th edition.

^a Inclusive (e.g., 2–6 years = from 2 years, 0 months through 6 years, 11 months).

^b Minimal: little to no training required, but presumes familiarity with instrument; moderate: presumes prior basic interview/cognitive assessment training; intensive: additional specialized training, such as workshop attendance, suggested.

nized at an older age (Bolte & Poustka, 2000). In addition, some characteristics of ASD are low base-rate behaviors that are not always apparent during an observation or structured interaction with a practitioner. Thus, for diagnosis, it is critical both to observe the child directly and to obtain information from parents; we recommend choosing one measure of each type from the list in Table 10.2. On occasion, when these measures provide discordant information (de Bildt et al., 2004; Mildenerger et al., 2001), we recommend that further data be collected from teachers (see below) and other informants in an attempt to resolve the discrepancy.

Intellectual Assessment

A second important domain that must be part of the assessment is intellectual functioning. Intellectual assessment helps to frame the interpretation of many observations about the child. Level of intellectual functioning is associated with severity of autistic symptoms, ability to acquire skills, and level of adaptive function, and is one of the best predictors of outcome (Harris & Handleman, 2000; Lotter, 1974; Rutter, 1984; Stevens et al., 2000; Venter et al., 1992). Major goals of intellectual assessment include generating a profile of the child's cognitive strengths and weaknesses, facilitating educational planning, determining eligibility for certain IQ-related services (e.g., state-funded developmental disability services), and suggesting prognosis. Measured IQ is more stable and predictive the older the age of the child at assessment (Lord & Schopler, 1989). Scores can and do change with development and intervention (Freeman et al., 1991; Mayes & Calhoun, 2003a), and also as a function of the assessment instrument chosen (Magiati & Howlin, 2001).

The child suspected of having ASD often presents an assessment challenge due to social difficulties, unusual use of language, frequent off-task behaviors, high distractibility, and variable motivation. Motivation can have a tremendous influence on test results, and assessments that incorporate reinforcement procedures can result in very different test scores (Koegel, Koegel, & Smith, 1997). It is important to enhance motivation as much as possible, without altering the standard administration of the instrument, and to consider the motivational element when interpreting scores.

More frequent breaks may be needed, and testing may need to be conducted over multiple, shorter sessions. When experienced clinicians evaluate children with autism, few should be "untestable." Untestability reflects primarily lack of availability of appropriate tests or clinician inexperience. There are special concerns about the validity of testing younger, lower-functioning, and nonverbal children, and care must be taken in choosing appropriate tests. It is important that the test chosen (1) be appropriate for both the chronological *and* the mental age of the child, (2) provide a full range (in the lower direction) of standard scores, and (3) measure verbal and nonverbal skills separately (Filipek et al., 1999).

There are several commonly used tests for children with lower mental ages (e.g., those who are younger, nonverbal, and/or who have moderate to severe mental retardation). The Leiter International Performance Scales—Revised (Roid & Miller, 1997; Tsatsanis et al., 2003) is appropriate for individuals with a mental age of 2 years or higher and requires no expressive or receptive language skills. The Differential Abilities Scales (DAS; Elliott, 1990), which assess both intellectual and academic skills, have grown in popularity and use, and may be administered to children across a wide chronological and mental age range (2.5–17 years), making these scales ideal for repeat administrations, for tracking progress, and for research projects in which the developmental range of participants may vary considerably. Especially helpful for the ASD population is the option of out-of-range testing (i.e., administration of tests usually given to children of a different age): Norms for school-age children are available for the preschool battery, permitting use of the test with older children with significant intellectual limitations. For younger children (below age 5) or those with skills that fall below the entry levels of the tests just described, a few additional choices for assessment of intellectual functioning include the Bayley Scales of Infant Development—II (for ages 1–42 months—Bayley, 1993) and the Mullen Scales of Early Learning (MSEL; for ages 1–60 months—Mullen, 1995). For children suspected of having an ASD, the MSEL is often chosen over the Bayley due to its wider age range and five distinct scales that allow separate assessment of verbal and nonverbal abilities. The Bayley has a longer research tradition than the MSEL but yields less detailed infor-

mation, with one score averaging memory, problem-solving, communication, and other abilities. These instruments provide both standard scores and developmental age equivalents. Thus, they may be used to evaluate children who are older than the test norms but whose developmental skills are not high enough to administer more age-appropriate instruments.

For children capable of spoken language, the Wechsler Intelligence Scales for Children are the most widely used intellectual instruments. There are not yet any published studies of the most recent revision, the WISC-IV (Wechsler, 2003), but in studies of earlier editions (i.e., WISC-R, WISC-III), individuals with ASD often exhibit uneven subtest profiles. Performance IQ (PIQ) is often higher than Verbal IQ (VIQ; Lincoln, Allen, & Kilman, 1995), but the verbal–performance discrepancy is severity dependent, and the majority of individuals with ASD do not show a significant split (> 12 points; Siegel, Minshew, & Goldstein, 1996). When present, a $PIQ > VIQ$ pattern may have important implications for how the child learns best and what activities may be most and least enjoyable. One study suggests that children with significantly uneven intellectual development (in favor of nonverbal skills) are more socially impaired than those with similar overall intelligence but smaller or reversed nonverbal–verbal discrepancies (Joseph, Tager-Flusberg, & Lord, 2002). As a group, they also demonstrate larger head circumference and brain volume than children without large nonverbal $>$ verbal discrepancies (Tager-Flusberg & Joseph, 2003), suggesting potentially an etiologically distinct subtype of autism.

Children with Asperger syndrome may exhibit the opposite intellectual test profile, with VIQ significantly higher than PIQ (Klin et al., 1995), but this is by no means universal and has not been replicated in all studies (see Ozonoff & Griffith, 2000, for a review). Thus, intellectual test profiles should *never* be used for diagnostic confirmation or differential diagnosis of ASD subtypes (e.g., between Asperger syndrome and HFA). However, when a $VIQ > PIQ$ profile is evident, the child may prefer verbally based leisure activities, benefit from verbal explanations, and excel in subjects that require good verbal processing (Klin et al., 1995), unlike a child with the opposite ($PIQ > VIQ$) intellectual profile.

There are fewer published studies of the Stanford–Binet Intelligence Scale with children

with ASD, but they suggest similar patterns (e.g., $PIQ > VIQ$, particularly in young children; Mayes & Calhoun, 2003b). One benefit of the Stanford–Binet is the very wide age range of individuals for whom it is appropriate (2–85 years). The standardization study of the revised fifth edition (Roid, 2003) included 108 children with autism in the normative sample and added entry items, improving measurement of young children, lower-functioning older children, and adults with mental retardation. It is appropriate for both verbal and nonverbal individuals, because half the subtests utilize a nonverbal mode of testing. The Stanford–Binet V may be a good choice when examiners must select an instrument before knowing a child’s abilities, or when planning a longitudinal assessment.

Short forms of intelligence tests are often used in clinical settings, because they reduce both the economic burden of assessment for families and the stress of testing for the individual. Because autism involves significant behavioral disturbances that might limit compliance during testing, short forms are especially appealing for this group. A recent study demonstrated that short forms of intelligence tests provide very good estimates of IQ for individuals with autism (Minshew, Turner, & Goldstein, 2005). Prediction accuracy was high for both high-functioning individuals and those with significant levels of mental retardation. Even when there was significant intersubtest variability and the subtest profile was atypical relative to individuals without autism, short forms provided excellent estimates of IQ. Administration of full intelligence scales is recommended for initial assessment, particularly when placement decisions or treatment plans are being formulated, but short forms appear useful for purposes such as educational reassessment, research, or assessment with significant time constraints.

Language Assessment

Expressive language level, along with IQ, is the other best predictor of long-term outcome, so it is another important characteristic to measure (Lotter, 1974; Rutter, 1984; Stone & Yoder, 2001). A variety of general instruments, such as the third edition of the Peabody Picture Vocabulary Test (PPVT-III; Dunn & Dunn, 1997), the Expressive One-Word Picture Vocabulary Test–2000 (EOWPVT-2000; Brownell, 2000),

the fourth edition of the Clinical Evaluation of Language Fundamentals (CELF-4; Semel, Wiig, & Secord, 2003), and the fourth edition of the Preschool Language Scales (PLS-4; Zimmerman, Steiner, & Pond, 2002), have been used to measure receptive and expressive language abilities in children with ASD, but referral for a more comprehensive evaluation by a speech-language pathologist, who can give detailed language recommendations, is also often helpful (Filipek et al., 1999). Children with adequate spoken language who score in the average range on these tests may still exhibit deficits in the use of language in a social context. Pragmatic communication includes non-verbal behaviors (e.g., eye contact, gestures, facial expression, “body language”), turn taking, and understanding of inferences and figurative expressions. Tests that examine pragmatic language include the Test of Language Competence (TLC; Wiig & Secord, 1989) and the Children’s Communication Checklist (CCC; Bishop & Baird, 2001).

Adaptive Behavior Assessment

This domain comprises the final component of the core autism assessment. It is an essential component for three reasons. First, assessment of adaptive behavior should always accompany intellectual testing, because a diagnosis of mental retardation cannot be made unless functioning is compromised across both standardized tests of intelligence and measures of adaptive function and daily living. Second, measuring adaptive behavior is also important for setting appropriate treatment goals. Adaptive abilities largely determine whether an individual requires constant supervision or is capable of some independence. Finally, it is an important measure of outcome that has been used in many longitudinal and treatment studies (e.g., Freeman, Del’Homme, Guthrie, & Zhang, 1999; Szatmari, Bryson, Boyle, Streiner, & Duku, 2003). Children with autism consistently demonstrate lower adaptive behavior levels than their intelligence levels, and this pattern is most pronounced for individuals with HFA and Asperger syndrome and those with normal IQ (Bolte & Poustka, 2002).

The most widely used adaptive measure with children suspected of having an ASD (Luiselli et al., 2001) is the Vineland Adaptive Behavior Scales (Sparrow, Cicchetti, & Balla, 2006). Domains of functioning include communication,

daily living skills, socialization, and, for children under age 5, motor skills. The Vineland is completed during an interview with a parent or teacher and is appropriate for children up to age 19 and for mentally retarded adults (separate norms are provided for each population). In a recent study, the Vineland was moderately sensitive to changes due to developmental progress (Charman, Howlin, Berry, & Prince, 2004). The Vineland has just undergone restandardization and now includes supple- mental norms for children with ASD (Sparrow et al., 2006; see also Carter et al., 1998). There are no published studies that used other adaptive measures, such as the Scales of Independent Behavior—Revised (SIB-R; Bruininks, Woodcock, Weatherman, & Hill, 1996) or the second edition of the Adaptive Behavior Assessment System (ABAS-2; Harrison & Oakland, 2003), with individuals with ASD, but these may be reasonable choices when time is a constraint, because they are questionnaires completed by parents, rather than interviews, and require little or no training to score and interpret.

Additional Domains of Assessment: Beyond the Core Battery

Depending on the referral question(s), goals of the assessment, and practical constraints such as finances, insurance reimbursements, and waiting lists, a more comprehensive evaluation might include a number of additional components.

Neuropsychological Assessment

The neuropsychology of ASD has been studied extensively. As reviewed earlier, children with ASD often exhibit spared rote, mechanical, and visual-spatial processes, and deficient higher-order processes, such as organization, reasoning, and interpretation (Minshew et al., 1997). They often perform acceptably on simple language, memory, and perspective-taking tasks but show deficits when tasks become more complex. Data from neuropsychological testing may be able to provide greater clarity about the individual’s profile of strengths and weaknesses, an important foundation for treatment and educational planning. However, neuropsychological testing is costly and time-consuming, and its use may be impacted by managed care concerns (Piotrowski, 1999).

The decision to carry out neuropsychological assessment, the choice of domains to evaluate, and the selection of instruments should be done thoughtfully and emphasize instruments with the most relevance for educational and treatment plans (Groth-Marnat, 1999; Klin & Shepard, 1994; Ozonoff, Dawson, et al., 2002). Space issues preclude a comprehensive review of all domains of neuropsychology; below, we discuss three areas of particular interest with this population. Neuropsychological assessment is not usually useful (or even possible) with nonverbal and/or mentally retarded children with ASD. It may be warranted for higher-functioning individuals when there are unexplained discrepancies or weaknesses in school performance, behavioral difficulties that appear to stem from undiagnosed learning disorders, and suspected organic problems. For example, neuropsychological assessment of children with unexpected school failure or behavioral issues at school may reveal attention, flexibility, or organization problems that cause frustration, anxiety, or disorganization, and significantly interfere with school function.

ATTENTION

Children with ASDs do not usually have problems with sustained attention (Garretson, Fein, & Waterhouse, 1990). They do, however, have difficulty with focused attention. In particular, they tend to overfocus their attention on extraneous details, while missing meaning, a difficulty that has also been called “impaired central coherence” (Frith & Happé, 1994). Some children with ASD do exhibit classic ADHD symptoms of distractibility and hyperactivity, as discussed earlier (Noterdaeme, Amorosa, Mildnerberger, Sitter, & Minow, 2001; Perry, 1998). For these children, a traditional ADHD workup is indicated (see Smith, Barkley, & Shapiro, Chapter 2, this volume). Along with parent and teacher ratings of attention problems, measures such as continuous performance tests may be helpful in examining treatment response in such children (Aman et al., 2004) but should never be the sole basis for determining medication response.

EXECUTIVE FUNCTION

One of the most consistently replicated cognitive deficits in individuals with ASD is executive dysfunction (Pennington & Ozonoff,

1996; Russell, 1997). The executive function domain includes the many skills required to prepare for and execute complex behavior, such as planning, inhibition, organization, self-monitoring, cognitive flexibility, and set shifting. Because executive functions are important to school success (Clark, Prior, & Kinsella, 2002), predict response to treatment (Berger, Aerts, van Spaendonck, Cools, & Teunisse, 2003) and long-term outcome (Szatmari, Bartolucci, Bremner, Bond, & Rich, 1989), and are associated with “real-world” adaptive skills (Clark et al., 2002; Gilotty, Kenworthy, Sirian, Black, & Wagner, 2002), they are important skills to measure.

The “gold standard” executive function task, the Wisconsin Card Sorting Test (WCST; Grant & Berg, 1948; Heaton, Chelune, Talley, Kay, & Curtiss, 1993), measures cognitive flexibility and set shifting. It is available in both an examiner- and a computer-administered version. Individuals with ASD often perform better on the computer-administered version of the test (Ozonoff, 1995). If this executive function test is being given to document deficits for the purposes of treatment eligibility, it may therefore be best to use the examiner-administration format. If, however, the examiner wants to evaluate achievement under supportive conditions or to see how well the child is potentially capable of performing, then the computer-administration format may be preferable (Ozonoff, South, & Provencal, 2005). Computer administration is also more time- and cost-efficient, so when evaluators face such practical constraints, as they often do (Groth-Marnat, 1999), it may be an acceptable choice.

The Delis–Kaplan Executive Function System (D-KEFS; Delis, Kaplan, & Kramer, 2001) provides a battery of tests that assess cognitive flexibility, concept formation, planning, impulse control, and inhibition in children and adults. The D-KEFS was standardized on a sample of over 1,700 children and adults ages 8–89. Most of its nine subtests are adaptations of traditional research measures of executive function that have been refined to examine skills more precisely, with fewer confounding variables. Subtests include Trail Making, Verbal Fluency, Design Fluency, Color–Word Interference (similar to a Stroop test), Sorting (similar to the WCST), Twenty Questions, Tower (similar to the Towers of Hanoi or London), Word Context, and Proverbs. The only published study in which this instrument was

used with children with ASD (Lopez, Lincoln, Ozonoff, & Lai, 2005) demonstrates the familiar pattern of deficits (e.g., deficits in cognitive flexibility and planning, with intact inhibitory processes). The NEPSY (Korkman, Kirk, & Kemp, 1998) is a test like the D-KEFS that includes several measures of executive function, but it can be used with younger children (ages 3–12) and has been used successfully with children with autism (Joseph, McGrath, & Tager-Flusberg, 2005).

The Behavioral Rating Inventory of Executive Function (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000), a parent- or teacher-rated questionnaire for children ages 5–18 years, has 86 questions and takes about 10 minutes to complete. Clinical subscales measure Inhibition, Cognitive Flexibility, Organization, Planning, Metacognition, Emotional Control, and Initiation. Specific items tap everyday behaviors indicative of executive dysfunction that may not be captured by performance measures, such as organization of the school locker or the home closet, monitoring of homework for mistakes, or trouble initiating leisure activities. Thus, this measure may have more ecological validity than other executive function tests. It may be especially useful to document the impact of executive function deficits on the child's "real-world" function and to plan treatment and educational accommodations. Correlational analyses with other behavior rating scales and executive function tests provide evidence of both convergent and divergent validity (Gioia et al., 2000), and the BRIEF has been used empirically in samples with autism (Gilotty et al., 2002).

Assessment of Academic Functioning

Assessment of academic ability, even in younger children, is helpful for the purposes of educational decision making. It is often an area of strength that may go unrecognized. Many children with ASD have precocious reading skills and can decode words at a higher level than others of the same age and functional ability. Reading and other academic strengths may be used to compensate for weaknesses, such as when a written schedule is provided to facilitate transitions (Bryan & Gast, 2000) or written directions are supplied to improve compliance. The good memory of children with ASD may mean that they learn spelling lists and multiplication tables more easily (Mayes &

Calhoun, 2003a). Conversely, specific areas of weakness also exist, most consistently in reading comprehension. This academic profile is quite different from the problem patterns most teachers and school psychologists are trained to detect (e.g., the poor decoding but good comprehension seen in dyslexia). Thus, it is important to include appropriate test batteries that highlight both academic strengths and weaknesses in the comprehensive evaluation, to interpret the learning patterns they suggest in the feedback to parents and in the written report, and to make appropriate educational recommendations. For young children, the Bracken Basic Concepts Scale (Bracken, 1998), the Young Children's Achievement Test (YCAT; Hresko, Peak, Herron, & Bridges, 2000), and the Psychoeducational Profile—Revised (PEP-R; Schopler, Reichler, Bashford, Lansing, & Marcus, 1990) are useful instruments that highlight both the strengths and the challenges typical of ASD. For older children who are verbal, the most frequently used academic tests are the Woodcock–Johnson Tests of Achievement (Mather & Woodcock, 2001) and the Wechsler Individual Achievement Test (WIAT; Wechsler, 2002).

Some children with ASD may exhibit a so-called nonverbal learning disability profile (NLD; Rourke, 1995). Children with NLD have difficulties in tactile perception, psychomotor coordination, mathematic reasoning, visual–spatial organization, and nonverbal problem solving. They have well-developed rote verbal skills, as well as strong verbal memory and auditory linguistic capabilities. Some children with Asperger syndrome and HFA display an NLD profile (Klin et al., 1995). They may require additional interventions, such as occupational therapy and math tutoring. NLD is an academic diagnosis that does not take the place of the primary ASD diagnosis, which is a more complete description of the full range of the child's behavioral and developmental limitations.

Assessment of Psychiatric and Other Comorbidities

Over the course of development, children with ASD may exhibit symptoms and behaviors not directly attributable to their autism that disrupt their daily functioning. These include problems with sleep, appetite, mood, anxiety, activity level, anger management, aggression, tics, mood instability, psychosis, and/or thought dis-

order. Many factors influence the presentation of psychiatric disorders in individuals with ASD and complicate their assessment. The decrement in functioning associated with having an ASD means that baseline is already lower than average and that a change in behavior has to be relatively marked to be identifiable. Autism, by itself, causes a variety of psychosocial deficits and maladaptive behaviors, and their presence may “mask” other psychiatric symptoms or make them difficult to identify. Cognitive limitations may mean that the range and quality of symptoms differ or that presentation is atypical. For example, anxiety may be manifest as obsessive questioning or insistence on sameness rather than rumination or somatic complaints. Individuals with ASD may not demonstrate certain symptoms, such as the feelings of guilt often seen in depression, or the grandiosity and inflation of self-esteem typical of mania. The diminished ability to think abstractly, communicate effectively, and be aware of and describe internal states also means that interview and self-report measures are often of less use. People with autism may lack the self-insight to recognize symptoms, or the motivation and social relatedness needed to report them (Perry, Marston, Hinder, Munden, & Roy, 2001). Some behaviors, including complex motor mannerisms and self-injury, may be responses to potentially painful medical problems that the individual is unable to describe. These can include gastrointestinal issues (e.g., reflux, esophageal scarring, constipation); endocrine imbalances, such as those occurring with the onset of menstruation; and/or metabolic disorders (Bauman, 2005). When the clinician can find no reason for a problem, referral to a gastroenterologist or endocrinologist may be helpful. Thus, the assessment of coexisting psychiatric illness and behavioral problems can be quite tricky. Nevertheless, it is important to add to an evaluation whenever significant behavioral issues outside the autism spectrum (inattention, mood instability, anxiety, sleep disturbance, aggression, etc.) are evident or when major changes in behavior from the typical baseline are reported. Comorbidity should also be carefully investigated when severe or worsening symptoms do not respond to traditional methods of treatment (Lainhart, 1999).

As reviewed earlier, depression and anxiety disorders are the most common coexisting psychiatric problems observed in individuals with

ASD, particularly individuals with HFA and Asperger syndrome, who can describe their difficulties (Kim et al., 2000; Lainhart & Folstein, 1994; Muris, Steerneman, Merckelback, Holdrinet, & Meesters, 1998). Assessment of these problems is challenging, because no specific tools for the autism spectrum have been developed. The validity of existing inventories (e.g., the Children’s Depression Inventory [Kovacs, 1992] or the Multidimensional Anxiety Scale for Children [March, 1997]) is uncertain, because these are self-report measures. Given the limited self-insight of children with ASD, reports of “no problems” should be interpreted with caution, and careful interviews of parents should also be included in the assessment. No empirical studies of the use of these instruments with ASD have been performed.

The Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001) is widely used to identify child behavioral and mental health issues, but it has only rarely been used with children with ASD. It does not provide an autism factor, but a few studies have suggested that certain patterns, such as high scores on the Social Problems and Thought Problems subscales, may be associated with an ASD diagnosis (Bolte, Dickhut, & Poustka, 1999; Duarte, Bordin, de Oliveira, & Bird, 2003). The CBCL’s utility in identifying comorbid internalizing and externalizing problems in children with ASD is not yet known, but it may well be useful as a screening tool given its excellent psychometric properties.

Another measure for assessing several symptom profiles simultaneously, the Behavioral Assessment System for Children–2 (BASC-2), includes parent report, teacher report, and self-report questionnaires for children ages 8–18 years (Kamphaus, Reynolds, & Hatcher, 1999). There are subscales for Internalizing, Externalizing, and Adaptive Behaviors. Subscales assess school, clinical, and personal adjustment. The self-report form also measures Sense of Inadequacy and Sense of Atypicality, which in our experience are helpful for understanding the struggles of children with ASD who can validly report on their internal states (Ozonoff, Provençal, & Solomon, 2002), and these subscales may also prove helpful for measuring treatment effects in ASD. Importantly, each form provides caution indices to inform the clinician of overly positive or negative responses and to provide a measure of the consistency of the respondent’s profile.

Another multisymptom scale often used with ASD, the Aberrant Behavior Checklist (Aman, Singh, Stewart, & Field, 1985), is a global behavior checklist completed by a caregiver or teacher familiar with the child in different settings. It was initially designed as a scale for rating inappropriate and maladaptive behavior of individuals with mental retardation in residential settings. However, the scale has been used often to monitor the effects of a variety of pharmacological, behavioral, dietary, and other treatments that may be expected to alter behavior, and the instrument appears sensitive to change in ASD samples (Arnold et al., 2000). There are five subscales (Irritability, Lethargy, Stereotypy, Hyperactivity, and Inappropriate Speech). The published validity and reliability studies report excellent test-retest reliability, internal consistency, and construct validity (Aman et al., 1985).

Another method of assessing problem behaviors that often coexist with ASD, such as aggression, destructiveness, tantrums, stereotypies, or self-injury, is functional analysis (Horner, 1994; O'Neill, Horner, Albin, Sprague, & Storey, 1997). Such challenging behaviors are rarely random and usually serve a purpose. Functional analysis is a systematic approach to determine the function or communicative equivalent of the behavior. Some common functions of problem behaviors include gaining access to a desired object, asking for help or attention, escaping a situation (e.g., schoolwork), and expressing a sensation (e.g., hunger, illness), emotion, or state (e.g., confusion, frustration). The ultimate goal of functional analysis is to provide the child with a more appropriate means of expressing the message (also called "functional communication training"; Carr & Durand, 1985). Although the functions of a particular problem behavior may seem obvious, the perceptions of informants who work with the child may not be confirmed through direct observations and analogue probes that replicate the environmental antecedents of the problem behavior (Calloway & Simpson, 1998). Thus, functional assessment may require referral of the child to a professional trained in these methods, such as a certified behavior analyst, who will also be able to assist in development of a behavioral support plan.

Upon collecting information about various potential comorbid conditions and associated problems, the clinician must finish the process

of case formulation by figuring out whether the child has an ASD only, another disorder, or both. The first step is to determine whether the child meets criteria for an ASD. The clinician examines information collected from parents and direct testing, and determines whether cut-offs or thresholds for ASD have been exceeded. Although this sounds deceptively simple, the instruments reviewed in this chapter have very good reliability and validity when used by trained personnel, and the diagnosis may be straightforward in many cases. More difficult is evaluating children who present with subclinical symptoms or behaviors that may be part of multiple conditions (e.g., the poor eye contact that might be seen in both autism and depression). Again, however, the answer is relatively simple. Children with depression alone do not exhibit the pervasive difficulties in social interaction, communication, and behavior that are characteristic of ASDs. If a child presents with both low mood and impaired peer relationships, lack of empathy, few gestures, pedantic speech, echolalia, and unusual interests, he or she likely has both a depressive disorder and an ASD. The package of social and communication limitations, combined with odd or repetitive behaviors, should alert the clinician that an ASD must be part of the differential diagnosis. No other condition includes all of these difficulties. Then, if additional problems not encompassed by ASD criteria are present, such as low mood, tics, or anxiety, the clinician can examine diagnostic criteria for these conditions and determine whether comorbidity is present.

The School Context

Since the goal of assessment should be to understand how ASDs affect individuals in the course of daily life, when feasible, it is helpful to augment the evaluation by obtaining information from teachers or others who interact with the child in the challenging and relatively unstructured school setting (Klin et al., 2000). Teachers may be excellent sources of information about the child's adaptive, social, and emotional functioning outside of home and thereby enrich the clinician's understanding of the child. For example, in typically developing children, as well as those with ADHD, teacher reports of peer relationships correspond more closely to ratings completed by peers than to parent ratings (Glow & Glow, 1980; Hinshaw

& Melnick, 1995). Information from the school setting may be obtained through interviews, questionnaires, and direct clinician observations. Measures include the classroom/teacher editions of the Vineland Adaptive Behavior Scales (Sparrow et al., 2006), the PDD Behavior Inventory (Cohen et al., 2003), the BASC-2, and the Aberrant Behavior Checklist. Although not specifically designed for children on the autism spectrum, the teacher report form of the Social Skills Rating System (Gresham & Elliott, 1989) has been used successfully in research to assess social skills in children with ASDs (Bauminger, 2002). In addition to questionnaires, school-based observations may yield a richer perspective on child social functioning and/or may be part of a functional analysis of behavioral problems (e.g., Dunlap & Kern, 1993; Wood, 1995). In many clinical settings, the resources required to conduct a school visit are not available; thus, this should be considered an optional, albeit helpful, addition to a comprehensive evaluation.

When information on a child is from multiple sources, there may be disagreements in reports of the severity of the disorder, the level of daily adaptive behaviors, and the level of compliance or disruptive behaviors (Offord et al., 1996; Szatmari, Archer, Fisman, & Streiner, 1994). High levels of family stress appear to contribute to higher parent than teacher reports of autistic behavior (Szatmari et al., 1994). Because these well-known discrepancies exist and may well reflect setting-dependent expression of symptoms, our recommendation is to conceptualize them as separate types of information, without attempting to reconcile them by considering one more or less accurate than another, as suggested by Offord and colleagues (1996).

Assessment of Family Functioning

Assessment of the family system may also be important (Hauser-Kram, Warfield, Shonkoff, & Krauss, 2001). Many studies have documented increased stress and depression in parents of children with ASDs (Bristol, 1984; Wolf, Noh, Fisman, & Speechley, 1989) that exceed that of parents of children with other disabilities (Olsson & Hwang, 2001). Stress levels are strongly correlated with severity of the child's disorder (Tobing & Glenwick, 2002). Of the several instruments that measure the impact of a disabled child on the family,

those with established psychometric properties that have been used with the ASD population include the Parenting Stress Index (Abidin, 1995), the Questionnaire on Resources and Stress (Holroyd, 1974; Konstantareas, Homatidis, & Plowright, 1992), and the Stress Index for Parents of Adolescents (Sheras, Abidin, & Konold, 1998).

Evaluation of Response to Treatment

One of the most practical contributions of assessment is the planning and evaluation of intervention (Hayes, Nelson, & Jarrett, 1987). We have highlighted this purpose frequently in this chapter, evaluating certain domains and specific instruments in terms of their sensitivity to change. There are, however, no widely agreed-upon skills that must change, nor any degree of change, for treatment effects to be considered clinically significant. There is general consensus that intervention outcomes should have social validity, making a genuine (functional, noticeable) difference in everyday life for the person treated or those who live with him or her (Foster & Mash, 1999; Kazdin, 1999). There is less agreement on the magnitude of change that must be shown to be considered clinically significant. It is often measured as an effect size, a percentage decline in symptoms, a change from baseline (pretreatment), or an attainment of functioning within the normal range (Kendall, Marrs-Garcia, Nath, & Sheldrick, 1999). Kazdin (1999), however, argues that when change does not meet such criteria, it may nevertheless be meaningful if it helps the person become more functional, even if symptoms remain well outside the normal range. Even no change in symptoms at all may be significant, if the treatment improves coping skills and the ability to deal with symptoms. These examples are particularly relevant to ASD, a lifelong condition in which functioning within the normative range may be possible for only a small proportion of affected individuals. Change in quantity, quality, or severity of autistic behaviors may be minimal, and many treatment studies do not consider this domain the primary target of the therapy (Kasari, 2002). Many drug studies, for example, focus on change in aberrant behaviors, such as irritability and aggression, or other target symptoms that make life difficult for individuals and families (e.g., Arnold et al., 2000, 2003). Therefore, domains of central impor-

tance in the evaluation of response to treatment are adaptive behavior, comorbid symptoms, quality of life, and family functioning (Wolery & Garfinkle, 2002).

CONCLUSION

In this chapter, we have reviewed the components of a core assessment battery and a more comprehensive evaluation of suspected ASD. In choosing the components of these batteries, we focused on their utility and relevance to identification, differential diagnosis, service delivery, and treatment response. We focused on assessment strategies and tools with good psychometric properties that are also practical for use in clinical settings (Luiselli et al., 2001). Few studies have directly compared different instruments; thus, there is little empirical evidence to guide practitioners' selections among different assessment tools. Therefore, we have highlighted features such as length of administration and training requirements, in addition to validity and reliability, to assist in instrument selection. We also highlighted several widely used but seriously flawed instruments, with some cautions about their real-world applications. Although challenges remain, this chapter summarizes the tremendous growth that has taken place in the last decade in evaluation methods for ASD. As recently as 10 years ago, autism was not considered a spectrum disorder and was thought to be very rare. Few clinicians knew how to evaluate it or considered it in a differential diagnosis. ASD was diagnosed through subjective clinical opinion, without the use of objective measures of development or behavior. As consensus about the diagnosis has been achieved, a number of standardized interviews and observational measures have been developed. In the next decade, the area that most needs refinement is the evaluation and differential diagnosis of the highest end of the autism spectrum (Asperger syndrome vs. HFA). Another pressing challenge is the paucity of professionals capable of evaluating suspected ASD, leading to very long waiting lists and delays in diagnosis. This chapter is an attempt to address these challenges and, we hope, to continue to broaden the preparation of trainees so that future professionals feel more competent to undertake this important area of assessment.

ACKNOWLEDGMENTS

Our comments in this chapter have been influenced by the membership of Sally Ozonoff on the National Institute of Mental Health's Workgroups on Interventions Research in Autism Spectrum Disorders (September 5–6, 2002, Rockville, Maryland, and May 6, 2004, Sacramento, California). Sally Ozonoff was supported during the writing of this chapter by funding from the National Institutes of Health (Grant Nos. R01-MH068398 and U19-HD35468). Beth L. Goodlin-Jones was supported by Grant No. R01 MH068232. Marjorie Solomon was supported by a Health Services Research Award from the University of California Davis School of Medicine. The opinions expressed here do not necessarily represent those of the funding institutes.

Early-Onset Schizophrenia

Michael G. McDonell
Jon M. McClellan

Schizophrenia is often a chronic, debilitating neuropsychiatric disorder with enormous individual, family, and societal burden. Early-onset schizophrenia (EOS) is defined as onset before age 18 years. The onset of schizophrenia in children is very rare, with the incidence increasing during adolescence. Some symptoms of schizophrenia may be difficult to differentiate from other psychiatric disorders or even normative childhood experiences. As with other low base rate disorders, comprehensive multi-informant, multimethod assessment is key to accurate diagnosis.

Accurate assessment of schizophrenia in children and adolescents can be a challenge. Historically the definition of childhood schizophrenia has varied. Rare cases of schizophrenia in children, described by Kraepelin (1919) in the early 1900s, were similar to the adult form of the disorder, and distinct from autism and pervasive developmental disorders (Werry, 1979). Beginning with the works of Bender, Kanner, and others (Fish & Ritvo, 1979), childhood schizophrenia was equated with the broader construct of childhood psychoses, including infantile autism. Whereas psychotic speech and thought were considered inherent components of childhood schizophrenia, hallucinations and delusions were not required criteria (Fish & Ritvo, 1979). The second edition of the *Diagnostic and Statistical Manual for Men-*

tal Disorders (DSM-II; American Psychiatric Association [APA], 1968) adopted this nosology by grouping all childhood psychoses under childhood schizophrenia, resulting in diagnostic overlap with that of autism and other psychotic disorders. However, seminal studies by Kolvin (1971) and Rutter (1972) demonstrated that autism and childhood-onset schizophrenia are distinct entities. Therefore, beginning with DSM-III (APA, 1980), the diagnosis of schizophrenia in childhood has used the same criteria as those for adults, regardless of age of onset.

DEFINITIONS

Diagnostic Criteria for Schizophrenia

Psychotic Symptoms

The diagnosis of EOS is made when DSM-IV-TR (APA, 2000) or *International Classification of Diseases* (ICD-10; World Health Organization [WHO], 1992) criteria are met (Tables 11.1 and 11.2). Psychotic symptoms are the hallmark of the disorder. In terms of DSM-IV-TR, active psychotic symptoms (e.g., hallucinations, delusions, disorganized speech, disorganized or catatonic behavior) and/or negative symptoms must be present for at least a period of 1 month.

TABLE 11.1. DSM-IV-TR Diagnostic Criteria for Schizophrenia

-
- A. *Characteristic symptoms*: Two (or more) of the following, each present for a significant period of time during a 1-month period (or less if successfully treated):
- (1) delusions
 - (2) hallucinations
 - (3) disorganized speech (e.g., frequent derailment or incoherence?)
 - (4) grossly disorganized or catatonic behavior
 - (5) negative symptoms (i.e., affective flattening, avolition, or anhedonia)
- Note:** Only one Criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts, or two or more voices are conversing with each other.
- B. *Social/occupational dysfunction*: For a significant portion of the time since onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).
- C. *Duration*: Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in Criterion A present in the attenuated form (e.g., odd beliefs, unusual perceptual experiences).
- D. *Schizoaffective and Mood Disorder exclusion*: Schizoaffective Disorder and Mood Disorder with Psychotic Features have been ruled out because either (1) no Major Depressive, Manic, or Mixed Episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred concurrently with the active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.
- E. *Substance/general medical condition exclusion*: The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.
- F. *Relationship to Pervasive Developmental Disorder*: If there is a history of Autistic Disorder or another Pervasive Developmental Disorder, the additional diagnosis of Schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).
-

Hallucinations may occur in any sensory modality, including olfactory or tactile. Auditory hallucinations are the most common and often are experienced as voices separate from a person's thoughts (APA, 2000; American Psychiatric Association, Steering Committee on Practice Guidelines [APASCPG], 2004). Delusions are often bizarre and unrealistic in the context of one's life experience and culture. Delusions may be persecutory (e.g., being followed by the CIA), referent (e.g., receiving special messages from the television), grandiose (e.g., believing in special powers), somatic (e.g., believing that one suffers from a terminal illness despite medical evidence to the contrary), or religious (e.g., believing that one is a religious prophet) (APA, 2000; APASCPG,

2004). Delusions may also involve thought withdrawal or insertion, or the belief that one is controlled by an outside force (APA, 2000; APASCPG, 2004).

Disorganized speech includes loosening of associations (i.e., frequent, sudden, and apparently unrelated changes in the subject of conversation), as well as tangential or incoherent speech (APA, 2000; APASCPG, 2004). Persons with schizophrenia may often change subjects suddenly or provide oblique responses to questions. Similar to disorganized speech, disorganized behavior is often characterized as difficulty in sustaining goal-oriented behavior (APASCPG, 2004). As a result, a range of activities, from planning a meal to personal hygiene, may be impaired. Catatonic behavior, which

TABLE 11.2. ICD-10 Diagnostic Criteria for Schizophrenia

The schizophrenic disorders are characterized in general by fundamental and characteristic distortions of thinking and perception, and affects that are inappropriate or blunted. Clear consciousness and intellectual capacity are usually maintained, although certain cognitive deficits may evolve in the course of time. The most important psychopathological phenomena include thought echo, thought insertion or withdrawal, thought broadcasting, delusional perception and delusions of control, influence or passivity, hallucinatory voices commenting or discussing the patient in the third person, and thought disorders and negative symptoms.

The course of schizophrenic disorders can be either continuous or episodic with progressive or stable deficit, or there can be one or more episodes with complete or incomplete remission. The diagnosis of schizophrenia should not be made in the presence of extensive depressive or manic symptoms unless it is clear that schizophrenic symptoms antedate the affective disturbance. Nor should schizophrenia be diagnosed in the presence of overt brain disease or during states of drug intoxication or withdrawal. Similar disorders developing in the presence of epilepsy or other brain disease should be classified under F06.2, and those induced by psychoactive substances under F10–F19 with common fourth character .5.

Excludes:

1. Acute schizophrenia-like disorder (F23.2), symptoms persisting for less than 1 month
2. Schizoaffective disorder, mixed type (F25.2)
3. Schizotypal disorder (F21)

Note. From WHO (1992). Copyright 1992 by the World Health Organization. Adapted by permission.

involves a general lack of response to one's environment, may present as motor immobility, mutism, posturing or stereotyped behavior, excessive motor behavior, echolalia, or echopraxia (APA, 2000; APASCPG, 2004).

Negative symptoms describe a variety of deficit symptoms, such as avolition, alogia, and affective flattening (APA, 2000). "Avolition" is defined as difficulties initiating and maintaining motivation to complete tasks necessary for successful functioning. Alogia typically manifests itself as poverty in the content and amount of speech. Persons with schizophrenia may also demonstrate a limited range of facial affective expression (affective flattening). Limited eye contact and "body language" are also indicative of affective flattening. Persons

with schizophrenia may also have a general lack of interest in previously enjoyable activities (anhedonia). Negative symptoms may be difficult to differentiate from comorbid depression or the side effects of antipsychotic medications (APASCPG, 2004).

Social–Occupational Dysfunction

The symptoms listed earlier must be associated with a marked decline in the level of social, occupational, and self-care functioning below preonset levels. In children and adolescents, this may include the failure to achieve age-appropriate levels of interpersonal, academic, or occupational development. This decline in functioning should be pervasive rather than limited to one or two specific situations (e.g., quitting a job because of a persecutory delusion). Although functioning may improve with treatment, deficits are often chronic and functioning may not return to premorbid levels (APA, 2000).

Duration

The disturbances must be present for a period of at least 6 months. This period must include an active phase of illness (i.e., psychotic symptoms) with or without a prodromal or residual phase. The prodromal phase involves deterioration in functioning prior to the onset of psychotic symptoms. The residual phase typically involves an improvement of psychotic symptoms and follows the active phase of illness. Prodromal and residual phases may include lower intensity psychotic symptoms, such as social isolation, deterioration in occupational functioning, peculiar behavior, blunted or inappropriate affect, disordered thought processes (tangentiality, circumferentiality), poverty of speech or speech content, odd beliefs or perceptions, and lack of energy (anergia).

Differential Diagnosis

Schizoaffective disorder and mood disorders with psychotic features should be ruled out. For a diagnosis of schizophrenia, psychotic symptoms must persist when the episodes of depression and mania remit. If psychotic symptoms persist for at least 2 weeks in the absence of mood disturbance and criteria for a major depressive, manic, or mood episode are met for a substantial portion of the active and residual phase of the illness, then a diagnosis of

schizoaffective disorder should be made (APA, 2000). Persons with a chronic and debilitating disorder such as schizophrenia are likely to experience difficulties with mood. If these difficulties with mood neither meet criteria for a depressive, manic, or mixed episode, nor present for a substantial portion of the period of the disorder, then a diagnosis of schizophrenia is appropriate.

Psychosis as a result of other general medical conditions, substance use, or medications also should be ruled out. A thorough medical evaluation is necessary to rule out psychosis secondary to a general medical condition, such as acute intoxication or delirium. Prolonged abstinence from a substance or medication often differentiates between substance- or medication-induced psychosis and schizophrenia. A diagnosis of schizophrenia should be made when psychotic symptoms persist despite prolonged abstinence from the substance believed to have caused psychotic symptoms.

In cases where diagnostic criteria are met for autism or other pervasive developmental disorders, symptoms of active psychosis (e.g., overt hallucinations and/or delusions) must be present for at least 1 month, and other explanations for psychotic symptoms must have been ruled out (e.g., belief in fantasy vs. delusions or hallucinations, a lack of interest in social relationships vs. negative symptoms).

ICD-10 Criteria for Schizophrenia

ICD-10 diagnostic criteria are similar to DSM-IV-TR criteria except that the diagnosis can be made once sufficient symptoms have been present for a period of 1 month or more, rather than 6 months (WHO, 1992). Armenteros and colleagues (1995) found a high rate of diagnostic agreement between DSM-III-R, DSM-IV, and ICD-10 in hospitalized psychotic adolescents.

Schizophrenia Subtypes

Subtypes of schizophrenia are found in both DSM-IV-TR and ICD-10, including paranoid, disorganized (hebephrenic), catatonic, undifferentiated, and residual. The paranoid subtype is characterized by hallucinations and persecutory delusions, without substantial disorganized behavior or speech. Persons with disorganized or hebephrenic schizophrenia demonstrate predominately disorganized thought and/or behavior, and may be too con-

fused to provide descriptions of organized delusions and hallucination. Catatonic schizophrenia is rare, especially in EOS, and is marked by unresponsiveness to one's environment. Undifferentiated schizophrenia characterizes individuals who meet criteria for schizophrenia but do not meet criteria for paranoid, catatonic, or disorganized subtypes. The residual subtype describes persons with schizophrenia who no longer manifest symptoms consistent with an active phase of illness (e.g., hallucinations, disorganized speech and behavior) but still manifest negative symptoms, and other symptoms of the illness in an attenuated form.

In addition, the subtypes simple and post-schizophrenic depression are found in ICD-10, but not in DSM-IV-TR. Simple schizophrenia, as defined by ICD-10, is a form of the illness with an insidious onset of decreased functioning and residual symptoms of schizophrenia (e.g., blunting of affect and avolition), without previous overt psychotic symptoms. Postschizophrenic depression describes the presence of a depressive episode after onset of the schizophrenic illness. Symptoms of schizophrenia must persist during episodes of depression (WHO, 1992).

Reports vary as to whether the paranoid subtype (Eggers, 1978) or the undifferentiated subtype (McClellan, Werry, & Ham, 1993; Werry, McClellan, & Chard, 1991) is more common in EOS. Furthermore, an individual's subtype may vary, depending in part on response to treatment. Therefore, it is not clear whether these subtypes represent truly distinct clinical or biological entities. There is not sufficient evidence currently to justify categorizing EOS as a separate diagnostic subcategory (Werry, 1992).

Developmental Factors and DSM-IV-TR and ICD-10 Criteria

Although the criteria for the diagnosis of schizophrenia are the same for children and adolescents as for adults (APA, 2000), developmental factors still need to be considered in the assessment of EOS. In general, the extant research has defined "early onset" as onset prior to age 18 years, with childhood onset, prior to age 12 years. Some developmental differences in symptom presentation are noted. Children with EOS are more likely to present with hallucinations, thought disorder, and negative symptoms, and are less likely to experience complex

or systematized delusions (Pavuluri, Herbener, & Sweeney, 2004). An earlier age of onset is also generally associated with other developmental delays and a high rate of premorbid problems (Ropcke & Eggers, 2005). These differences are mostly qualitative and likely relate to the timing of the illness with regard to neural development. Younger children in general have less abstract thinking; therefore, not surprisingly, those with schizophrenia are less likely to have complex delusions. The timing of the onset of the illness may be in part a “dose effect.” Therefore, the association between greater premorbid and cognitive difficulties, and earlier onset may simply reflect a greater neurodevelopmental insult.

Appropriate developmental assessment includes determining whether symptom reports suggestive of schizophrenia represent the underlying diagnosis as opposed to normative developmental experiences or symptoms of other psychiatric disorders. Distinguishing psychotic symptoms from other developmental issues can be challenging, especially in children. Very young children’s idiosyncratic logical reasoning, overactive perceptions, or magical belief systems may be misinterpreted as psychosis by clinicians that apply adult criteria without developmental accommodations. True psychosis is exceedingly rare in very young children. Therefore, clinicians need to be very cautious when interpreting psychotic-like reports in this age group.

Most children and adolescents reporting psychotic symptoms do not actually have a psychotic disorder (Del Beccaro, Burk, & McCauley, 1988; Garralda, 1984a, 1984b). Atypical psychotic symptoms may represent a number of phenomena, including posttraumatic stress disorder (PTSD), factitious or conversion disorders, personality disorders, or developmental delays that interfere with the accurate reporting of internal experiences; difficulty distinguishing fantasy from reality; and/or misunderstanding the questions asked by the clinician (Hlastala & McClellan, 2005; Hornstein & Putnam, 1992; McClellan et al., 1993; McClellan & McCurry, 1999). In these cases the psychotic symptom reports are often atypical in the following manner: (1) The reports are inconsistent, and there is no other documented evidence of a psychotic process (e.g., thought disorder, bizarre disorganized behavior); (2) the qualitative nature of the reports are not typical of psychotic symptoms

(e.g., greatly detailed descriptions or reports more suggestive of fantasy or imagination); and/or (3) the reported symptoms only occur in specific situations (e.g., hearing voices only after an aggressive outburst) (Hlastala & McClellan, 2005).

EPIDEMIOLOGY

The prevalence of schizophrenia in the general population is approximately 1% and occurs worldwide in all known cultural and ethnic groups. Although the prevalence of EOS has not been adequately studied, the few studies available, plus clinical experience, suggest that onset prior to age 13 years is quite rare. In children younger than 15 years of age, the prevalence rate has been estimated at 14 per 100,000 (Beitchman, 1985; Volkmar, Cohen, Hoshino, Rende, & Paul, 1988). Gillberg (1984) estimated the prevalence of very early-onset schizophrenia (VEOS) in Sweden at 1.6 per 100,000. Thomsen (1996) reported that only 1% of hospitalized youth with schizophrenia were younger than 13 years of age, and only 9% were younger than 15 years of age. The rate of onset increases during adolescence, with onset for the disorder typically ranging from 15 to 30 years (APA, 2000). Although the onset of puberty has been theorized to play some type of neurobiological role, pubertal status was not associated with the onset of psychosis in a study of youth with childhood schizophrenia (Frazier et al., 1997).

EOS occurs predominantly in males (Bettes & Walker, 1987; Green & Padron-Gayol, 1986; Green, Padron-Gayol, Hardesty, & Bassiri, 1992; Kolvin, 1971; McClellan & McCurry, 1998; Russell, Bott, & Sammons, 1989; Werry et al., 1991). Because the adult literature suggests that the average age of onset in males is 5 years earlier than that in females (Loranger, 1984), the male predominance in EOS may be a cross-sectional effect.

CLINICAL PRESENTATION

Symptomatology

Historically, schizophrenia has been characterized as having positive and negative symptoms. Positive symptoms of schizophrenia refer to florid hallucinations and delusions, whereas negative symptoms refer to deficits (i.e., flat

affect, anergy, and paucity of speech and thought; APA, 2000). Hallucinations, especially auditory hallucinations, thought disorder (e.g., loose associations), and flattened affect all have been consistently found in EOS, whereas systematic delusions and catatonic symptoms are less frequent (Biederman, Petty, Faraone, & Seidman, 2004; Green et al., 1992; McClellan, McCurry, Speltz, & Jones, 2002; Pavuluri et al., 2004; Russell et al., 1989; Werry et al., 1991). Social deficits, such as withdrawal and social isolation, have also been observed in EOS and are correlated with negative symptoms (Hollis, 2003; McClellan, Breiger, McCurry, & Hlastala, 2003).

Youth with schizophrenia also display evidence of formal thought disorder. In comparison to normal children, those with schizophrenia have three characteristic communication deficits: loose associations, illogical thinking, and impaired discourse skills (Caplan, Guthrie, Gish, Tanguay, & David-Lando, 1989; Pavuluri et al., 2004). Rates of incoherence and poverty of speech content are low (Caplan et al., 1989). When assessing a child's thinking, it is important to differentiate between the thought disorder of psychosis and language disorders or developmental delays. For instance, typical language difficulties in EOS (i.e., disorganized speech, loose associations) are manifestations of disorganized thought rather than language difficulties, such as word finding or word recognition.

Associated Cognitive Symptoms

Neuropsychological studies suggest that children with schizophrenia have global impairments across tasks that require greater capacity for information processing rather than deficits isolated to specific functions or areas of the brain (Asarnow, Tompson, & Goldstein, 1994; McClellan, Prezbindowski, Breiger, & McCurry, 2004). However, it is important to recognize that there are no specific neuropsychological profiles diagnostic of schizophrenia (Kumra et al., 2000; McClellan et al., 2004). Youth with EOS who have identified genetic disorders, such as velocardiofacial syndrome, may demonstrate greater neuroanatomical and neuropsychological abnormalities (Rapoport & Inoff-Germain, 2000; Usiskin et al., 1999).

Language and communication and global cognitive deficits are common in youth with schizophrenia (Baltaxe & Simmons, 1995;

Caplan, Guthrie, & Komo, 1996; Helgeland & Torgersen, 2005; McClellan et al., 2004). Of those with EOS, 10–20% have IQs in the borderline to mentally retarded range (Asarnow & Ben-Meir, 1988; Eggers, 1978; Goldberg, Karson, Leleszi, & Weinberger, 1988; Green et al., 1992; Kenny et al., 1997; McClellan et al., 1993; McClellan & McCurry, 1998; Werry et al., 1991). Because many research studies have excluded patients with mental retardation, these rates may actually be lower than what otherwise would be found in a clinical population.

Developmental and Cognitive Influences on Symptom Presentation

Developmental differences in language and cognition may affect the range and quality of symptom presentation (Caplan et al., 1989; Volkmar et al., 1988; Watkins, Asarnow, Tanguay, & Perdue, 1988; Werry, 1992). Bettes and Walker (1987) found that among youth with EOS and other psychiatric disorders, positive symptoms increased linearly with age and were associated with IQs greater than 85. Young children are also less likely to present with systematic delusions. Thus, the complexity of psychotic symptoms appears to be correlated with cognitive development, with the capacity for more systematic delusional beliefs and complex hallucinations linked to the capacity for abstract thinking and a general fund of knowledge. This is not surprising, because psychotic thought emanates from an individual's own experiences and belief systems.

Course of Illness

Schizophrenia is a phasic disorder, with a great deal of individual variability. As a result of the fluctuation of symptoms across phases, accurate assessment must take into account these variations in clinical presentation.

Premorbid Functioning

The majority of patients with EOS (with some reports as high as 90%) have premorbid developmental and/or behavioral abnormalities (Alaghband-Rad et al., 1995; Asarnow & Ben-Meir, 1988; Eggers, 1978; Green & Padron-Gayol, 1986; Helgeland & Torgersen, 2005; Hollis, 1995, 2003; Kolvin, 1971; McClellan et al., 2003; McClellan & McCurry, 1998; Rus-

sell et al., 1989; Schaeffer & Ross, 2002; Vourdas, Pipe, Corrigan, & Frangou, 2003; Watkins et al., 1988; Werry et al., 1991). A wide range of premorbid difficulties is described, including idiosyncratic or bizarre pre-occupations, unusual behaviors, social withdrawal and isolation, deteriorating self-care, disruptive behavior disorders, academic difficulties, speech and language problems, and developmental delays (Hollis, 1995; McClellan et al., 2003; McClellan & McCurry, 1998). Autism and pervasive developmental disorders also have been reported (Alaghband-Rad et al., 1995; Nicolson et al., 2001; Russell et al., 1989), although these conditions should be considered distinct and separate from schizophrenia (American Academy of Child and Adolescent Psychiatry [AACAP], 2001; Cantor, Evans, Pearce, & Pezzot-Pearce, 1982; Watkins et al., 1988). McClellan and colleagues (2003) found that greater premorbid global impairment, social withdrawal and schizoid/schizotypal personality types differentiate between youth with EOS and those with bipolar disorder or atypical psychosis. Hollis (2003) also found that impaired premorbid social functioning differentiates between youth with EOS and those with other psychotic disorders.

Prodromal Phase

The prodromal phase represents a significant decline from baseline functioning or a worsening of premorbid personality/behavioral characteristics. In general, this phase is characterized by changes in social, cognitive, and/or academic functioning. Presentations can include the development of odd or idiosyncratic beliefs, worsening school performance, social isolation and withdrawal, and/or worsening hygiene. The duration of the prodromal phase can vary from an acute change (days to weeks) to chronic impairment (months to years) (AACAP, 2001). Children generally have an insidious onset (Asarnow & Ben-Meir, 1988; Green & Padron-Gayol, 1986; Kolvin, 1971; Rapoport & Inoff-Germain, 2000). In young adolescents, both acute onset (less than 1 year) and insidious onset are noted (Kolvin, 1971; McClellan et al., 1993; McClellan & McCurry, 1998; Ropcke & Eggers, 2005; Werry et al., 1991). Insidious onset has been found to be predictive of a more severe course of illness (Ropcke & Eggers, 2005). Furthermore, because many youth with EOS have an insidious onset, it is often difficult to distinguish between

premorbid personality/cognitive abnormalities and the onset of the disorder.

Acute Phase

Diagnosis is most common in this phase of the illness, because the acute phase is marked by a predominance of positive symptoms (i.e., hallucinations, delusions, disorganized speech and behavior), as well as a significant deterioration in functioning. This phase generally lasts 1 to 6 months or longer, depending in part on the response to treatment (AACAP, 2001). Most youth with EOS will have subsequent acute episodes (Ropcke & Eggers, 2005).

Recovery Phase

Following the acute phase, with remission of the acute psychosis, the patient generally continues to experience a significant degree of impairment for several months (AACAP, 2001), primarily due to negative symptoms (flat affect, anergia, social withdrawal), although some psychotic symptoms may persist (Renschmidt, Martin, Schulz, Gutenbrunner, & Fleischhaker, 1991). In addition, some patients may develop a postschizophrenic depression characterized by dysphoria and flat affect.

Residual Phase

Youth with EOS may have prolonged periods (several months or more) between acute phases, in which they do not experience significant positive symptoms. However, most patients continue to be at least somewhat impaired by negative symptoms.

Longitudinal Outcome

In the adult literature, schizophrenia typically follows a pattern characterized by cycles of the previously discussed phases, with increasing deterioration after each cycle. However, after approximately 10 years, the acute phases of the disorder tend to remit, leaving a residual state (predominately negative symptoms) with varying disability (AACAP, 2001). Further research is needed to clarify whether this long-term pattern holds for EOS. Some youth with schizophrenia may have only one cycle, although most have more (Asarnow et al., 1994; Eggers, 1978; Hollis, 2003; McClellan et al., 1993; Ropcke & Eggers, 2005; Werry et al., 1991). Others remain chronically symptomatic despite

adequate treatment (Asarnow et al., 1994; Eggers & Bunk, 1997; Maziade, Gingras, et al., 1996; McClellan et al., 1993; Werry et al., 1991). These patients are generally the most severely impaired and require the most comprehensive treatment resources.

Generally, the literature suggests moderate to severe impairment across the lifetime (Eggers, 1978, 1989; Eggers & Bunk, 1997; Hollis, 2000; Jarbin, Ott, & von Knorring, 2003; Maziade, Bouchard, et al., 1996; Maziade, Gingras, et al., 1996; McClellan et al., 1993; Ropcke & Eggers, 2005; Werry et al., 1991). Premorbid characteristics, such as cognitive ability, treatment response, and adequacy of therapeutic resources invariably influence short-term outcome (Remschmidt et al., 1991). Poor long-term outcome is predicted by family history of nonaffective psychosis, low premorbid functioning, insidious onset, diagnosis prior to adolescence, low intellectual functioning, and severe symptoms during acute phases (Eggers, 1989; Jarbin et al., 2003; Maziade, Bouchard, et al., 1996; Ropcke & Eggers, 2005; Werry, 1992). When followed into adulthood, youth with EOS demonstrated greater social deficits, lower levels of employment, and were less likely to live independently relative to those with other childhood-onset psychotic disorders (Hollis, 2000; Jarbin et al., 2003).

Individuals with EOS also have a high risk of eventual suicide. The risk of suicide or accidental death directly due to behaviors caused by psychotic thinking appears to be at least 5% (Eggers, 1978; Werry, 1991), although the numbers studied are small and the follow-up periods are short in some subjects. In adults with schizophrenia, there is an increased risk for medical illnesses and mortality, including a suicide rate of approximately 10% (APA, 2000). Adults with schizophrenia are also at higher risk for other morbidities, such as heart disease, obesity, human immunodeficiency virus, hepatitis, and diabetes (Goff et al., 2005).

ETIOLOGY AND PATHOGENESIS

Genetic and Environmental Factors

Current research suggests that schizophrenia is a neurodevelopmental disorder that stems from both genetic and environmental risk factors. The phenotype is heterogeneous and complex, with multiple genes and environmental exposures likely involved. Identifying preventable causes and means to avert the disorder remains

a public health priority. Furthermore, unraveling molecular mechanisms underlying schizophrenia may shed light on factors responsible for the development of other mental illnesses.

In the general population, family, twin, and adoption studies all support a strong genetic component for schizophrenia. The lifetime risk of developing the illness is 5–20 times higher in first-degree relatives of affected probands compared to the general population (Cardno & Murray, 2003; Thaker & Carpenter, 2001). The rate of concordance among monozygotic twins is approximately 40–60%, whereas the rate of concordance in dizygotic twins and other siblings is 5–15% (Cardno & Gottesman, 2000).

Large, collaborative studies evaluating linkage of schizophrenia in multiply affected families have identified multiple-candidate chromosomal regions (Straub et al., 1995; Zammit, Lewis, & Owen, 2003). Regions best supported by genome-wide scans include 6p22–p24 (Straub et al., 1995), 1q21–q22 (Brzustowicz et al., 2000), and 13q32–q34 (Blouin et al., 1998). Other regions with positive linkage findings include 1q42, 5q21–q33, 6q21–q25, 8p21–p22, 10p15–p11, and 22q11–q12 (Owen, Williams, & O'Donovan, 2004). These regions combined represent a substantial portion of the genome. This is not surprising given genetic heterogeneity and the complexity of neural development.

Candidate genes have been suggested in several of these regions, including dysbindin on 6p22, neuregulin on 8p22, *G72* on 13q34, *COMT* on 22q11, *RGS4* on 1q21, *DISC1* on 1q42, and *GRM3* on 7q21 (see review, Harrison & Weinberger, 2005). Each of these genes is biologically plausible (Harrison & Weinberger, 2005). However, for each candidate gene, both positive and negative associations have been reported; strengths of effects are generally weak; the specific allele or haplotype associated with the illness varies across studies; and definitive causative mutations for the most part have not been identified.

Etiological research for EOS remains limited, although the National Institute of Mental Health's (NIMH) Childhood-Onset Schizophrenia Program has contributed substantially to this area. In its cohort of youth with adolescent-onset schizophrenia, positive associations have been reported for several candidate genes of interest, including dysbindin (Gornick et al., 2005), *GAD1* (Addington et

al., 2005) and G72 (Addington et al., 2004). Furthermore, in this series, the rate of cytogenetic abnormalities, including 22q11 deletion (which is associated with an elevated rate of schizophrenia) appears to be higher than that in reports of adults (Nicolson et al., 1999; Usiskin et al., 1999).

In addition to genetic contributions, environmental factors likely play a role in the development of schizophrenia. Disruptions in prenatal brain development may contribute to the illness. Individuals with schizophrenia have higher rates of minor physical anomalies (Gourion et al., 2004; Hata, Iida, Iwasaka, Negoro, & Kishimoto, 2003; Ismail, Cantor-Graae, & McNeil, 1998; McGrath et al., 2002), deficits in smooth pursuit eye movements (Frazier et al., 1996; Jacobsen & Rapoport, 1998; Jacobsen et al., 1997; Karp et al., 2001; Zahn et al., 1997), developmental disturbances in childhood (Bearden et al., 2000; Cannon et al., 1999; Crow, Done, & Sacker, 1995; Jones, Rogers, Murray, & Marmot, 1994), and structural anomalies on brain imaging (Collinson et al., 2003; Gogtay et al., 2004; James, James, Smith, & Javaloyes, 2004; Keller et al., 2003; Kumra et al., 2004; Kumra, Ashtari, et al., 2005; Lawrie & Abukmeil, 1998; Matsumoto et al., 2001; Sporn et al., 2003).

At the onset of illness, many affected individuals already have ventricular enlargement and decreased hippocampal volume, with some evidence suggesting that individuals with earlier onset have more progressive neuroanatomical changes (Gogtay et al., 2004). Relative to normal controls, greater longitudinal decreases in overall volume of gray matter (Sporn et al., 2003), in frontal lobe (Gogtay et al., 2004), prefrontal cortex (James et al., 2004), temporal lobe (Gogtay et al., 2004), parietal lobe (Gogtay et al., 2004), and thalamus (James et al., 2004) have been described. Deficits in white matter have also been noted in the frontal lobe, anterior and posterior commissures, anterior cingulate, corpus callosum, and the right occipital lobe (Keller et al., 2003; Kumra, Ashtari, et al., 2005). Rapoport and Inoff-Germain (2000) suggest that these changes may peak in adolescence, representing critical neurodevelopmental delay during this time.

In the adult literature, gestational exposures, including maternal starvation, are also suspected risk factors for schizophrenia (Brown, Cohen, Greenwald, & Susser, 2000; Brown et al., 2004; Buka et al., 2001; Neugebauer, 2005;

Opler et al., 2004; Smil, 2005; St. Clair et al., 2005; Susser et al., 1996). These putative risk exposures may interact with genetic factors in susceptible individuals.

Psychological and Social Factors

There is no evidence that psychological or social factors cause schizophrenia. Rather, environmental factors interact with biological risk factors to mediate the timing of onset, course, and severity of the disorder. Psychosocial stressors, including family expressed emotion, influence the onset and/or exacerbation of acute episodes, and relapse rates (APA, 2000). Communication deficits are often found in families of youth with EOS, although these may be shared phenotypic traits rather than etiological agents (Asarnow & Ben-Meir, 1988). Similarly, family members of youth with EOS appear to have subtle deficits in neuropsychological functioning (Gochman et al., 2004) that may contribute to increased communication and social difficulties. The interactions between psychological, social, and illness-related factors are complex. Therefore, causal mechanisms cannot be inferred based on positive associations. In terms of social factors, adults with schizophrenia typically have lower socioeconomic status (SES). Overall, adult research has suggested that this is likely a result of the illness causing disability and lower SES, rather than vice versa (Munk-Jorgensen & Mortensen, 1992). Available studies investigating the link between EOS and economic factors have a selection bias toward inpatient samples, with higher rates of low SES found in some studies (Green et al., 1992; Kolvin, 1971; McClellan et al., 1993), but not others (Russell et al., 1989; Werry et al., 1991).

COMORBID DISORDERS

As with other chronic conditions, children and adolescents with EOS have a number of comorbid conditions, including depression, anxiety, and externalizing disorders (McClellan et al., 2003; Russell et al., 1989). In adolescents with EOS, substance abuse is also a major concern (Kumra, Thaden, & Kranzler, 2005; McClellan et al., 2003). Finally, youth with EOS also have a high rate of developmental delays and cognitive difficulties. Many youth with EOS are diagnosed with pervasive developmental disorders.

ASSESSMENT

A diagnosis of schizophrenia is made in youth when DSM-IV-TR, or ICD-10, criteria are met, and other pertinent disorders have been ruled out. The standard principles and procedures of psychological and psychiatric assessment, outlined in this volume, apply to the assessment of EOS. Although a variety of assessment tools (e.g., checklists, rating scales, neuropsychological measures) may be helpful in the assessment of children with EOS, multi-informant interviews, observation and mental status examinations, symptom rating scales, record reviews, and a comprehensive medical evaluation comprise the “gold standard.” Long-term monitoring and reassessment are also needed to ensure diagnostic accuracy (AACAP, 2001). Comprehensive assessment techniques are necessary, because the clinical complexity of youth who present with possible EOS often leads to misdiagnosis and inadequate treatment (AACAP, 1998a; Schaeffer & Ross, 2002; Stayer et al., 2004). Assessment of comorbid diagnoses and other domains of functioning (e.g., cognitive, academic, social) are also important for treatment planning.

The procedures for reliable and valid assessment of EOS outlined below should be administered by clinicians using an informed hypothesis-testing approach. The information presented earlier, regarding epidemiology, symptomatology, and course of illness help to guide assessment. Perhaps most importantly, clinicians should remember that EOS, especially childhood onset, is rare, and most children who present with symptoms suggestive of psychosis have neither EOS nor, for that matter, a psychotic illness. Therefore, the diagnosis of EOS requires that clinicians establish the validity of psychotic symptoms while ruling out other, possible conditions with similar presentations (see “Differential Diagnosis” section below).

Typical Referral Questions

Youth with possible EOS may present with psychotic symptoms (i.e., hallucinations, delusions), disorganized behavior or speech, social impairment, academic difficulties, and/or aggression (McClellan et al., 2003; Schaeffer & Ross, 2002; Vourdas et al., 2003). Schaeffer and Ross (2002) found that among youth with schizophrenia, the most frequent initial clinical concerns were school failure and aggressive

behavior. Although important issues, these nonspecific concerns present with a number of different clinical situations.

Referrals from medical and mental health professionals typically require accurate diagnostic assessment. The first step of the diagnostic process involves determining whether psychotic symptoms are present (vs. atypical reports concurrent with nonpsychotic disorders or normative childhood phenomena). The second step entails determining the type of psychotic disorder present (EOS vs. other psychotic disorders). Other referral questions include assessing comorbid diagnoses, neuropsychological strengths and weaknesses, and functional impairment; and determining treatment recommendations.

Appropriate treatment is dependent upon an accurate diagnosis. For instance, Schaeffer and Ross (2002) found that prior to an accurate diagnosis of EOS, the majority of children received inappropriate or insufficient treatment (88% received individual psychotherapy, 77% were prescribed stimulant medications). Treatment planning may also be informed by assessment of neuropsychological, academic, social, vocational, and other areas of functioning associated with EOS.

Assessment Procedures

Multi-Informant Assessment

Interviews with the child, caregivers, teachers, and other relevant adults provide rich and ecologically valid data that aid in diagnosis and treatment planning. Involving parents and other important adults in the assessment process is key, because youth at risk for EOS may have difficulty reporting on current symptomatology and relevant history. The multi-informant assessment can provide information relevant to current and previous clinical presentation and course, as well as comorbid conditions. A multi-informant assessment also rules out the possibility of single informant bias.

The interview with the child or adolescent with EOS provides an opportunity to obtain his or her description of current symptoms, as well as to observe the youth’s mental status. Youth with EOS can generally describe relevant aspects of their psychotic symptoms, although acutely ill youth may be too disorganized and confused to provide a cogent history. In those cases, however, clinician observations and the

mental status exam (see section below) are the best evidence of the disorder. Similarly, negative symptoms, and disorganized speech and thought, may be best assessed through observation and by interviewing other informants.

Involving parents or caregivers in assessment is particularly important when gathering information about developmental, psychological, medical, and family psychiatric history. In addition, caregivers are typically able to provide information about the child's functioning in a variety of settings. Caregiver interview and observation also provide information about important family factors, such as expressed emotion, social support, caregiver burden, and overall caregiver functioning. Because EOS appears to be related to genetic factors, assessment of family psychiatric history is important. Whenever possible, diagnostic verification of an affected family member from a third party (e.g., an affected family member's psychiatrist) is advisable.

Involving other important adults in the assessment is optimal. Teachers, therapists, medical providers, and other professionals can often provide information to supplement child and caregiver interviews. The teacher interview is particularly important, because school is the primary area of functioning for most youth, and data obtained from teachers inform later academic, behavioral, and social intervention. Interviews of teachers should focus on academic performance and social functioning.

STRUCTURED INTERVIEWS

In terms of assessment procedures, diagnostic accuracy of EOS may be substantially improved through the use of structured diagnostic interviews (Carlson Bromet, & Sievers, 2000). Diagnoses made in clinical settings are notorious for being unreliable (McClellan & Werry, 2000). Structured interviews are particularly helpful in the assessment of EOS, as a result of the complexity of the illness. While these tools have been used primarily in epidemiological and clinical research (McClellan & Werry, 2000), they provide a format for reliably assessing both schizophrenia and comorbid conditions. For a full review of structured diagnostic interviews see Doss (2005) and the special issue of the *Journal of the American Academy of Child and Adolescent Psychiatry* edited by McClellan and Werry (2000). Table 11.3 summarizes characteristics of structured interviews

for youth that contain either screening items for psychosis or complete diagnostic criteria for schizophrenia.

It is important to remember that although structured interviews improve reliability, validity is more difficult to establish (McClellan & Werry, 2000). This is a major limitation in all psychiatric research given the lack of biological or other markers for disorders. For complex illnesses such as EOS, it is important for the clinician administering the interview to be familiar with both the illness and, more broadly, developmental psychopathology in youth. Clinician-based structured diagnostic interviews, such as the K-SADS and Kid SCID, are recommended when assessing EOS. These assessments are being used in clinical research (McClellan et al., 2002, Sikich, Hamer, Bashford, Sheitman, & Lieberman, 2004). Clinician-based tools balance structure and flexibility, and provide a structure for the diagnostic interview while allowing for clinician probes, rewording of items, and clinical judgment.

Screening interviews, or nonclinician-based interviews, are not sufficient for the diagnosis of EOS, because the complexity of psychotic symptom presentation in children and adolescents makes it necessary that clinicians, not laypersons or computers, determine the veracity of psychotic symptoms. However, they may be useful screening tools and help to identify youth at risk for EOS and other comorbid disorders.

Clinician familiarity with developmental psychopathology is key, because structured interviews with youth have demonstrated a substantial rate of false-positive results related to psychosis (Breslau, 1987). In general, most youth may not understand the wording of questions relevant to psychosis; therefore, they respond based on their own normal experiences. Few children and adolescents have familiarity with the concept of psychosis. Therefore, they may respond honestly in trying to describe normal mentation. Furthermore, many traumatized youth report unusual sensory experiences that may relate to dissociative symptoms (Hlastala & McClellan, 2005). Although important clinically, these symptoms should not be equated with true psychosis.

When utilizing structured diagnostic interviews, clinicians must be aware of the general nature of psychosis. In general, psychotic symptoms are confusing to the individual and are experienced as external phenomena beyond

TABLE 11.3. Characteristics of Structured Diagnostic Interviews That Assess Psychotic Symptoms in Children and Adolescents

Instrument	Disorders covered	Informant	Age range (years)	Type	Time (minutes)	Interviewer qualifications	Special issues
Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 2000)	BEH, ANX, MOOD, EAT, ELIM, SUB, TIC, SCH, SOM	Child Parent	9–17	Interviewer	60–150	Bachelor plus training program	Glossary used to define symptoms and severity ratings; Spanish version available
Related instruments YAPA (young adult) PAPA (preschool age)		Patient Parent	18+ 3–6				
Diagnostic Interview Schedule for Children—Version IV (DISC-IV; Shaffer et al., 2000)	BEH, ANX, MOOD, EAT, ELIM, SUB, TIC, SCH	Child Parent	6–17	Respondent	70–120	Trained lay interviewers	Self-administered computer and Spanish versions available
Versions DISC-Y (youth) DISC-P (parent)			9–17 6–17				
Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Ambrosini, 2000)	BEH, ANX, MOOD, EAT, SUB, SCH	Child Parent	6–18	Interviewer	75–90	Trained clinicians	Although designed for clinicians, many researchers use trained interviewers
K-SADS-E (epidemiological) K-SADS-P/L (present and lifetime) K-SADS-P (present state) Washington University K-SADS	Also assesses TIC and ELIM Expands definitions of mania						
Diagnostic Interview for Children and Adolescents (DICA; Reich, 2000)	BEH, ANX, MOOD, EAT, ELIM, SUB, SOM, TIC, PSYCH	Child Parent	6–17	Respondent/ interviewer	60–120	Trained lay interviewers	Used both as structured and semistructured interview
Structured Clinical Interview for DSM-IV, Childhood Diagnoses (KID-SCID; Matzner et al., 1997)	BEH, ANX, MOOD, SUB, SCH, SOM	Child Parent	?–17	Interviewer	60–120	Clinicians	Only preliminary data available
Interview Schedule for Children and Adolescents (ISCA; Sherrill & Kovacs, 2000)	BEH, ANX, MOOD, EAT, ELIM, SUB, SOM, TIC, PSYCH	Child Parent	8–17	Interviewer	120 (parent) 60 (child)	Clinicians	Organized around symptom reports
Follow-Up Schedule for Adults (FISA)		Young adults	18+		60–120		Designed for longitudinal research
Children's Interview for Psychiatric Syndromes (ChIPS; Weller et al., 2000)	BEH, ANX, MOOD, EAT, ELIM, SUB, SCH	Child Parent	6–18	Respondent	40	Trained lay interviewers	Primarily a screening tool

Note. Disorders: BEH, disruptive behavior disorders; MOOD, mood disorders (depressive and bipolar); DEP, depressive disorders; ANX, anxiety disorders (often includes posttraumatic stress disorder); ELIM, enuresis and encopresis; SUB, substance abuse/dependence; TIC, Tic disorders; SCH, schizophrenia and psychotic disorders; PSYCH, nondiagnostic screen for psychotic symptoms; SOM, somatoform disorders. Type of interview: Respondent, answers coded based on response, also described as structured; Interviewer, interviewer allowed to make clinical judgments regarding respondents answers, also called semistructured. Interview times are approximates, and may vary depending on the case and interviewer. From McClellan (2005). Copyright 2005 by American Psychiatric Publishing, Inc. Adapted by permission.

his or her control. The more detailed, organized, or ego-syntonic the symptom reports, the less likely such symptoms represent true psychosis. Moreover, psychosis is a process, not just a positive response to a question. When individuals develop psychotic illnesses, there are a number of associated symptoms, including disorganized thinking and behavior, and a deterioration in functioning. Without such symptoms, the validity of psychotic-like symptom reports needs to be scrutinized carefully.

Finally, clinicians should be cautious when investigating psychosis, with or without structured interviews, in children younger than age 12. Among young children and youth with cognitive delays, it is a challenge to identify true psychotic symptoms. In these cases, the clinician must not only ensure that the child understands the context of the question but also take developmental considerations into account. Extrapolating adult symptom definitions onto children's experiences may result in misdiagnosis.

Observation and Mental Status Examination

Observation and mental status examination are key components of a comprehensive evaluation of EOS. Observation should take place during the interview, and whenever possible, in the child's natural environment (e.g., school, home). Observation and mental status examination provide information regarding psychotic, negative, and disorganized symptoms. It is important to observe and assess the structure and form of the youth's speech and language, and also to assess overt behavioral evidence of psychosis, such as responding to internal stimuli. Negative symptoms, such as flat and inappropriate affect, poverty of amount and content of speech, and anhedonia should also be assessed as part of the mental status examination. Disorganized speech and behavior are also observable behavior. Assessment of attention (e.g., serial sevens or fives), problem solving (e.g., "What would you do if you were lost in the forest?"), abstract reasoning (e.g., similarities: "How are . . . and . . . alike?"), and memory should also be assessed. Difficulty with attention, problem solving, abstract reasoning, and memory functioning may suggest a need for neuropsychological assessment. Mental status examination and observation should be conducted in a developmentally

appropriate fashion, especially when assessing cognitive function.

Symptom Rating Scales

Brief clinician-administered rating scales may also be used to assess EOS. Scales developed for adults with schizophrenia and administered by clinicians, such as Scale for the Assessment of Positive Symptoms (SAPS; Andreasen & Olsen, 1982), Scale for the Assessment of Negative Symptoms (SANS; Andreasen & Olsen, 1982), and the Positive and Negative Syndrome Scale (PANSS; Kay, Fiszbein, & Opler, 1987) are widely used in research and clinical practice to assess the treatment effects. These rating scales have also been used in studies with juveniles (e.g., McClellan et al., 2002). In addition, utilizing a modified version of the PANSS, Fields and colleagues (1994) found acceptable internal consistency and interrater reliability. Finally, there are also general ratings of psychopathology, such as the Brief Psychiatric Rating Scale for Children (BPRS-C—Hughes, Rentelmann, Emslie, Lopez, & MacCabe, 2001; Lachar et al., 2001), that include questions regarding psychotic symptoms.

McClellan and colleagues (2002) used the SAPS and SANS (Andreasen & Olsen, 1982) and the BPRS-C to assess adolescents with psychotic disorders. Factor analysis of these items identified four factors: negative symptoms, positive symptoms, behavior, and dysphoria. Scores on the negative symptoms factor differentiated between youth with EOS and those with other a bipolar or psychotic disorder, not otherwise specified, suggesting that negative symptoms, as measured by clinician rating scales, may be clinically useful in differential diagnosis. Tools such as the PANSS, SAPS, SANS, and BPRS-C may be helpful in differential diagnosis and assessment. These tools have also been used to measure treatment outcomes (e.g., Kumra et al., 1996, Sikich et al., 2004). Clinician rating scales are recommended, because they are relatively brief tools that can differentiate between children with EOS and those with other psychiatric disorders.

Record Review

Record review is an informative and often neglected assessment tool. Accurate diagnostic assessment requires a longitudinal overview of the pattern of illness rather than a sole focus on

cross-sectional symptom presentation. Record review is a helpful tool that provides detailed information that may have been forgotten by the youth and his or her family (e.g., when the child first qualified for special education). In this sense, it can corroborate or question the veracity of a child's and his or her parents' historical report. The clinician should focus on identifying a pattern of declining function and a prodromal phase of illness.

All school-age youth have academic records that provide a measure of school and often social-emotional functioning (e.g., level of class participation, discipline record, social functioning). Academic records of children and adolescents who have been evaluated for or have received special education services may include intellectual, achievement, and social-emotional testing, as well as a functional behavior analysis and other assessments. Youth who qualify for special education services may also have received documented academic, behavioral, emotional, speech and hearing, and occupational interventions.

Outside of the academic setting, because youth who present with possible EOS often have a long history of psychological and, possibly, medical difficulties, they may have received psychological, psychiatric, developmental, neurological, speech and hearing, and other relevant types of assessment. A review of these assessments may be helpful in establishing onset and characterizing the prodromal phase of illness. In addition, a medical record review is likely to be helpful in the current medical evaluation.

Treatment history should also be investigated, because youth with EOS are likely to have received a variety of psychiatric treatments prior to accurate diagnosis (Schaeffer & Ross, 2002). Information on development, premorbid functioning, onset of illness, and the effectiveness of previous treatments should be collected.

Comprehensive Medical Examination

Before a diagnosis of EOS can be made, organic causes must be ruled out. The list of potential exposures or neuropsychiatric conditions associated with psychosis is lengthy. However, entities that should be considered include (1) delirium, (2) seizure disorders, (3) central nervous system lesions (e.g., brain tumors, congenital malformations, head trauma),

(4) neurodegenerative disorders (e.g., Huntington's chorea, lipid storage disorders), (5) metabolic disorders (e.g., endocrinopathies, Wilson's disease), (6) developmental disorders (e.g., velocardiofacial syndrome), (7) toxic encephalopathies (e.g., substances of abuse, such as amphetamines, cocaine, hallucinogens, phencyclidine, alcohol, marijuana, and solvents; medications, such as stimulants, corticosteroids, or anticholinergic agents; and other toxins, such as heavy metals), and (8) infectious diseases (e.g., encephalitis, meningitis, and/or HIV-related syndromes).

Laboratory and neuroimaging procedures are not helpful for making a diagnosis of schizophrenia but may be indicated to rule out other neurological or medical problems. Tests and procedures should be justified based on the clinical presentation and significant findings in either the history or physical examination. As part of the basic medical evaluation (and for medication monitoring), laboratory tests to be considered include blood counts, serum chemistries, thyroid functions, and toxicology screens. If the risk factors are present, HIV testing should be done. Chromosomal analysis may be indicated for patients with clinical presentations/features suggestive of a developmental syndrome. Evidence of neurological dysfunction warrants a more thorough evaluation, including consideration of neuroimaging studies, electroencephalography (EEG), and/or a neurological consultation.

Other Recommended Assessment Procedures

Other assessment tools may be helpful in assessing clinical features associated with EOS and assist in treatment planning, but they are not necessary for diagnosis. Assessment of the youth should include cognitive, academic, and functional measures, as indicated by the clinical presentation. These assessments are particularly helpful in formulating effective psychiatric, academic, social, and vocational interventions.

Behavioral checklists provide useful and efficient methods of screening youth at risk for psychotic disorders and assessing comorbid conditions. Multi-informant checklists such as the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2001), the Behavioral Assessment System for Children-2 (BASC-2; Reynolds & Kamphaus, 2004), the Conners Scales—Revised (Conners,

1997) and the Personality Inventory for Children–2 and Personality Inventory for Youth (PIC-2, PIY; Lachar & Gruber, 2001) are standardized self-report, parent report, and teacher report measures of social and emotional functioning. These measures have acceptable psychometric properties and efficiently assess global psychopathology. They are designed to identify typical DSM-IV-TR disorders of childhood and adolescence. Most include subscales relevant to the assessment of EOS that measure social and cognitive functioning and atypical behavior. Youth with EOS scored higher on subscales of the Child Behavior Checklist (CBCL) that measure social functioning, thought and attention problems, and school competencies (Muratori, Salvadori, Arcangelo, Viglione, & Picchi, 2005). Among youth at a high risk of developing schizophrenia, CBCL ratings in adolescence were found to discriminate between youth who went on to develop the disorder and those who did not (Miller, Byrne, Hodges, Lawrie, & Johnstone, 2002). Despite these data, the CBCL and other checklists are not diagnostically specific to psychotic disorders, much less EOS. Therefore, checklists can identify children and adolescents who may be at risk for EOS, provide information about global psychological functioning, allow for comparison of informants, and assess comorbid conditions. Although neither necessary nor sufficient for a diagnosis of EOS, checklists can be efficient and informative assessment tools. Checklists may also be helpful in treatment planning and in measuring treatment effects.

Cognitive testing can identify specific deficits that may require remediation or accommodation. For EOS, measures of attention, intelligence, memory, and executive functioning (i.e., problem solving, inhibition, working memory) may be particularly relevant. Self-, parent and teacher report checklists, such as the Behavioral Rating Inventory of Executive Functioning (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000) may also be helpful in assessing cognitive functioning.

Academic assessment, a primary area of concern for most youth with EOS, is also recommended. A comprehensive assessment of academic achievement through standardized academic skills measures is necessary to identify academic strengths and weaknesses, and to screen for specific learning disabilities. In addition, a behavioral assessment in structured (i.e.,

classroom) and unstructured (i.e., playground, lunchroom) environments may assist in identifying behaviors that interfere with academic functioning. Other assessments relevant to the school setting, such as assessments by occupational and speech therapists, may also be helpful. Based on these assessments, an individualized educational program may then be formulated to improve academic functioning. Academic assessment and remediation are also important, because academic skills may form the foundation for later vocational functioning.

In terms of functional abilities, interviews such as the Vineland Adaptive Behavior Scales, Second Edition (Sparrow, Cicchetti, & Balla, 2005) and checklists such as the Adaptive Behavior Assessment System, Second Edition (Harrison & Oakland, 2000) provide comprehensive measures of adaptive skills. These assessments assist in identifying specific skills deficits that may require remediation. More specifically, they provide specific assessment of social and communication skills.

Although schizophrenia is not caused by family functioning, research suggests that family functioning influences the outcome of the disorder (Leff & Vaughn, 1985). Therefore, assessment of family functioning is important for treatment planning. Assessment of parenting stress, caregiver burden, social support, and expressed emotion is recommended. The Parenting Stress Index, Third Edition (Abidin, 1995) is a brief parent report measure of distress related to parenting. Measures of burden and expressed emotion, such as the Child and Adolescent Burden Assessment (CABA; Messer, Angold, Costello, & Burns, 1996) and the Five Minute Speech Sample (FMSS; Magana, 1993) may also be helpful in measuring caregiver functioning. Although measures such as the CABA and FMSS have been utilized primarily in research, measurement of expressed emotion may be particularly important, because it has been shown to impact relapse rates in adults (Leff & Vaughn, 1985) and is positively correlated with outcomes for a variety of childhood psychiatric and medical disorders (Wamboldt & Wamboldt, 2000).

Other Assessment Issues

Personality assessments are standard components of psychological practice. However, no evidence supports the discriminative validity of objective or projective measures of personality

when assessing EOS. Whereas measures such as the Rorschach Inkblot Test or the Thematic Apperception Test have been used by many clinicians to identify psychotic thinking processes, no projective assessment has demonstrated an ability to increase the diagnostic accuracy of EOS. Objective personality tests, including the Minnesota Multiphasic Personality Inventory—Adolescent Edition (MMPI-A) and the Millon Adolescent Clinical Inventory (MACI), are also of limited clinical utility in terms of diagnosis. Instead, they may provide information about comorbid diagnoses and global personality functioning.

Differential Diagnosis

When assessing a child or adolescent with symptoms suggestive of schizophrenia, a thorough diagnostic evaluation is needed to rule out other conditions that present with similar symptomatology and to identify comorbid disorders. Overall, an accurate assessment includes a thorough review of presenting symptoms, course and premorbid functioning, adherence to DSM-IV-TR or ICD-10 criteria, familiarity with how psychotic symptoms present in this youth age group, and determination of family psychiatric history. However, discriminating among these various disorders still may be difficult, especially at the initial presentation, and periodic diagnostic reassessments are always indicated (AACAP, 2001).

Schizophreniform Disorder

Schizophreniform disorder is diagnosed when the duration of illness has not yet reached 6 months. Most of the cases are presumed to meet full criteria eventually for a schizophrenia spectrum disorder, and are treated accordingly.

Psychotic Disorder Not Otherwise Specified

A diagnosis of psychotic disorder not otherwise specified (PD NOS) simply implies that criteria for a defined psychotic illness have not been met. This term is used broadly in clinical settings, perhaps in part based on reticence to label youth with schizophrenia (McClellan, McCurry, Speltz, & Jones, 1999). However, this classification has also been used in research to describe youth with transient or atypical reports of psychotic symptoms, some of whom likely do not have a true psychotic illness. In

the NIMH Childhood Schizophrenia Study, adolescents with PD NOS had similar significant overall impairment, and risk factor profiles and neurobiological abnormalities to those with EOS (Kumra, Jacobsen, et al., 1998; Kumra, Wiggs, et al., 1998; Kumra et al., 2000). Half of those with PD NOS received a later diagnosis of a psychotic mood disorder (e.g., schizoaffective disorder, bipolar disorder, major depressive disorder with psychotic features; Nicolson et al., 2001).

In a prospective study of youth with psychotic disorders, subjects with PD NOS were more likely to have been abused and to have a diagnosis of PTSD in comparison to those with EOS or bipolar disorder (Hlastala & McClellan, 2005). This suggested that their psychotic symptoms may be posttraumatic phenomena, and, clinically, these cases often met criteria for borderline personality disorder. In this study, none of the subjects with PD NOS went on to develop schizophrenia.

Schizoaffective Disorder and Mood Disorders

Schizophrenia, schizoaffective, and psychotic mood disorders (especially bipolar disorder) may present with psychotic symptoms (AACAP, 2001). In children and adolescents with schizophrenia, negative symptoms may be mistaken for depression, especially since it is common for patients to experience dysphoria with their illness. Alternatively, mania in teenagers often presents with florid psychosis, including hallucinations, delusions, and thought disorder (Pavuluri et al., 2004). Psychotic depression may present with mood congruent or incongruent hallucinations or delusions (AACAP, 1998a).

This overlap in symptoms increases the likelihood of misdiagnosis at the time of onset. Historically, approximately one-half of adolescents with bipolar disorder were originally misdiagnosed as having schizophrenia (AACAP, 1997). Awareness of the phenomenon changed diagnostic practices, but did not necessarily improve accuracy (McClellan et al., 1993, 1999). Longitudinal reassessment is needed to ensure accuracy of diagnosis. Family psychiatric history may also be a helpful differentiating factor. Psychotic illnesses have a strong familial component. Therefore, if a youth with psychosis has a close relative with a psychotic disorder, then it is likely that he or she has the same illness.

Youth with bipolar disorder tend to have more mood-congruent delusions and a lower percentage of hallucinations, loosening of associations, and negative symptoms than those with schizophrenia (Calderoni et al., 2001; McClellan et al., 2002; Pavuluri et al., 2004). Bipolar disorder is also more likely to be associated with grandiose delusions, pressured speech, irritability, depression, and elevated mood (Pavuluri et al., 2004). In addition to differences during the acute phase of illness, youth with schizophrenia have higher rates of pre-morbid social withdrawal and global impairments than do youth with bipolar disorder (McClellan et al., 2003). Furthermore, psychotic symptoms, by definition, must only present during active periods of depression or mania for a diagnosis of bipolar disorder (see Youngstrom, Chapter 6, this volume).

Schizoaffective disorder and major depression with psychotic features may be the most difficult disorders to distinguish from schizophrenia (Calderoni et al., 2001). Negative symptoms of EOS are sometimes mistaken for depression, especially because dysphoria is commonly experienced as a part of EOS. Although an accurate picture of the temporal overlap between mood episodes and psychotic symptoms can be extremely difficult to obtain, this retrospective understanding is necessary to distinguish between EOS and other psychotic disorders. For a diagnosis of depression with psychotic features, psychosis is only present in the context of a severe major depressive episode.

A diagnosis of schizoaffective disorder requires that one meet diagnostic criteria for both schizophrenia and mood disorders independently, over the course of illness. Early-onset schizoaffective disorder has not been well studied in this age group. Follow-up studies of psychotic youth have found low rates of this condition (McClellan et al., 1993; Stayer et al., 2005; Werry et al., 1991). However, the diagnosis is commonly used in clinical settings, perhaps unreliably, since many youth with mood and behavioral dysregulation problems are now characterized as having schizoaffective disorder without clear evidence of true psychosis (McClellan & Hamilton, 2006).

General Medical Conditions

As described earlier, all youth who are evaluated for EOS should receive a comprehensive

medical evaluation to rule out a medical cause of symptoms. Given the significant rates of comorbid substance abuse in adolescents with schizophrenia (as high as 50% comorbidity in some studies), it is common to obtain a history of substance abuse at the first onset of psychotic symptoms (Kumra, Thaden, et al., 2005; McClellan et al., 1993, 2002; McClellan & McCurry, 1998). Patients with a substance-induced psychosis generally present with an acute onset of psychotic symptoms that are temporally related to the intake of the drug. Psychostimulants can produce paranoid delusions and disorientation, whereas hallucinogens may produce vivid hallucinations and delusions. Substance intoxication and/or withdrawal can also induce delirium, which is associated with fluctuating mental status, varied levels of consciousness, and altered short-term memory. If psychotic symptoms persist significantly beyond documented detoxification from the abused substance(s), the clinician must consider the diagnosis of a primary psychotic disorder. In adolescents, it is not uncommon for the first psychotic break to occur with comorbid substance abuse, which may be an exacerbating (and possibly a triggering) factor rather than a primary etiological agent (Kumra, Thaden, et al., 2005).

Nonpsychotic Behavioral and/or Emotional Disorders

Youth with conduct disorder and other non-psychotic emotional disorders may report psychotic-like symptoms and, as a result, be improperly diagnosed as having a primary psychotic disorder (Del Beccaro et al., 1988; Garralda, 1984a, 1984b; Hlastala & McClellan, 2005; Hornstein & Putnam, 1992; McClellan et al., 1993; McClellan & Hamilton, 2006). When compared to youth with psychotic disorders, these youth have lower rates of negative symptoms, bizarre behavior, and thought disorder (Hlastala & McClellan, 2005). At follow-up, an increase in personality dysfunction, including personality disorders but not psychotic disorders, has been found (Garralda, 1984a, 1984b; Lofgren et al., 1991; McClellan et al., 1993; Thomsen, 1996).

Youth who report atypical, psychotic-like phenomena may have problems with tumultuous relationships, and behavioral and affective dysregulation, and are often described as having borderline characteristics (McClellan & Hamilton, 2006). At follow-up, these youth

do not seem to have an increased risk for schizophrenia or affective disorders (Lofgren, Bemporad, King, Lindem, & O'Driscoll, 1991; Hlastala & McClellan, 2005). Their reported hallucinations and delusions may be associated with dissociative symptoms, especially when there is a history of abuse or neglect (Altman, Collins, & Mundy, 1997; Hlastala & McClellan, 2005; Hornstein & Putnam, 1992). Maltreated youth, especially those with PTSD, report significantly higher rates of psychotic symptoms than controls (Famularo, Kinscherff, & Fenton, 1992). However, the lack of observable psychotic phenomena, such as formal thought disorder, plus the characteristics of their relationship skills help to distinguish between such youth and those with schizophrenia.

Pervasive Developmental Disorders and Autism

Autism and pervasive developmental disorder (PDD) are distinguished by the absence or transitory nature of psychotic symptoms and the predominance of the characteristic deviant language patterns, aberrant social relatedness, and other key symptoms that characterize these disorders (see Ozonoff, Goodlin-Jones, & Solomon, Chapter 10, this volume; Kolvin, 1971; Volkmar et al., 1988; Volkmar & Cohen, 1991). The onset of schizophrenia is later than that of autism, although some youth with schizophrenia have early premorbid histories of developmental delays (Alaghband-Rad et al., 1995; Russell et al., 1989; Watkins et al., 1988). However, compared to autism, the premorbid abnormalities in EOS tend to be less pervasive and severe. It is important to recognize that symptoms of schizophrenia include social withdrawal and communication problems, which are also criteria for PDD. Schizophrenia is an exclusion criterion for autism and, when present, supercedes the diagnosis of PDD.

Obsessive–Compulsive Disorder

Youth with obsessive–compulsive disorder have intrusive thoughts and repetitive ritualistic behaviors, symptoms that may be difficult to differentiate from psychosis. Patients with obsessive–compulsive disorder generally recognize their symptoms as unreasonable and excessive products of their own thinking (although this may not be the case for young

children) (AACAP, 1998b). Conversely, psychotic symptoms are usually experienced as phenomena occurring independently of the patient's own cognitive processes. However, some obsessive–compulsive symptoms are so severe that distinguishing them from delusions is difficult. Conversely, patients with schizophrenia may have significant obsessive–compulsive features. Therefore, assessment of disorganized thought and behavior, negative symptoms, and other psychotic symptoms is key to differentiating between these disorders.

Other Disorders

Other disorders that need to be differentiated from schizophrenia include speech problems, language disorders, and developmental disorders. Youth with language and communication problems may be mistakenly diagnosed as having a thought disorder. Such children and adolescents do not, however, have other prerequisite symptoms of schizophrenia, such as hallucinations, delusions, or odd social relatedness (Baker & Cantwell, 1991).

TREATMENT

An accurate diagnostic assessment is needed for appropriate treatment. Effective treatment of schizophrenia requires both intensive psychopharmacological and psychosocial interventions (Lehman et al., 2004). In adults, early diagnosis and treatment improve outcome (Harrison et al., 2001). Therefore, it is important that the diagnosis be made when the illness first presents (Shaeffer & Ross, 2002). As Shaeffer and Ross also highlight, misdiagnosis and inadequate treatment are common in children with EOS.

A comprehensive multidisciplinary approach is generally required to address adequately the complexity of the disorder (AACAP, 2001), with the goals of reducing symptomatology, morbidity, and relapse rates, while maintaining patients in their homes and communities. Only a few randomized studies have demonstrated the efficacy of either typical or atypical antipsychotic medications for EOS (Kumra et al., 1996; Pool, Bloom, Mielke, Roniger, & Gallant, 1976; Realmuto, Erikson, Yellin, Hopwood, & Greenberg, 1984; Sikich et al., 2004; Spencer, Kafantaris, Padron-Gayol, Rosenberg, & Campbell, 1992). Thus, current

pharmacological practices are largely informed by clinical experience, case reports, and the adult literature (AACAP, 2001). Psychosocial interventions such as cognitive-behavioral psychotherapy (Rector & Beck, 2001) and family psychoeducation and support interventions (for a review, see McDonell & Dyck, 2004) may also be effective in reducing symptoms in youth with EOS. The one study that has investigated the efficacy of a psychosocial treatment in those with EOS yielded promising results (Rund, Moe, Sollien, & Fjell, 1994).

The diagnostic assessment dictates other important domains of treatment planning, including comorbid disorders, cognitive functioning, and academic functioning. Treatments are needed to address these associated areas. Finally, systematic assessment is also important when measuring treatment effectiveness.

SUMMARY AND CONCLUSION

EOS is a neurodevelopmental disorder associated with significant morbidity and chronic impairment. Assessment should include clinician interview with multiple informants, observation and mental status examination, clinician rating scales, record review, and comprehensive medical evaluation. In addition, cognitive, academic, functional, and family assessments may assist in treatment planning. Future research is needed to improve the reliability, validity, and feasibility of assessment tools designed to measure EOS. As advancements in genome and neurodevelopmental sciences occur, mechanisms underlying the disorder are likely to be elucidated, leading to improved diagnostic, treatment, and prevention strategies.

Intellectual Disability (Mental Retardation)

Benjamin L. Handen

The field of intellectual disability, or mental retardation, went through a number of sweeping changes during the latter half of the 20th century. The catalyst for such changes began in the 1960s, with the movement to deinstitutionalize residents in State schools for individuals with intellectual disability. Today, almost 50 years later, a significant number of institutions have closed, and it is the exception rather than the rule that a child or adult with intellectual disability is placed in such a large group setting. Over this same period of time, an important series of laws were enacted, guaranteeing appropriate educational services for children with intellectual disability, beginning with Public Law 94-142 in 1975, in which the concepts of normalization and least restrictive environment were stressed. Others, such as Public Law 99-457, enacted in 1986, recognized the need for comprehensive early intervention and enhanced educational services for infants and young children with disabilities (including intellectual disability). And most recently, we have seen a growing movement to include children with intellectual disability in our schools and communities (the Individuals with Disabilities Education Act [IDEA], 1990, 2004). This is exemplified by the inclusion of children with intellectual disability on a full-time basis in classrooms with typically developing peers.

With such significant changes in the field, assessing children with intellectual disability has become evermore challenging. It requires knowledge of the service delivery system, and etiological and developmental issues; the ability to work with families; experience in using and adapting standardized assessment tools; and an understanding of the legal rights of children and their families, and best clinical practices for assessment and intervention. My purpose in this chapter is to present best practices guidelines for the assessment of children with intellectual disability that take into account the rapidly changing service delivery system.

HISTORY

Treatment of individuals with intellectual disability and other disabilities has changed considerably during the past 200 years (Wolfensberger, 1969; Zigler & Hodapp, 1986). Significant changes in the field of intellectual disability in the United States began in the middle of the 19th century. This was motivated largely by the work of Edouard Seguin in France, who felt that individuals with a variety of handicapping conditions could be taught, if provided appropriate training. During this same period of time, a number of schools for children and adults with intellectual disability

(as well as training centers for deaf, blind, or mentally ill individuals) were established. These early institutions were based on the principle of “moral education,” which assumed that, through education, individuals with intellectual disability could be elevated to a level of normal human existence. However, only a small percentage of individuals with intellectual disability were able to return successfully to society and independent living situations. Gradually, institutions began to change in character, serving a less educational and a more custodial purpose to protect individuals with intellectual disability from society (Wolfensberger, 1969).

With the publication of Galton’s work on genius across British families, Dugdale’s (1910) study of the Juke family, and Goddard’s (1913) study of the Kallikaks, there became greater acceptance of the role of heredity in intelligence. Related studies reported that adults with intellectual disability had higher than expected rates of illegitimacy, criminality, and poverty (see Baumeister, 1970). At around this same time, intelligence testing was introduced to the United States by Henry Goddard and quickly gained popularity. Repeated testing by Goddard of individuals with intellectual disability found little improvement in intellectual functioning over time (see Zigler & Hodapp, 1986). The number of institutions also grew, with placement farther from urban areas, as the role of the institution changed to that of protecting society from individuals with intellectual disability. As public fears grew, the first eugenics laws were passed in the early 20th century, requiring the forced sterilizations of men and women with intellectual disability. By 1936, 25 States had passed such laws (see Zigler & Hodapp, 1986). With the exception of a few experiments in the provision of community services, institutions and the number of individuals residing in them grew steadily until the 1960s.

According to Zigler and Hodapp (1986), the deinstitutionalization movement began in earnest in the 1960s, due in large part to four events and trends. First, a number of individuals made public the deplorable conditions in some of our nation’s institutions. This included publication of *Christmas in Purgatory* (Blatt & Kaplan, 1966), a pictorial documentary of several institutions, as well as increased media attention (such as a television exposé of the Willowbrook facility in Staten Island by Geraldo Reviera). Second, the National Associ-

ation for Retarded Citizens began to apply increasing political pressure to change institutions. Third, was the development of the principle of “normalization,” which promotes the idea that individuals have the right to experience a life-style that is as normal as possible. Finally, laws such as Public Law 94-142, were enacted, stressing the doctrine of “least restrictive environment.” This law, known as the Education for All Handicapped Children Act of 1975, mandated “a free appropriate public education” as a right for all children, regardless of level of impairment of disability. All children were to be placed in the “least restrictive” school environment and provided with an Individual Education Program (IEP).

Today we have a wide continuum of services for children with intellectual disability: from early intervention programs for infants to developmental preschool programs, and from special education programs in regular public schools to full inclusion programs. The goal of today’s service provider is to include children within the community in the least restrictive setting.

The enactment of recent laws affecting individuals with disabilities, as well as changes in the service provision model, have significantly influenced assessment practices. For example, with the enactment of Public Laws 94-142 (1975) and 99-457 (1986), families have been given a more central role in the assessment and decision-making process. Additionally, with the use of the IEP, children and adolescents with disabilities must receive programming designed to meet their individual needs rather than simply being fitted into existing programs or services. Consequently, assessment must focus on identifying a child’s or adolescent’s strengths and deficits to develop an appropriate educational program. As I discussed below, the definition of “intellectual disability” itself is now more functionally based, stressing both cognitive and functional deficits (American Association on Mental Retardation [AAMR], 2002).

DEFINITION OF INTELLECTUAL DISABILITY/ MENTAL RETARDATION

“Intellectual disability” (mental retardation) refers to a particular state of functioning that begins prior to age 18, characterized by significant limitations in both intellectual functioning

and adaptive behavior (AAMR, 2002). The definition of “intellectual disability” has been revised a number of times during the past few decades as our understanding of the disorder has changed, and in response to various consumer, professional, political, and social forces. Even now, there is some controversy regarding how one defines and diagnoses intellectual disability (AAMR, 2002). Yet without an agreed-upon definition, it is difficult for professionals to understand fully the nature of this disorder and to make significant gains in improving the lives of children and adults with intellectual disability (Zigler & Hodapp, 1986). The confusion in this area can be illustrated by examining changes in the definition of “intellectual disability” adopted by the American Association on Intellectual and Developmental Disabilities (AAIDD; previously known as the American Association on Mental Deficiency [AAMD] and the American Association on Mental Retardation [AAMR]) during the past half-century.

In 1959 the AAIDD definition of “intellectual disability” specified that individuals with IQ scores one standard deviation or greater below the mean of 100 were considered to have intellectual disability (Heber, 1959). With most IQ tests having a mean of 100 and a standard deviation of 15–16 points, this placed a significant portion of the population (up to 16%, or 32 million people) in this group. The definition was amended in 1973 to a two standard deviation cutoff (IQ below 70), thereby lowering the incidence of intellectual disability to around 2–3%, or 6 million individuals. The subsequent 1983 revision of the AAIDD definition read as follows: “Mental retardation [intellectual disability] refers to significantly subaverage intellectual functioning resulting in or associated with impairments in adaptive behavior and manifested during the developmental period” (Grossman, 1983, p. 11). This definition involved three specific factors: (1) intellectual functioning below 70, (2) associated adaptive deficits, and (3) deficits occurring prior to age 18. Whereas this revision represented an improvement over earlier attempts to define intellectual disability, it also placed greater emphasis than did prior definitions on associated deficits in adaptive functioning. This created some difficulties, because few, if any, reliable and valid measures of adaptive functioning were available at the time, and there was little agreement over both the definition of “adap-

tive behavior” and how to assess it (Zigler & Hodapp, 1986).

Basing a diagnosis of intellectual disability on an IQ score alone was not without its problems as well. For example, the past few decades have seen much criticism of the use of intelligence tests for school placement purposes, because of concerns that such tests are biased against certain minorities (Hawkins & Cooper, 1990). Therefore, using a single factor, such as a score on an IQ test, to define intellectual disability may have resulted in a greater number of children from minority groups being labeled with intellectual disability and placed in special education classes. Such concerns were reflected in a 1974 court decision in California (*Larry P. v. Riles*, 1974), in which the use of IQ tests for purposes of special education placement by California school districts was eliminated.

1992 AAIDD Definition

In 1992, the AAIDD proposed and adopted a new definition that reads as follows:

Mental retardation [intellectual disability] refers to substantial limitations in present functioning. It is characterized by significantly subaverage intellectual functioning, existing concurrently with related limitations in two or more of the following applicable adaptive skills areas: communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work. Mental retardation manifests before age 18. (AAMR, 1992, p. 5)

Three aspects of this new definition were controversial. First, the IQ range had again been changed, this time suggesting “an IQ standard score of approximately 70 to 75 or below” (p. 5). The second concern about this new definition was the requirement that up to 10 areas of adaptive functioning be assessed. However, there continued to be no agreed-upon parameters for assessing adaptive behavior in a number of these areas (MacMillan, Gresham, & Siperstein, 1995). Finally, the new definition eliminated the previously used classification system that divided individuals with intellectual disability into four IQ categories based on level of cognitive functioning (*Mild*, *Moderate*, *Severe*, and *Profound*), opting instead for a classification system based the level and intensity of supports needed (*Intermittent*, *Limited*, *Extensive*, and *Pervasive*) by individuals across a range of domains.

With the elimination of IQ as a means of describing individuals' levels of functioning, there was no clear substitute terminology. Many researchers, educators, and providers criticized the elimination of the severity levels, because it was no longer possible to classify individuals with intellectual disability. Additionally, the use of levels of support had no psychometric properties, making them subjective and unreliable. At the same time, the use of intensity levels (i.e., levels of support) was felt to be cumbersome. The elimination of severity levels even affected teacher certification requirements in some states, where teachers were specifically certified in *Severe/Profound* or *Mild/Moderate* mental retardation. Although proponents argued that the intensity levels were not meant to be psychometrically sound, these levels were often used as if they were. Others were concerned that the number of individuals diagnosed with intellectual disability would increase when the IQ cutoff was raised from 70 to "70 to 75." It was feared that this would result in an overrepresentation of minorities diagnosed with intellectual disability. Finally, there were issues related to the imprecision of the 10 adaptive behavior domains, which had not been determined empirically.

2002 AAIDD Definition

The most recent, 2002, AAIDD definition of intellectual disability contains a number of noteworthy revisions. First, the 2002 revision resulted in a return to the two standard deviation IQ test cutoff for intellectual disability (lowering the cutoff from a standard score of "70 to 75" back to 70). Second, IQ range was once again deemed appropriate for use in describing individuals with intellectual disability (i.e., individuals could be described as having *Mild*, *Moderate*, *Severe*, or *Profound* levels of mental retardation). Third, a revision in the definition of adaptive behavior deficits was made. Whereas the 1992 AAIDD definition required specific deficits in at least 2 of 10 specific skills areas, the 2002 definition requires significant limitations in "adaptive behavior as expressed in conceptual, social and practical adaptive skills" (AAMR, 2002, p. 1). These three broader domains were felt to be more consistent with available research on adaptive behavior. However, the support intensity needs were retained as well, because feedback from many families and individuals with intellectual

disability indicated a preference for the shift away from a focus on impairment to one describing the supports necessary for an individual; the focus on supports was also felt to provide guidance regarding the types of services needed (Polloway, 1997, p. 176).

As discussed in the newest AAIDD publication on definition, classification, and systems of support in mental retardation (AAMR, 2002), there was also some controversy regarding the names for the various subtypes of mental retardation, as well as pressure to explore an alternative to the term "mental retardation" itself. MacMillan, Siperstein, and Gresham (1996) proposed using the terms "cognitive impairment" or "general learning disability" for individuals with mild mental retardation. This same group recommended that the term "mental retardation" be reserved for individuals with organicity. Many European professional journals had been using the term "intellectual disability" in place of the term "mental retardation." This same terminology was recently accepted by the AAIDD Board of Directors, and in 2007 the name of the Association was officially changed from the AAMR to the AAIDD. In this chapter I use the terms "mental retardation" and "intellectual disability" interchangeably, because not all organizations and systems serving this population have accepted this new terminology.

CLASSIFICATION

A number of ways have been developed to classify children with intellectual disability during the past few decades. Such systems are clearly required due to the heterogeneous makeup of this group of individuals and serve a number of purposes. Most importantly they serve as a means of distinguishing between subgroups to determine level and intensity of required services and to examine long-term prognosis and treatment outcome. The two most common means of classification involve division by either functional ability or etiology. In some aspects, these two systems have considerable overlap.

Different professional groups have tended to develop their own classification systems. For example, as discussed earlier, in 1992, the AAIDD adopted a system based on level of support needed (*Intermittent*, *Limited*, *Extensive*, and *Pervasive*). Conversely, the American

Psychiatric Association chose to retain levels of cognitive functioning to describe individuals with intellectual disability (i.e., mild, moderate, severe, and profound mental retardation). Educators have used a separate system of classification based on IQ level, with associated deficits in adaptive functioning (e.g., Special Education Services, 1990; West Virginia Department of Education, 1985). Consequently, it is important that clinicians who assess children with intellectual disability both understand the different classification systems and be able to move comfortably among these systems, depending on the agency with which one is communicating.

The 1973 and 1983 AAIDD definitions of intellectual disability divided severity of disability into four categories (mild, moderate, severe, and profound mental retardation), a classification system that continues to have widespread acceptance and use (see Table 12.1). Children who function within the mild range of mental retardation comprise approximately 85% of children diagnosed with intellectual disability. Most children with mild mental retardation can be expected to succeed within an academic curriculum, although most will remain below their typically developing peers in terms of reading and arithmetic levels. Many of these children participate in vocational training and succeed in competitive employment, and live independent and self-supporting lives. Children with moderate mental retardation comprise approximately 10% of children with intellectual disability. The curriculum for these individuals often focuses on life skills and functional academics. With proper vocational training and community support, individuals with moderate mental retardation may be able to manage competitive, or semicompetitive, employment situations. Children with severe mental retardation make

up approximately 3.5% of the population of children with intellectual disability. These individuals typically have less extensive communication and social skills. A more life-skills, functional curriculum is often provided, with emphasis on self-help skills. Finally, less than 1.5% of children with intellectual disability fall in the category of profound mental retardation. These children tend to develop very basic communication skills and limited self-help skills.

Schools have tended to develop their own classification systems for purposes of educational placement. Terms such as “classrooms for the educable mentally retarded” (for children functioning in the mild range of mental retardation) or for the trainable mentally retarded (children functioning within the moderate range of mental retardation) have been used for some time. However, with the growing trend of inclusion practices, such educational labels may be of little use. Some districts have moved toward more functional descriptors for children’s needs, because placement is less and less likely to be based on level of cognitive functioning. Instead, appropriate services follow the child, who may be served in any number of settings, including the regular education classroom.

An alternative classification system divides individuals based on etiology. It has been generally accepted that between 25 and 50% of individuals with intellectual disability have an organic etiology for their cognitive and adaptive skills deficits. Specific biomedical causes have been found in as many as 70% of individuals with severe/profound mental retardation (Shapiro, 2002). The remaining individuals are assumed to have intellectual disability due to psychosocial or familial factors. However, both the AAIDD (AAMR, 1992, 2002) publications on the definition and classification of intellectual disability suggested that this two-factor

TABLE 12.1. Classification of Mental Retardation

Level of mental retardation	IQ range	Approximate mental age in adulthood	% of persons with mental retardation at this level
Mild	55–69	8 years, 3 months to 10 years, 9 months	85.0
Moderate	36–51	5 years, 7 months to 8 years, 2 months	10.0
Severe	20–35	3 years, 2 months to 5 years, 6 months	3.5
Profound	<20	<3 years, 2 months	1.5

Note. From Sattler (2002, p. 337). Copyright 2002 by Jerome M. Sattler, Publisher. Adapted by permission.

classification system was no longer appropriate. First, as Masland (1988) argued, simply because there is no known cause for the presence of an intellectual disability does not necessarily mean that an organic etiological explanation does not exist. It may be that our knowledge and technology are not yet at an advanced enough stage to detect many of the causes of intellectual disability. For example, not until 1969 was fragile X syndrome discovered (Lubbs, 1969). This syndrome may account for a considerable number of males with intellectual disability and is caused by what appears to be a pinching of the tips of the long arm of the X chromosome. Similarly, during the past few decades, there has been a greater appreciation of the potential adverse effects of environmental teratogens, such as lead poisoning, even at subclinical levels (Mendola, Selevan, Gutter, & Rice, 2002). The current view is that intellectual disability has multiple causal factors, including genetic predisposition, environmental insults, developmental vulnerability, heredity, and environment (Harris, 2006). Consequently, the AAIDD proposed a multifactorial approach to etiology, involving the following four categories (AAMR, 2002, p. 127):

1. *Biomedical*: factors that relate to biological processes, such as genetic disorders or nutrition.
2. *Social*: factors that relate to social and family interaction, such as stimulation and adult responsiveness.
3. *Behavioral*: factors that relate to potentially causal behaviors, such as dangerous (injurious) activities or maternal substance abuse.
4. *Educational*: factors that relate to the availability of educational supports that promote mental development and the development of adaptive skills.

PREVALENCE OF INTELLECTUAL DISABILITY

There are about twice as many males as females among individuals with mild mental retardation; the male to female ratio decreases somewhat to 1.5:1.0 among those with severe mental retardation (Chiurazzi & Oostra, 2000). Historically, the incidence of intellectual disability in the United States has been estimated to be approximately 3% of the population (Heward, 2006). Based on the normal dis-

tribution of intelligence, approximately 2.3% of the population would be expected to fall two standard deviations below the mean IQ of 100 (i.e., IQ below 70). On the one hand, this could be seen as a slight underestimate, because it fails to take into account those individuals whose intellectual disability is due to organic factors that would not reflect normal variations in intelligence. On the other hand, basing estimates of the incidence of intellectual disability on IQ alone may result in a considerable *overestimate* of the true prevalence rate. Two recent studies suggest incidence rates of closer to 1% if significant deficits in both IQ and adaptive functioning are required for a diagnosis of intellectual disability (Fujiura, 2003; Larson et al., 2001). Another factor making it difficult to determine easily the “true” incidence of intellectual disability is that differences exist in reported rates across age groups. For example, infants, toddlers, and preschoolers are generally not diagnosed with intellectual disability unless a child evidences severe developmental delays. Conversely, the incidence of intellectual disability seems to be greatest at school age, when children having learning difficulties are typically assessed and diagnosed. Yet even recent estimates from the U.S. Office of Special Education Programs (2004) indicates that only around 1% of students receive special education due to cognitive deficits. McLaren and Bryson (1987) reported that the prevalence of intellectual disability in children peaks between 10 and 14 years of age, because children with milder impairments tend to be identified much later than children who are more severely involved. Once individuals reach adulthood, the reported rate of intellectual disability decreases, due in part to the fact that once the academic demands of school end, some adults with previous diagnoses of intellectual disability obtain jobs, evidence only minimal adaptive skills deficits, and need few, if any, supportive services. According to the 2002 AAIDD definition of mental retardation, such individuals may no longer meet criteria for a diagnosis of intellectual disability.

Clinicians are generally reluctant to make a diagnosis of intellectual disability in children under 5–6 years of age, preferring instead to use the term “development delay.” The reasons for this are threefold, according to Fotheringham (1983): (1) Measurement of intelligence in infants and preschoolers, which focuses primarily on developmental progress, is

not always reliable; (2) other conditions (e.g., cerebral palsy, aphasia) may affect communication or motor skills required to assess intelligence; and (3) various family circumstances, such as neglect or abuse, may adversely affect functioning (whereas functioning may improve as these issues are addressed). Children with developmental delays should receive intervention services and periodic reassessment to assist in determining whether diagnosis of intellectual disability should eventually be made.

The reliability of early intelligence testing is highly dependent upon factors such as age of the child and level of cognitive functioning. Assessment of infants tends to focus on developmental progress, especially sensory-motor functions. Thus, infant tests do not assess the same factors as those designed for children at and above preschool age. Assessment results during infancy that suggest average or above functioning have little predictive power (Sattler, 2001). Conversely, for infants whose scores suggest a developmental disability, there is a much higher correlation with later functioning. For example, Brooks-Gunn and Lewis (1983) found that 73% of a group of infants who had tested within the moderate to profound range of mental retardation continued to be classified with intellectual disability 1 to 3 years later. However, this study did not include infants with milder delays. Sattler (2001) rightfully cautioned that such findings are based on group data, that no diagnosis should be based on a single score, and that infants may have very individualized rates of development. Test scores have been found to be rather unstable for otherwise normally developing preschoolers. Conversely, such scores tend to be fairly stable for preschoolers with disabilities in the cognitive domain (Kamphaus, 2001). In general, children's intelligence test scores appear to stabilize around 6 years of age (Kamphaus, 2001). It is around this period of time (which correlates with entry to school) that clinicians are likely to begin to use the term "intellectual disability" (rather than "developmental disability") for children who continue to evidence significant deficits in cognitive and adaptive functioning.

CAUSES OF INTELLECTUAL DISABILITY

Approximately 70% of individuals with severe mental retardation and 50% of individuals

with mild mental retardation have an organic or biological basis for their disorder (McLaren & Bryson, 1987). Some children's cognitive deficits may simply reflect the lower end of the normal IQ distribution (Achenbach, 1982). In such cases, functioning represents an interaction of both genetic and environmental factors. Factors such as poverty, neglect, abuse, limited stimulation, and poor parent-child interactions are but a few of the psychosocial factors that have been found to be related to intellectual functioning (AAMR, 2002). In attempting to determine possible biological causes of intellectual disability in an individual, three time spans should be examined: prenatal onset, perinatal onset, and postnatal onset. Table 12.2 outlines the general hypotheses and strategies for determining possible causes of intellectual disability for each of these areas. It should be noted that the presence of a particular etiology in and of itself does not indicate that an individual will have an intellectual disability. For example, approximately 50% of individuals with cerebral palsy have intellectual disability. Other disorders, such as neurofibromatosis, involve a gradual regression in skills and cognitive functioning over time. Consequently, a child with this disorder may exhibit age-appropriate functioning during early assessments but will likely be diagnosed with intellectual disability at some later point in time.

According to the American Psychiatric Association (APA; 2000), heredity accounts for about 5% of cases of intellectual disability; inherited factors include metabolic errors present at conception (e.g., Tay-Sachs disease), single-gene anomalies with Mendelian inheritance patterns and varying expression (e.g., tuberous sclerosis), and chromosomal abnormalities (e.g., translocation Down syndrome). Early alterations of embryonic development account for approximately 30% of intellectual disability cases and include chromosomal aberrations (e.g., trisomy 21 Down syndrome) or toxin-induced prenatal injury (e.g., maternal alcohol consumption). Postnatal problems account for about 6% of cases; these include fetal malnutrition, hypoxia, various infections, and traumas. General medical conditions acquired in infancy or childhood account for approximately 5% of cases and include traumas, infections, and poisoning. Finally, environmental influences (e.g., deprivation) and other mental disorders (e.g., autism) account for approximately 15-20% of cases.

TABLE 12.2. Hypotheses and Strategies for Determining Etiology

Hypothesis	Possible strategies
I. Prenatal onset	
A. Chromosomal disorder	<ul style="list-style-type: none"> • Extended physical examination • Referral to geneticist • Chromosomal analysis, including fragile X study and high-resolution banding
B. Syndrome disorder	<ul style="list-style-type: none"> • Extended family history and examination of relatives • Extended physical examination • Referral to clinical geneticist or neurologist
C. Inborn error of metabolism	<ul style="list-style-type: none"> • Screening for amino acids and organic acids • Quantification of amino acids in blood, urine, and/or spinal fluid • Analysis of organic acids by gas chromatography–mass spectroscopy or other methods • Blood levels of lactate, pyruvate, carnitine, and long-chain fatty acids • Arterial ammonia and gases • Assays of specific enzymes • Biopsies of specific tissue for light and electron microscopic study and biochemical analysis
D. Developmental disorder	<ul style="list-style-type: none"> • Computed tomographic (CT) scan of brain formation • Magnetic resonance imaging (MRI) scan of the brain
E. Environmental influence	<ul style="list-style-type: none"> • Growth charts • Placental pathology • Maternal history and physical examination of mother • Toxicological screening of mother at prenatal visits of child at birth • Referral to clinical geneticist
II. Perinatal onset	<ul style="list-style-type: none"> • Review maternal records (prenatal care, labor, and delivery) • Review birth and neonatal records
III. Postnatal onset	
A. Head injury	<ul style="list-style-type: none"> • Detailed medical history • Skull X-rays, CT, or MRI scan (for evidence of sequelae)
B. Infection	<ul style="list-style-type: none"> • Detailed medical history
C. Demyelinating disorder	<ul style="list-style-type: none"> • CT or MRI scan
D. Degenerative disorder	<ul style="list-style-type: none"> • CT or MRI scan • Evoked potential studies • Assays of specific enzymes • Biopsy of specific tissue for light and electron microscopy and biochemical analysis
E. Seizure disorder	<ul style="list-style-type: none"> • Electroencephalography
F. Toxic–metabolic disorder	<ul style="list-style-type: none"> • See “Inborn error of metabolism” (IC) • Toxicological studies, heavy metal assays
G. Malnutrition	<ul style="list-style-type: none"> • Body measurements • Detailed nutritional history • Family history of nutrition
H. Environmental deprivation	<ul style="list-style-type: none"> • Detailed social history • Psychological evaluation • Observation in new environment
I. Hypoconnection syndrome	<ul style="list-style-type: none"> • Detailed morphological study of tissue (Huttenlocher, 1991)

Determining the etiology of intellectual disability may be useful for a number of reasons. First, families often have a desire to understand why their children have cognitive and adaptive skills deficits. This may help with the process of coming to accept a child's difficulties and allow the family to move ahead to ensure that the child's needs are appropriately met. Second, if a genetic basis for a child's disability is identified, there may be a need for other family members, such as siblings or parents, to pursue genetics counseling for future planning. Third, with a clear etiology, one may be able to provide information on long-term course and the types of supports a child will be likely to need. Fourth, there may be clear treatment implications if certain etiologies are determined (e.g., phenylketonuria, hydrocephalus, lead intoxication, seizure disorders). Finally, determining the etiological basis for intellectual disability in general allows individuals to be placed into more homogeneous groupings and results in improved research in the field.

PSYCHIATRIC DISORDERS IN CHILDREN WITH INTELLECTUAL DISABILITY

Children and adolescents with intellectual disability can experience the entire range of psychiatric disorders and appear to be at greater risk than the general population for developing such disorders (Emerson, 2003; Quay & Hogan, 1999). In fact, the presence of behavioral and/or comorbid psychiatric disorders in children with intellectual disability may present the most significant obstacle toward inclusion in both educational and community settings (Johnson, 2002). A number of recent prevalence studies have documented that between 30 and 50% of children with intellectual disability have psychiatric diagnoses or behavior problems, which is up to three times that found among the typically developing population (Dekker & Koot, 2003a; Emerson, 2003; Linna et al., 1999; Stromme & Diseth, 2000). Such rates are consistent with those reported by Rutter, Tizard, Yule, Graham, and Whitmore (1976) in the Isle of Wight study. Whereas males and older children with intellectual disability appear to be at greatest risk for developing psychiatric disorders according to some studies (Emerson, 2003; Stromme & Diseth, 2000), this finding is less robust in others (Dekker & Koot, 2003a). Level of intellec-

tual disability does not appear to increase an individual's risk of a psychiatric diagnosis (Dekker & Koot, 2003a; Emerson, 2003; Stromme & Diseth, 2000). Outcome predictors for continued mental health problems appear to include poor social competence and daily living skills, child health problems, negative life events, and parental mental health issues (Dekker & Koot, 2003b)

Externalizing disorders, such as attention-deficit/hyperactivity disorder (ADHD) and conduct disorders, appear to be among the most common behavioral disorders diagnosed in children with intellectual disability (Emerson, 2003). Surveys indicate that between 9 and 16% of children with intellectual disability meet diagnostic criteria for ADHD, a rate that is three to five times greater than that of the general population (Dekker & Koot, 2003a; Emerson, 2003; Stromme & Diseth, 2000). Longitudinal studies have found that the majority of children with intellectual disability and ADHD continue to exhibit symptoms 2–4 years posttreatment (Aman, Pejeau, Wolford, Rojahn, & Handen, 1996; Handen, Janosky, & McAuliffe, 1997). Between 17 and 25% of children with intellectual disability exhibit conduct problems, with oppositional defiant disorder being the most commonly reported diagnosis (Dekker & Koot, 2003a; Emerson, 2003).

Estimates regarding the rate of internalizing disorders (e.g., anxiety, depression) among children and adolescents with intellectual disability are quite variable. Whereas surveys have reported the rate of anxiety disorders to range from 3 to 8.7% (Emerson, 2003; Linna et al., 1999), studies using structured diagnostic interviews of parents have found rates approaching 22% (Dekker & Koot, 2003a). Similarly, survey data indicate that depression among children and adolescents with intellectual disability is around 1.5%, whereas structured parent interviews suggest a rate above 4% (Dekker & Koot, 2003a; Emerson, 2003; Linna et al., 1999). Although diagnosis of an externalizing disorder is generally based on observable behavior, diagnosis of anxiety or mood disorders often requires the description of internal states. Consequently, the rate of internalizing disorders among individuals with intellectual disability is likely to be an underestimate, because the available data are based solely on parental reports of observable symptoms (e.g., crying, loss of appetite, difficulty sleeping),

without the additional benefit of a clinical interview of the child or adolescent.

In diagnosing psychiatric disorders in children and adolescents with intellectual disability, the clinician must often rely on observable behavior rather than self-report (MacLean, 1993). It is generally accepted that diagnostic criteria for psychiatric disorders, such as those found in DSM-IV-TR (APA, 2000) can be reasonably applied to children and adolescents functioning at IQs above 50. However, such criteria appear to be less appropriate for individuals functioning below that level (MacLean, 1993).

Numerous conditions with which the clinician should be familiar are often associated with specific maladaptive behavior disorders. For example, children with fragile X syndrome typically function in the mild to moderate range of mental retardation and often exhibit attentional deficits, hyperactivity, hand flapping, hand biting, perseverative speech, preoccupation with inanimate objects, shyness, and poor social interaction (Hagerman & Sobesky, 1989). Children with autism often engage in a range of maladaptive behaviors, such as stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping), impairments in social interactions, and deficits in communication (e.g., delayed expressive language development, stereotyped and repetitive use of language) (APA, 2000). Finally, Prader-Willi syndrome is characterized by mild mental retardation, impaired satiety, food-seeking behavior, and obesity (AAMR, 2002). The presence of specific maladaptive behaviors during an assessment may suggest that a particular disorder or syndrome be considered. This further informs the progress of the assessment, including the types of questions to be asked, the possible need for more extended observation of the child or adolescent, and the need for evaluation by clinicians in other professional fields (e.g., genetics, endocrinology). Similarly, when a child or adolescent with a specific disorder or syndrome is referred for evaluation, knowledge of the associated behavioral indices is necessary to guide the evaluation.

LEGAL ISSUES AND STATE POLICIES

The past few decades have seen the enactment of a number of laws that have significantly affected the assessment and delivery of

services for children and adolescents with intellectual disability. Among the most far-reaching pieces of legislation was the IDEA (Public Law 94-142), passed by Congress in 1975. This landmark piece of legislation resulted in significant changes in how children with intellectual and other disabilities are to be educated. The primary purpose of the IDEA is to “assure that all children with disabilities have available to them . . . a free appropriate public education which emphasizes special education and related services designed to meet their unique needs, to assure that the rights of children with disabilities and their parents or guardians are protected, to assist states and localities to provide for the education of all children with disabilities, and to assess and assure the effectiveness of efforts to educate children with disabilities” (IDEA, 1990, §1400[c]). The IDEA comprises six primary principles:

1. *Zero reject.* Schools were required to educate all children with disabilities, ages 6 through 17 years (states that provided educational services for children 3–5 and 18–21 years of age would also be required to provide educational services to children with disabilities in those age groups).

2. *Nondiscriminatory identification and evaluation.* All testing needed to be conducted in the student’s native language, and students could not be discriminated against based on race, culture, or native language. Placement decisions could not be based on a single test score.

3. *Free, appropriate public education.* All children, regardless of disabilities, were entitled to a free, appropriate public education, with an IEP developed for each child with special needs.

4. *Least restrictive environment.* Students were to be educated in the least restrictive school environment. School districts were required specifically to justify why a student could not participate with typical peers in academic classes and nonacademic activities (e.g., lunch, gym, transportation). School districts were also mandated to provide a continuum of placement options to meet the least restrictive needs of each student.

5. *Due process safeguards.* Parents who disagreed with the results of an evaluation or placement decision could obtain a due process hearing.

6. *Parent and student participation and shared decision making.* Both parents and the identified student were to be involved in decisions regarding the design and implementation of services.

In addition, to these six principles, the IDEA required that a student be provided with related services and assistive technology, if the disability prevented the child from fully participating in educational activities. Such services included special transportation, speech and language therapy, physical and occupational therapy, and counseling.

The IDEA was reauthorized in 1997 (Pub. L. 105-17) and again in 2004 (Pub. L. 108-446). It is now referred to as the Individuals with Disabilities Education Improvement Act of 2004. In addition to maintaining most of the original provisions, the reauthorized bill includes a number of new regulations. For example, school districts are now allowed to use funds to provide early intervention services (i.e., services for students who have not yet been identified with disabilities but are in need of academic and/or behavioral support). Paperwork has been reduced to increase teacher instruction time. Additionally, the bill provides funds for the training of school staff in effective teaching strategies and outlines steps to be taken to prevent overidentification of minority students. Furthermore, both the definition of a learning disability and the process for amending IEPs has been revised (providing greater flexibility in identifying students with learning problems) (Council for Exceptional Children, 2005). Additional updates on the reauthorized bill may be found on websites hosted by advocacy groups such as the Council for Exceptional Children (2005).

Another law that has had a significant impact on the provision of services to children with special needs was Public Law 99-457 (enacted in 1986). An amendment to the 1975 Public Law 94-142, it extended IDEA rights and protections to children ages 3–5 with developmental disabilities. Additionally, early intervention services for infants and toddlers (birth to 2 years of age) with developmental disabilities and their families were authorized. Infants and toddlers were determined to be in need of early intervention services if they were diagnosed with a physical or mental condition with a high probability of resulting developmental delay, or if they exhibited developmental delays in one or more of the fol-

lowing areas (as measured by an appropriate diagnostic instrument): cognitive development, physical development, language and speech development, psychosocial development, or self-help skills. An individualized family service plan was to be developed for identified infants and toddlers.

The clinician must be well versed not only in the provisions of certain federal laws but also have a working knowledge of state legal decisions affecting the assessment and placement of children in special education programs. For example, two court cases in the early 1970s (*Pennsylvania Association of Retarded Children (PARC) v. Commonwealth of Pennsylvania*, 1971, and *Mills v. Board of Education*, 1972) were “class actions” that established the legal rights of children with intellectual disability to a free public education and as normalized an educational placement as possible. Such cases set the stage for the enactment of laws such as Public Law 94-142. In 1974, a California court decision (*Larry P. v. Riles*) disallowed the use of IQ tests for purposes of classroom placement in that state, because standardized intelligence tests were found by the court to be racially and culturally biased. A number of other states have been affected by similar court decisions regarding the assessment and placement of minority children in special education.

Other court cases, such as *Bales v. Clark* (1981) and *Battle v. Commonwealth of Pennsylvania* (1981), focused on a school district’s responsibilities in meeting a child’s educational needs. In the former case, the family of a 13-year-old girl who had sustained a head injury following an accident requested that the district provide funding for the girl to attend a specialized private school located outside the district. The Eighth U.S. Circuit Court of Appeals in Virginia sided with the school district by ruling that costs may be considered in placement decisions. The court also ruled that the family need not be reimbursed for the cost of a tutor over the summer. Only in cases where irreparable loss of progress during the summer months could be documented would districts be required to provide year-round schooling. Conversely, in the latter case in Pennsylvania, the U.S. Court of Appeals for the Third Circuit recognized that some children who are severely or profoundly impaired tend to acquire skills more slowly and to forget what has been learned more quickly than their typically devel-

oping peers. Consequently, a school year limited to 180 days may not meet the requirement of a free, appropriate public education for such individuals. Cases such as these impact a family's ability to obtain year-round services for their child and may require that all those working with a child with intellectual disability carefully document the impact of summer breaks on that child's or adolescent's progress.

In addition to delineating the types of services school districts must provide for children with intellectual disability, courts have also had an impact on districts' ability to manage disruptive students. For example, in *Honig v. Doe* (1988), the Supreme Court held that school systems could not unilaterally exclude a child from the classroom for dangerous or disruptive behavior resulting from his or her disability. For a more detailed description of both relevant court cases and federal legislation concerning the education and rights of children with disabilities, see Heward (2006).

Finally, states often use different terminology to describe the continuum of available special education services. For example, children in Pennsylvania with mild mental retardation are often placed in learning support classrooms. However, in the neighboring state of Ohio, the same child would be placed in a classroom for developmental handicaps. Older terms for programs serving children with intellectual disability, such as "educable mentally retarded" (for children with mild mental retardation) and "trainable mentally retarded" (for children with moderate mental retardation) tend to be outdated and are less often used (Beirne-Smith, Patton, & Kim, 2006). States also use different cutoff scores for determining eligibility for special education services. For example, in Pennsylvania a child with an IQ of up to 79 and significant deficits in adaptive functioning may be labeled as having an intellectual disability and be eligible for special education services (Special Education Services and Programs, 1990). However, if the same child's family moves across the state line to West Virginia, he or she might not be identified as needing special services and could be placed in a regular classroom without supports (West Virginia Department of Education, 1985). Therefore, it is incumbent upon clinicians to become well versed in their state's terminology, regulations, and relevant court decisions that affect the assessment and service provision of children and adolescents with intellectual disability.

APPROACH TO ASSESSMENT

Sattler (2001) defines *assessment* as "a way of gaining some understanding of the child in order to make informed decisions" (p. 3). A child may be referred for evaluation by families, school districts, or mental health agencies, typically for one of five possible reasons (Sattler, 2001): (1) *screening*: a relatively brief evaluation to determine eligibility for a certain program or the need for more thorough assessment; (2) *focused/problem-solving assessment*: a more in-depth evaluation to answer a specific question (e.g., does the child have obsessive-compulsive disorder?); (3) *diagnostic assessment*: a detailed evaluation to identify strengths and weaknesses in a range of areas (e.g., cognition, adaptive behavior, achievement) that may result in recommendation for specific services; (4) *counseling/rehabilitation assessment*: similar to a diagnostic assessment, but with an emphasis on a child's ability to manage daily responsibilities; and (5) *progress evaluation assessment*: a means of assessing treatment effectiveness and identifying needed changes in the intervention plan. Consequently, there is no standard battery of assessment tools and procedures for all individuals with intellectual disability. Instead, the assessment must be guided by the referral question.

Below are some guiding principles for assessing children with intellectual disability.

1. *Understand the referral question.* Obtain a clear understanding of what specific question(s) needs to be answered at the conclusion of the evaluation. Without such an understanding, even the most thorough assessment is of little value if it fails to answer the referral source's question. In cases where an unrealistic question may be posed, establishing the ground rules early on (e.g., "It is unlikely that we will be able to tell you exactly why your child has intellectual disability") facilitates discussion and helps the referral source to frame more appropriate questions. Only after the referral question is clear can the appropriate assessment tools and methods be selected. Some referral questions may have less to do with diagnosis or understanding the child's problems than with understanding the child's impact on parents or others within the family that led to the evaluation at this particular time.

2. *Use multiple sources.* Obtain information from as many sources as possible (e.g., parents,

schools, agencies, other clinicians), because children may behave differently across environments. There is some research evidence that parents and teachers describe the behaviors and skills of children with intellectual disability in different ways. For example, Handen, Feldman, and Honigman (1987) examined parent-teacher agreement on a questionnaire assessing self-help skills, speech and language, play skills, and behavior problems in a group of 98 children with developmental disabilities. Whereas significant levels of parent-teacher agreement were noted for 77% of items assessed, the mean level of agreement was only 68.1%. Additionally, when a specific behavior problem (e.g., temper tantrums, hitting others) was endorsed by either a parent or a teacher, the probability that the same problem would be endorsed by the other respondent was at or below chance levels. In another study of the reliability of parent and child reports of symptoms, parents were found to be more reliable informants (r 's of .73 to .76) than their typically developing children (r 's of .43 to .71) (Edelbrock, Costello, Dulcan, Kalas, & Conover, 1985). This same study found typically developing children under the age of 10 to be extremely unreliable informants (with the exception of reporting simple fears). Additionally, reliability of informant rating may be affected by population variables. For example, Havercamp (1986) found that internal and interrater reliability on the Reiss Screen for Maladaptive Behavior (RSMB; Reiss, 1994) and the Psychopathology Instrument for Mentally Retarded Adults (PIMRA; Matson, Kazdin, & Senatore, 1984) decreased significantly when used with individuals functioning within the profound range of mental retardation. Such findings cast suspicion upon the clinical utility of information provided by parents, children, or teachers alone, and suggest that additional information be gathered whenever conflicting reports are obtained from two or more sources.

3. *Use disorder-specific knowledge.* Whenever possible, use disorder-specific knowledge as a framework for organizing the approach to assessment. For example, if asked to assess a child with fragile X syndrome, one's focus might be on behaviors such as echolalia, social nonresponsiveness, and self-stimulation. Therefore, a behavioral assessment conducted as part of the evaluation would need to be designed to elicit such behaviors. Conversely, if

evaluating a child with Williams syndrome, one might expect feeding problems if the child is an infant or toddler. Therefore, the assessment would need to include observation of mealtime behavior. Other disorders often present with specific strengths and/or deficits that may influence the choice of assessment tools or the interpretation of results. For example, children with Down syndrome have a unique pattern of language development. Miller (1992) found that the vocabulary size and grammatical complexity of sentences of children with Down syndrome is smaller than expected in comparison to other children of the same mental age. Conversely, receptive language skills develop as expected for their cognitive abilities. Therefore, one may want to assess receptive and expressive language skills independently (i.e., use an assessment tool to measure receptive language skills that does not require an expressive language response).

4. *Use appropriate assessment strategies.* Use tools which are appropriate with respect to areas such as functional level, language skills, and motor skills. For example, a test such as the Wechsler Intelligence Scale for Children-IV (WISC-IV; Wechsler, 2003), which is standardized for children ages 6 years to 16 years, 11 months may be inappropriate for a 7-year-old child with suspected intellectual disability, because even the easiest test items might be below the child's ability level. A standardized IQ test such as the Kaufman Assessment Battery for Children (K-ABC-II; Kaufman & Kaufman, 2004c), which has an IQ floor of 60 for 6-year-olds would be inappropriate for a 6-year-old child with moderate mental retardation. A test of visual-motor skills, such as the Berry-Buktenica Developmental Test of Visual-Motor Integration, Third Edition (VMI; Beery, Buktenica, & Berry, 2004), will be of limited value when assessing a child with significant motor or visual impairments.

5. *Use a multiple assessment approach.* Sattler (2001) outlines "four pillars of assessment": norm-referenced tests (standardized tools), interviews (information from parents, teachers, the child, and other individuals familiar with the child), observations (both in the clinic and in settings such as the home or school), and informal assessment (nonstandardized tools, such as language samples or assessment of a child's ability to benefit from systematic cues). Significant discrepancies

among assessment findings require further investigation before a diagnosis and recommendations can be offered. For example, Sattler cited a case in which a child scored within the intellectual disability range on a test of cognitive functioning, but interviews and assessment of adaptive functioning suggested age-appropriate skills. Clearly, in such a case, a diagnosis of intellectual disability would not be made and additional assessment would be necessary.

6. *Collaborate with other professionals.* Refer to or include professionals from other disciplines (e.g., communication disorders, psychiatry, education, developmental pediatrics, genetics, occupational therapy) depending on the question being asked and the need to determine potential causes for a particular deficit or behavior problem. For example, a child's inattention may be due to a possible hearing loss (suggesting the need for an audiology evaluation), or the presence of a number of dysmorphic features may suggest the need for a genetics consultation. In a child with Down syndrome, receptive language skills that fall below expected levels may suggest the need for an audiology evaluation: About 50% of children with Down syndrome have some hearing loss due to ear infections or neurological impairment (Miller, 1992).

7. *Provide appropriate feedback.* Provide feedback at a level appropriate to the family with respect to language, education, and culture. Limit the use of overly professional language or simply stating numbers from various tests. When providing feedback regarding a diagnosis of intellectual disability, Shea (1984) recommends that the feedback session address three goals: (1) to provide specific information about the child's developmental functioning, and to answer all of the parents' questions about these findings; (2) to support and help parents as they begin to cope emotionally with the knowledge of their child's disability; and (3) to assist the parents in making plans to carry out specific recommendations and interventions. For schools, feedback should provide guidance about how best to meet the learning-behavioral-emotional needs of the student. Whereas a student may require additional academic support, for example, this might be accomplished in a variety of ways (depending on school resources, parental wishes, etc.), with a final determination made by the treatment team.

ASSESSMENT OF COGNITIVE FUNCTIONING

Despite the aforementioned issues regarding the role of adaptive behavior in children with intellectual disability, evaluation of cognitive functioning remains the first and primary step in assessing intellectual disability. Most school districts continue to overemphasize IQ testing for purposes of determining a child's eligibility for special needs services (Furlong & LeDrew, 1985; Reschly & Ward, 1991). Even among researchers in the field, the majority of published articles in the area of intellectual disability use IQ alone as an inclusionary or exclusionary criterion for entry into studies (Hawkins & Cooper, 1990). There are a range of cognitive assessment tools available to evaluate a child for the presence of intellectual disability. These tools are called norm-based or norm-referenced scales, in that they compare a child's test performance with others of similar age and gender (as well as possibly other dimensions, such as socioeconomic status or race). As a result, such tests must be standardized across a large group of individuals. Norm-referenced tests are able to assess relative performance across a wide range of developmental domains. These tests are almost exclusively individually administered and, according to Morgenstern and Klass (1991), meet a number of the following conditions:

1. The examiner must be skilled in test administration and have experience with a wide range of available tests.
2. The examiner must be knowledgeable about normal and abnormal development, and the needs of children with intellectual disability, in order to best interpret test results.
3. The tests given must be reliable and valid.
4. Tests are not valid for every purpose. Therefore, chosen tests must be appropriate for their purpose, particularly if they enhance the prediction of nontest behavior.
5. It is assumed that the child is giving his or her best performance. Problems with poor concentration, anxiety, or poor motivation compromise the reliability and validity of a test score.

Scales for Infants and Preschool-Age Children

Table 12.3 provides a summary of the most frequently used standardized cognitive assessment

TABLE 12.3. Frequently Used Standardized Tests for Cognitive Assessment

Test	Age range	Description/comments
<u>Cognitive assessment options</u>		
Bayley Scales of Infant Development, third edition (Bayley, 2005)	1 to 42 months	Provides indices of early cognitive and motor development. For children over 42 months, can use age equivalents.
Differential Ability Scales (DAS; Elliott, 1990)	2 years, 6 months to 17 years, 11 months	General Conceptual Ability and three subscale scores: Verbal Ability, Nonverbal Reasoning Ability, Spatial Ability.
Kaufman Assessment Battery for Children II (K-ABC-II; Kaufman & Kaufman, 2004c)	3 years, 0 months to 18 years, 11 months	Domains: Simultaneous Processing, Sequential Processing, Planning, Learning, and Knowledge. Includes a Mental Processing Index (IQ), Fluid Crystallized Index, as well as a Nonverbal Index.
Mullen Scales of Early Learning (Mullen, 1989)	0 to 42 months	Tests Language, Fine and Gross Motor, Cognitive, Personal–Social domains. For children over 42 months, must use age equivalents.
Stanford–Binet, fifth edition (Roid, 2003)	2 to 85+ years	Factor indexes: Fluid Reasoning, Knowledge, Quantitative Reasoning, Visual–Spatial Processing, and Working Memory. Both Verbal and Nonverbal IQ scores (as well as a Full-Scale IQ).
Wechsler Preschool and Primary Scale of Intelligence–III (Wechsler, 2002)	2 years, 6 months to 7 years, 3 months	Domains: Verbal, Performance, and Processing Speed (in addition to a Full Scale IQ). More of a screening tool for ages 2 years, 6 months to 3 years, 11 months. Best for IQs above 55.
Wechsler Intelligence Scale for Children (WISC-IV; Wechsler, 2003)	6 years to 16 years, 11 months	Four factors: Verbal Comprehension, Perceptual Reasoning, Working Memory, Processing Speed. Full-Scale IQ (40–160)
<u>Nonverbal cognitive assessment options</u>		
Blind Learning Aptitude Test (BLAT; Newland, 1971)	6 to 16 years	Assesses children with visual impairments, using a raised dot, braille-like format; directions are given verbally and require a pointing response.
Comprehensive Test of Nonverbal Intelligence (Hammill, Pearson, & Wiederholt, 1997)	6 to 90+ years	Three composite scores: Nonverbal Intelligence Quotient, Pictorial Nonverbal Intelligence Quotient, and Geometric Nonverbal Intelligence Quotient. Uses pictures of familiar objects and geometric designs; possible alternative for those with communication disorders, neurological impairments, autism, and mental retardation.
Leiter International Performance Scale—Revised (Leiter-R; Roid & Miller, 1997)	2 to 20 years	Comprised of two batteries (Visualization and Reasoning, Attention and Memory) and 20 subtests. A short form is also available.
Pictorial Test of Intelligence II (PTI-II; French, 2001)	3 to 8 years	No expressive language abilities required. As an untimed test, the PTI-II can be useful for children with a range of motor and developmental disorders.
Test of Nonverbal Intelligence (TONI-3; Brown, Sherbenou, & Johnson, 1997)	6 years to 89 years, 11 months	Requires no reading, writing, speaking, or listening. Is completely nonverbal and largely motor-free, requiring only a point, nod, or symbolic gesture to indicate response choices.
Universal Nonverbal Intelligence Test (UNIT, Bracken & McCallum, 1998)	5 years to 17 years, 11 months	Requires multiple response modes, including use of manipulatives, paper and pencil, and pointing.

tools for infants, preschool-age, and school-age children. As discussed earlier, infant and preschool scales do not correlate well with later levels of cognitive functioning. Only in the case of infants and preschoolers with significant developmental delays are early test results predictive of future functioning (DuBose, 1981). The most commonly used infant-toddler scale is the Bayley Scales of Infant Development, Third Edition (Bayley, 2005). The Bayley was standardized for infants, toddlers, and preschoolers between 1 and 42 months of age. Five developmental domains are available to identify deficits in very young children, including cognitive, language, motor, adaptive behavior, and social-emotional domains, as well as an optional sixth, behavior rating scale, domain. In addition, there is a screening test to determine whether further testing is needed. Another option, the Infant Mullen Scales of Early Learning (Mullen, 1989), was standardized on a sample of 1,231 children ages birth to 68 months and has five scales (including motor, visual, and language areas).

As children approach preschool age, tests tend to emphasize more language-mediated tasks. The Stanford-Binet Intelligence Scales (fifth edition; Roid, 2003) and the Wechsler Preschool and Primary Scale of Intelligence-III (WPPSI-III; Wechsler, 2002) are the most commonly used cognitive tests for this age group. The Stanford-Binet was revised in 2003 and standardized on nationally representative sample of 4,800 children and adults between 2 and 85+ years of age. It assesses functioning across five factor indexes: Fluid Reasoning, Knowledge, Quantitative Reasoning, Visual-Spatial Processing, and Working Memory. In addition, there are both Verbal and Nonverbal IQ scores (as well as a Full Scale IQ). The latter may be useful in assessing individuals with communication disorders, autism, or traumatic brain injury. Scores are expressed as a deviation IQ, with a mean of 100 and a standard deviation of 15. However, the test is not appropriate for individuals functioning in the severe to profound range of mental retardation, because 40 is the lowest Full-Scale IQ given.

The WPPSI-III (Wechsler, 2002) is appropriate for preschoolers between 2 years, 6 months and 7 years, 3 months of age. The test was standardized on a sample of 1,700 preschoolers, with a mean score of 100 and a standard deviation of 15. The WPPSI-III assesses functioning across three domains: Verbal, Perfor-

mance, and Processing Speed (in addition to a Full Scale IQ). Children between 2 years, 6 months and 3 years, 11 months of age are given only two core subtests in the Verbal domain and two in the Performance domain. A fifth, supplemental subtest is available in the Processing Speed domain. Consequently, the WPPSI-III is more a screening instrument than a comprehensive cognitive test battery for this age group (Sattler & Dumont, 2004). For the 4 years to 7 years, 3 months age group, three core subtests are available within both the Verbal and Performance domains, and an additional core subtest in the Processing Speed domain. Five additional supplemental subtests and two optional subtests are available for this age range. Sattler and Dumont recommend against the use of the WPPSI-III for children with IQs below 55 (moderate range of mental retardation), because the instrument fails to assess cognitive ability adequately in this population.

Another available option for assessing children under the age of 6 years is the KABC-II (Kaufman & Kaufman, 2004), which comprises 20 subtests spanning the age range of 3 years to 18 years, 11 months and was standardized on a sample of 3,025 children. The KABC-II assesses a child's capabilities in five areas: (1) simultaneous processing, which taps an individual's ability to integrate inputs from multiple sources at the same time; (2) sequential processing, which taps an individual's ability to solve problems based on the arrangement of arrays of information; (3) planning; (4) learning; and (5) knowledge. In addition, this instrument provides a Mental Processing Index (IQ), Fluid Crystallized Index, as well as a Nonverbal Index. The Nonverbal scale of the KABC-II is particularly useful in assessing children with hearing impairments or language disorders. However, the KABC-II should not be used to classify intellectual disability across the entire age range of the scale. For example, the Mental Processing Index has a floor of 45 for a 3-year-old, 54 for a 4-year-old, and 48 for a 5-year-old.

Two other alternative preschool tests are the Differential Abilities Scales (DAS; Elliott, 1990) and the Woodcock-Johnson III Tests of Cognitive Abilities (WJ-III; Woodcock, McGrew, & Mather, 2001). The DAS was normed on a national sample of 3,475 children between 2 years, 6 months and 17 years, 11 months of age. It comprises 20 subtests (17

cognitive and 3 achievement), yielding a General Conceptual Ability score, as well as three subscale scores: Verbal Ability, Nonverbal Reasoning Ability, and Spatial Ability. The Nonverbal Reasoning Ability subscale can be useful when assessing children with communication disorders or autism. The DAS-II (second edition) was published in early 2007. The WJ-III is normed for individuals ages 2–90+ years. It comprises 10 tests in the standard battery and 10 in the extended battery (although younger children are not given the entire battery). The scale, which can only be scored by a computer software program, provides seven clusters: Comprehension–Knowledge, Long-Term Retrieval, Visual–Spatial Thinking, Auditory Processing, Fluid Reasoning, Processing Speed, and Short-Term Memory.

Recommendations

The Bayley Scales of Infant Development, Third Edition (Bayley, 2005) remains the most used developmental assessment for infants and toddlers. It is certainly a good choice for evaluating a child under 2 years of age with suspected developmental delays. The Infant Mullen Scales of Early Learning (Mullen, 1989) remains a strong option for children between birth and 68 months of age. Because the Mullen is standardized on children starting from birth, it also allows for assessment of a child who may be functioning below the 24-month developmental age. Finally, the Stanford–Binet (fifth edition; Roid, 2003) is felt to be the best option for preschoolers with intellectual disability. The Nonverbal subscale also makes this a useful tool for nonverbal children. However, the Mullen may need to be substituted for preschoolers functioning within the severe to profound range of mental retardation.

Tests for School-Age Children

The Stanford–Binet (fifth edition), school-age version of the Wechsler (WISC-IV), the KABC-II, WJ-III, and the DAS are the most commonly used tools for assessing cognitive functioning in school-age children. The Stanford–Binet (fifth edition), KABC-II, and DAS were discussed earlier. The WISC-IV (Wechsler, 2003) is structurally similar to the WPPSI-III, but spans the age range of 6–16 years. It comprises 10 primary and 5 supplemental subtests di-

vided into four factors: Verbal Comprehension (Similarities, Vocabulary, Comprehension, Information, Word Reasoning), Perceptual Reasoning (Block Design, Picture Concepts, Matrix Reasoning, Picture Completion), Working Memory (Digit Span, Letter–Number Sequencing, Arithmetic), and Processing Speed (Coding, Symbol Search, Cancellation). The most recent revision was standardized on 2,200 children. The test has excellent reliability and validity. However, the full-scale IQ range of 40–160 does not meet the needs for assessing children who may function within the severe to profound range of mental retardation.

Nonverbal Cognitive Assessment Options

One option for assessing children who have limited expressive and receptive language skills, according to Morgenstern and Klass (1991), is to use a tool such as the Bayley to provide information on the course of growth and development across a range of areas (e.g., social, adaptive, language, and motor). It is often difficult to use measures such as the Stanford–Binet and the Wechsler tests to assess children with significant neuromotor or language-based disorders. These tools are also inappropriate for evaluating children functioning in the low end of the moderate to profound range of mental retardation, due to the limited IQ ranges covered by the tests. Additionally, tests such as the Stanford–Binet, WISC-IV, WJ-III, and KABC-II require the evaluator to present items in a highly standardized manner; deviations from this may significantly affect the validity of the test results. The option of making alterations in response modalities (e.g., using yes–no responses or gestures) or excluding those items that require responses a particular child is unable to provide (e.g., eliminating all verbal items or all items that require motor responses) may not allow for comparison with the standardization group. Therefore, alternative measures often need to be used that provide valid estimates of cognitive functioning for this group of children, that are normed for children with specific handicaps (e.g., visual or motor impairments), or that have standardized adaptations for children with intellectual disability (Neisworth & Bagnato, 1987).

There are a number of options for assessing children and adolescents with limited expressive language skills. One option is to use subtests comprising the nonverbal scales of

some of the IQ tests discussed earlier (e.g., KABC-II, WISC-IV, DAS). However, most of these subtests are administered with the use of verbal directions and might best be described as “language-reduced instruments with verbal directions” (McCallum, 2003). There are a few alternative tools administered in a nonverbal manner that can be used to obtain estimates of cognitive functioning in children with severe language deficits. The Pictorial Test of Intelligence II (PTI-II; French, 2001) was designed to assess intellectual functioning in both typically developing and children with disabilities, ages 3–8 years. It includes three subtest areas (Verbal Abstraction, Form Discrimination, and Quantitative Concepts) that are combined to obtain a Pictorial Intelligence Quotient, as well as a global index of performance. Standardized with a sample of 972 children, the PTI-II does not require any expressive language abilities. However, individuals are required to have normal vision and hearing. As an untimed test, the PTI-II may be useful for children with a range of motor and developmental disorders.

The Comprehensive Test of Nonverbal Intelligence (Hammill, Pearson, & Wiederholt, 1997) was standardized on 2,500 individuals between 6 and 90+ years of age. It provides three composite scores: Nonverbal Intelligence Quotient, Pictorial Nonverbal Intelligence Quotient, and Geometric Nonverbal Intelligence Quotient. Stimuli that include pictures of familiar objects and geometric designs make it a possible alternative for school-age children and adolescents with communication disorders, neurological impairments, autism, and intellectual disability.

The Leiter International Performance Scale—Revised (Leiter-R; Roid & Miller, 1997) was designed to assess general cognitive functioning in children and adolescents between 2 and 20 years of age with language or motor deficits. The test depends on the use of visual demonstration to provide instructions. The Leiter-R comprises two batteries (Visualization and Reasoning, Attention and Memory) and 20 subtests. It was standardized on a sample of 1,719 individuals for the Visualization and Reasoning battery and 763 individuals for the Attention and Memory battery. A short form of the Leiter, called the Stoelting (Leiter) Brief Nonverbal Intelligence Tests (S-BIT; Roid & Miller, 1999) is also available for individuals between 6 and 20 years of age. Other nonverbal cognitive assessment options include the

third edition of the Test of Nonverbal Intelligence (TONI-3; Brown, Sherbenou, & Johnson, 1997), which was standardized on individuals between 6 years and 89 years, 11 months of age, and the Universal Nonverbal Intelligence Test (UNIT, Bracken & McCallum, 1998), which was standardized for individuals between 5 years and 17 years, 11 months of age.

Finally, the Blind Learning Aptitude Test (BLAT; Newland, 1971) was specifically developed to assess children with visual impairments, using a raised dot, braille-like format; directions are given verbally and require a pointing response. Although this tool provides normative data for individuals 6–16 years of age, the standardization sample is over 30 years old. An additional option is to assess children and adolescents who have visual impairments using subtests from the verbal domains of tools such as the WISC-IV or WPPSI-III, to obtain a Verbal IQ score (Chaudry & Davidson, 2001). However, Van Hasselt and Sisson (1987) caution that variability among subtest scores is common among children with visual impairments; therefore, subtest scores are not necessarily indicative of a learning disability.

Recommendations

The WISC-IV and Stanford–Binet (fifth edition) remain the most commonly used tests of cognitive functioning for both typically developing children and children with intellectual disability. The challenge is selecting alternative tools for children who are nonverbal and for children whose IQs fall below 40. One option is to use the Nonverbal scales from the WISC-IV and Stanford–Binet (fifth edition), with the caveat that most of the items involve the use of verbal directions. The best known purely nonverbal assessment tool is the Leiter-R. Finally, for children functioning within the severe to profound range of mental retardation we often use the Infant Mullen Scales of Early Learning (for which an estimated age-equivalent score needs to be derived).

ASSESSMENT OF ACADEMIC ACHIEVEMENT

Table 12.4 includes a summary of the most frequently used tests to assess academic achievement skills. The assessment of academic achievement is the primary means of determin-

TABLE 12.4. Tests Frequently Used to Assess Achievement Skills

Test	Age range	Description/comments
Grey Oral Reading Test—Fourth Edition (GORT-4; Wiederholt & Bryant, 2001)	6 years to 18 years, 11 months	Assesses skills in reading rate, accuracy, fluency, comprehension, and overall reading ability. Two parallel forms available.
Kaufman Test of Educational Achievement II—Comprehensive Form (K-TEA-II; Kaufman & Kaufman, 2004a)	4 years, 6 months to 25 years	Individually administered comprehensive assessment of reading, mathematics, written language, and oral language.
Kaufman Test of Educational Achievement—II—Brief Form (Kaufman & Kaufman, 2004b)	4 years, 6 months to 90 years	Assesses skills in reading, mathematics, and written expression. Serves as a screening tool. Because items do not overlap with K-TEA-II, can be used for retesting.
KeyMath-R/NU (Connolly, 1998)	5 to 22 years	Assesses skills in basic concepts, operations, and applications. Absence of reading requirements makes this a good assessment tool for children with mental retardation. Two parallel forms available.
The Peabody Individual Achievement Test—Revised/Normative Update (PIAT-R/NU; Markwardt, 1998)	5 years to 22 years, 11 months	Requires that a child respond by pointing to the correct picture from an array of four items. Good choice for children with motor impairments, language deficits, or mental retardation.
Wechsler Individual Achievement Test—II (WIAT-II; Wechsler, 2001)	4 to 85 years	Seven subtests covering Oral Expression, Listening Comprehension, Written Expression, Basic Reading, Reading Comprehension, Mathematics Calculation, and Mathematics Reasoning.
Wechsler Individual Achievement Test—II—Abbreviated (WIAT-II-Abbreviated; Kaplan et al., 2001)	Kindergarten to adult	Assesses skills in word reading, spelling, and numerical operations. Serves as a screening tool.
Wide Range Achievement Test Expanded edition (WRAT-E; Robertson, 2002)	Grades 2–12: group administered Ages 4–24 years: individually administered	Areas assessed include reading comprehension, mathematics, and nonverbal reasoning (for group administration only).
Wide Range Achievement Test 4 (WRAT-4; Wilkinson & Robertson, 2006)	5 to 94 years	Assesses skills in word reading, sentence comprehension, spelling, and math computation. Serves as a screening tool.
Woodcock–Johnson–III Tests of Achievement (WJ-III; Woodcock, McGrew, & Mather, 2001)	2 to 90+ years	Twenty-two subtests covering reading, mathematics, written language, and academic knowledge. A Total Achievement score can be derived.
Woodcock Reading Mastery Tests—Revised/Normative Update (WRMT-R/NU; Woodcock, 1998)	5 to 75+ years	Assesses skills: Visual–Auditory Learning, Letter Identification, Word Identification, Word Attack, Word Comprehension, and Passage Comprehension. Two parallel forms are available (last four subtests only).

ing how a child with intellectual disability is faring in school. Such data also allow for the comparison between a child's abilities (as estimated with a test of cognitive functioning) and actual school performance. A child who is achieving significantly below what would be expected based on IQ score may present with other problems that need to be investigated as part of the overall assessment. These might include psychiatric disorders (e.g., ADHD, depression) that may adversely affect the child's ability to concentrate and perform in school, significant family stressors, a specific learning disability, or inappropriate classroom placement and instruction.

Tests of academic achievement can serve as either a screening function or as a more comprehensive assessment of skills. Screening tests take considerably less time to administer and typically are used to determine whether a more comprehensive evaluation is required. For the child with an intellectual disability, however, a more comprehensive assessment is generally recommended to provide as much information as possible on the child's current levels of functioning and to assist in developing plans for remediation. Academic achievement tests may be designed to be given either individually or in a group format. However, it is generally recommended that a child with intellectual disability be evaluated individually. A good number of norm-referenced assessment tools are available to assess a child's abilities in reading, spelling, and mathematics.

The Wide Range Achievement Test-4 (WRAT-4; Wilkinson & Robertson, 2006), a screening tool that requires 20-30 minutes to administer, assesses skills in word reading, sentence comprehension, spelling, and math computation for ages 5 through 94. An Expanded edition (WRAT-E; Robertson, 2002) provides both group and individual assessment of academic achievement in reading comprehension, mathematics, and nonverbal reasoning. It can be group administered (for grades 2-12) with a multiple-choice format or individually administered (for ages 4-24) with a flipbook form of presentation. A second achievement measure, the WJ-III (Woodcock et al., 2001), includes 22 subtests (comprising 12 in the Standard battery and 10 in the Extended battery) covering a range of areas, such as reading, mathematics, written language, and academic knowledge. A Total Achievement score can be derived. The test was standardized on a sample of 8,818 in-

dividuals (including 1,143 preschoolers and 4,784 school-age children) ranging in age from 2 to 90+ years. Results can be presented as standard scores ($X = 100$, $SD = 15$), age/grade equivalents, percentile ranks, instructional ranges, discrepancy scores, and a Relative Proficiency Index.

Another option for assessing academic achievement, the Wechsler Individual Achievement Test-II (WIAT-II, Wechsler, 2001), is empirically linked with the WISC-IV and WPPSI-III. This test was normed with a sample of individuals ages 4-85 years and comprises seven subtests covering a range of areas, such as reading, oral and written expression, listening comprehension, and mathematics. An abbreviated version is also available (WIAT-II-Abbreviated; Kaplan, Fein, Kramer, Delis, & Morris, 2001), covering word reading, spelling, and numerical operations. The Peabody Individual Achievement Test-Revised/Normative Update (PIAT-R/NU; Markwardt, 1998) uses a somewhat different format than the tools discussed previously. Rather than providing paper-and-pencil tasks, the PIAT-R/NU requires that a child respond by pointing to the correct picture from an array of four items. Consequently, the PIAT-R/NU is a good choice for assessing children with motor impairments, language deficits, or intellectual disability. However, the Reading Comprehension subtest requires some memory skills as well. The test was recently restandardized on approximately 3,000 individuals from 5 years through 22 years, 11 months of age. The Kaufman Test of Educational Achievement-Second Edition, Comprehensive form (K-TEA-II; Kaufman & Kaufman, 2004c), covering ages 4 years, 6 months to 25 years, also remains an option. There is a companion screening version, the TEA-II Brief Form (Kaufman & Kaufman, 2004b) for ages 4 years, 6 months to 90 years.

Finally, there are achievement tests available that focus more specifically on either reading or mathematics. For example, the Woodcock Reading Mastery Tests-Revised/Normative Update (WRMT-R/NU; Woodcock, 1998), covering ages 5 years through 75+ years, as well as the Grey Oral Reading Test-Fourth Edition (GORT-4; Wiederholt & Bryant, 2001), covering ages 6 years through 18 years, 11 months, provide a more detailed assessment of reading skills. Similarly, the KeyMath-Revised/Normative Update: A Diagnostic Inventory of Essential Mathematics (KeyMath-R/

NU; Connolly, 1998) is an individually administered test of arithmetic skills. It provides considerably more depth than most other available tools, comprising 13 subtest areas. The test was standardized on over 3,000 individuals from 5 to 22 years of age. It was co-normed with the K-TEA/NU and PIAT-R/NU. The absence of reading requirements makes this a good assessment tool for children with intellectual disability. The availability of two parallel forms allows individuals to be pretested and retested at a later time.

Recommendations

The WRAT-4 (Wilkinson & Robertson, 2006) has always offered a means of providing a quick, but fairly narrow picture of current achievement. This can then provide guidance regarding the need for more in-depth assessment. The WJ-III, the only tool that assesses children as young as 2 years of age (most others start at age 5), may be helpful when evaluating younger school-age children with intellectual disability. The PIAT-R (Markwardt, 1998) uses a pointing response, which makes it also a reasonable choice with this population.

ASSESSMENT OF RELATED NEUROPSYCHOLOGICAL PROCESSES: LANGUAGE SKILLS, PERCEPTUAL–MOTOR SKILLS, AND MEMORY

There are a range of measures designed to assess specific neuropsychological processes such as language, attention, memory, and perception (see Table 12.5). Neisworth and Bagnato (1987) provide a number of reasons why the use of such tools may be helpful in assessing children with intellectual disability: (1) to define a child's strongest individual modality for learning, (2) to monitor medication efficacy, (3) to assess progress or deterioration in children with traumatic brain injuries, and (4) to better understand how the brain mediates control of behavior (e.g., verbal mediation and self-control). A wide range of options are available for assessing processes that reflect specific brain functions. Tools discussed previously, such as the KABC-II, can assess functions such as attention, memory, and processing. The study of patterns of subtest performance on the WISC-IV or Stanford–Binet (fifth edition) can also provide information on brain functions. A

variety of assessment tools are also available to evaluate more specific areas.

Language Skills

For children who are nonverbal or have significant language-based deficits, a number of alternative assessment tools are available for assessing receptive language skills. One such tool, the Peabody Picture Vocabulary Test–4 (PPVT-4; Dunn & Dunn, 2006) requires an individual to point to one of four pictorial plates in response to an instruction from the evaluator (e.g., “Point to the ball”). The PPVT-4 was normed on 4,000 children and adults, and has excellent reliability and validity. Age range for the tool is 2 years, 6 months to 90+ years. The PPVT-4 should be considered a screening device for identifying language comprehension difficulties.

The Receptive–Expressive Emerging Language Scale, Third Edition (REEL-3; Bzoch, League, & Brown, 2003) is designed to assess children from birth to 3 years of age with language impairments or disabilities that affect language development. Results are based on parental report. The Preschool Language Scale 4 (PLS-4; Zimmerman, Steiner, & Pond, 2002) assesses expressive and receptive language skills for ages birth through 6 years. It combines screening of the child and a parental interview.

The Test of Auditory Comprehension of Language—Third Edition (TACL-III; Carrow-Woolfolk, 1999) is an individually administered test of auditory comprehension (receptive language functioning) that requires only a pointing response. It contains three subtests: Vocabulary, Grammatical Morphemes, and Elaborated Phrases and Sentences. The TACL-III was standardized on a sample of 1,102 children between the ages of 3 years and 9 years, 11 months. Reliability studies have been carried out with children with intellectual disability (Carrow-Woolfolk, 1999). The second edition of the Clinical Evaluation of Language Fundamentals—Preschool (CELF-2 Preschool; Wiig, Secord, & Semel 2004) and Clinical Evaluation of Language Fundamentals, Fourth Edition (CELF-4; Semel, Wiig, & Secord, 2003) may be used to assess a wide range of both receptive and expressive language functions in preschool and school-age children. The preschool version was standardized on 1,500 preschool children (ages 3 to 6

TABLE 12.5. Tests Frequently Used to Assess Language Skills, Perceptual–Motor Skills, and Memory

Test	Age range	Description/comments
<u>Language skills</u>		
Clinical Evaluation of Language Fundamentals—Preschool, Second Edition (CELF-2 Preschool; Semel, Wiig, & Secord, 2004)	3 to 6 years	Provides a core language score, receptive language index, expressive language index, language content index, and language structure index.
Clinical Evaluation of Language Fundamentals–4 (CELF-4; Semel et al., 2003)	5 to 21 years	Provides composite scores in the areas of language structure, language content, language memory, and working memory.
Clinical Evaluation of Language Fundamentals–4—Screening Test (Semel et al., 2003)	5 to 21 years	A criterion-referenced screen used to determine whether further evaluation is needed.
Peabody Picture Vocabulary Test–III (PPVT-III; Dunn & Dunn, 1997)	2 years, 6 months to 90+ years	A screening device for identifying language comprehension difficulties.
Preschool Language Scale–4 (PLS-4; Zimmerman, Steiner, & Pond, 2002)	Birth to 6 years	Combines screening of the child, along with a parental interview.
Receptive–Expressive Emerging Language Scale, Third Edition (REEL-3; Bzoch, League, & Brown, 2003)	Birth to 3 years	Results are based on parental report.
Test of Auditory Comprehension of Language–III (TACL-III; Carrow-Woolfolk, 1999)	3 years and 9 months to 11 years	Assesses receptive language functioning, requiring only a pointing response. Contains three subtests: Vocabulary, Grammatical Morphemes, and Elaborated Phrases and Sentences.
<u>Perceptual–motor tests</u>		
Beery–Buktenica Developmental Test of Visual–Motor Integration, Third Edition (VMI; Beery, Buktenica, & Beery, 2004)	2 years to 17 years, 11 months	Individually administered paper-and-pencil test. Child is asked to copy 24 geometric figures. Assesses visual–motor integration skills. A short form is available for use with children 2 to 8 years of age.
Bender Visual–Motor Gestalt Test, Second Edition (Branigan & Decker, 2003)	4 to 85 years	Individually administered paper-and-pencil test. Child is asked to copy up to 14 geometric figures. Assesses visual–motor memory and visual–motor skills.
Bruininks–Oseretsky Test of Motor Proficiency—second edition (Bruininks & Bruininks, 2005)	4 to 21 years	Assesses both fine and gross motor skills. Both short and long forms available, but age equivalents can be derived from the full battery only.
Full Range Test of Visual–Motor Integration (Hammill et al., 2005)	5 to 74 years	Includes norms for special education students in the 19- to 21-year age range.
Motor-Free Visual Perception Test, third edition (Colarusso & Hammill, 2002)	4 to 85 years	Useful for assessing children with motor impairments. Child is asked to point to one of four figures on a page that matches a target figure.

(continued)

TABLE 12.5. (continued)

Test	Age range	Description/comments
		<u>Memory</u>
Children's Memory Scale (Cohen, 1997)	5 to 16 years	Comprises six subtests tapping immediate and delayed verbal memory, general memory, and immediate and delayed visual memory.
NEPSY (Korman, Kirk, & Kemp, 1990)	3 to 12 years	Assesses five functional domains, including Executive Functions, Language and Communication, Sensorimotor Functions, Visuospatial Functions, and Learning and Memory.
Test of Memory and Learning (TOMAL; Reynolds & Bigler, 1994)	5 to 19 years	Comprises 10 regular and four supplementary subtests. The three primary derived indices include a Verbal Memory Index, a Nonverbal Memory Index, and a Composite Memory Index.
Wide Range Assessment of Memory and Learning, second edition (WRAML-2; Sheslow & Adams, 2003)	5 to 90 years	Comprises six subtests and three indices (Verbal Memory, Visual Memory, and Attention/Concentration) as well as a General Memory Index. There is also an available screening battery.

years) and contains nine subtests (e.g., Expressive Vocabulary, Following Directions, Word Structure). The school-age version was standardized on 2,650 individuals (ages 5–21 years) and provides composite scores in the areas of Language Structure, Language Content, Language Memory, and Working Memory. The CELF-2-Preschool and CELF-4 both require a considerable amount of time to complete, if the entire battery is administered. A screening test for the CELF-4 is available (Semel et al., 2003).

Visual–Motor Skills

Evaluation of visual–motor perception and integration is particularly useful in assessing children with possible learning and neurological deficits (see Table 12.5). Children with intellectual disabilities also often have deficits in perceptual–motor skills. However, one must be cautious when interpreting test results for children with accompanying visual impairments or motor delays.

The most widely known visual–motor test is the Bender Visual–Motor Gestalt Test, Second Edition (Braningan & Decker, 2003). In this individually administered paper-and-pencil test, the child is asked to copy 14 geometric figures

drawn on template cards. The newly revised edition includes recall procedures to assess visual–motor memory, in addition to assessing visual–motor skills. It has been standardized for ages 4–85 years.

The VMI (Beery et al., 2004) is a paper-and-pencil test that provides scores in three areas: Motor Coordination, Visual–Motor Integration (in which the child is required to copy up to 24 geometric forms of increasing difficulty), and Visual Perception. The Visual–Motor Integration subtest provides somewhat greater structure than the Bender, in that forms are copied in clearly outlined spaces. The test was normed on a national sample of 2,512 children ages 2 years through 17 years, 11 months. Results can be presented as percentiles, standard scores ($X = 10$, $SD = 3$), or age equivalents. An available short form can be used with children 2 to 8 years of age. Another option, the Full Range Test of Visual–Motor Integration (Hammill, Pearson, Voress, & Reynolds, 2005), provides norms for both children and adults (ages 5–74 years).

The Motor-Free Visual Perception Test, Third Edition (Colarusso & Hammill, 2002) is a useful tool for assessing children who have significant motor impairments. The child is

asked to point on a page to one of four figures that matches a target figure. The test was standardized for individuals between the ages of 4 and 85 years. Finally, the Bruininks–Oseretsky Test of Motor Proficiency, Second Edition (Bruininks & Bruininks, 2005) provides a comprehensive assessment both gross and fine motor skills. The test contains 53 items arranged into eight subtest areas. Four subtest scores are obtained: Fine Manual Control, Manual Coordination, Body Coordination, Strength and Agility, and a Total Motor Composite. There are both short and long forms, but age equivalents can be derived for the full battery only, which may take 45–60 minutes to complete. The test was standardized on a sample of children and adolescents ages 4–21 years of age.

Memory

There are a number of available assessment options that provide a more in-depth means of examining memory processes. Such information can be extremely helpful when developing specific treatment or instructional recommendations. The Wide Range Assessment of Memory and Learning, Second Edition (WRAML-2; Sheslow & Adams, 2003) provides a means of examining memory processes for individuals ages 5 to 90 years. The core battery, which requires less than 60 minutes to complete, comprises two verbal, two visual, and two attention/concentration subtests. Three indices are derived (Verbal Memory, Visual Memory, Attention/Concentration) as well as a General Memory Index. There is also a screening battery that comprises four subtests. The Children's Memory Scale (Cohen, 1997) is normed for ages 5–16 years and requires approximately 30 minutes to administer. The scale comprises six subtests tapping immediate and delayed verbal memory, general memory, and immediate and delayed visual memory.

Another option is the NEPSY (Korman, Kirk, & Kemp, 1990), a developmental neuropsychological assessment scale for children ages 3–12 years. The NEPSY assesses five functional domains, including Executive Functions, Language and Communication, Sensorimotor Functions, Visual–Spatial Functions, and Learning and Memory. Finally, The Test of Memory and Learning (TOMAL; Reynolds & Bigler, 1994), developed for ages 5–19 years, requires approximately 45 minutes to administer. The TOMAL comprises 10 regular and

four supplementary subtests. The three primary derived indices include a Verbal Memory Index, a Nonverbal Memory Index, and a Composite Memory Index.

Recommendations

The assessment of specific language skills in a child with significant language-based deficits depends in part on the child's level of cooperation. For the child who is noncompliant or reluctant to respond, the REEL (which is based solely on parental report) and the PLS-4 (which includes parental report) are appropriate options. Although these tools were developed for the younger child, language age equivalents can still be calculated/estimated for the older child and relative areas of strength and weakness identified. The PPVT is fairly fast to administer and requires only a pointing response. The other options, such as the CELF-2 Preschool and CELF-4, are much more comprehensive. Only specific subtests might be used, depending on the question, or the entire battery might be administered if the assessment of language skills is deemed to be an area of considerable importance. In the area of visual–motor skills, the VMI is often the preferred option when assessing children with intellectual disability. It provides more structure than the Bender and also has normative data that begins at 2 years of age. For children with significant motor impairments, the Motor-Free Visual Perception Test is also an option. Finally, in the area of assessing memory, the NEPSY has a number of advantages for assessing children with intellectual disabilities. First, it can be used with children as young as 3 years of age (the other options start at 5 years of age). Second, it requires limited motor skills on the part of the child. However, the NEPSY is considerably better at assessing verbal memory than visual memory (for which there is only a single subscale). Finally, the Children's Memory Scale is also a good option for children who have some motor skills deficits.

ALTERNATIVE ASSESSMENT METHODS

Norm-referenced assessment tools present numerous problems for individuals with intellectual disability and other developmental disabilities. For many such children who are unable to sit still, to follow directions, or to attend to the

types of tasks utilized in traditional assessments, the result is invalid measures of functioning and abilities. Additionally, many conventional tests have not been normed for either young children with disabilities or for older children functioning within the severe to profound range of mental retardation (Neisworth & Bagnato, 2004). Alternative tools, such as curriculum-based and performance-based assessments, typically allow evaluation of the child in a more natural environment, and often by individuals who know them best. This is in contrast to more traditional assessment situations, in which the child is taken to a separate room to be evaluated by a psychologist with whom he or she likely has had little, if any, prior interactions. Additionally, some alternative assessment tools involve a questionnaire or interview format for caregivers.

Curriculum-Based Assessment Tools

Whereas norm-referenced assessment tools are used primarily for diagnostic purposes, curriculum-based assessment tools allow test results, teaching, and progress evaluation to be merged within a single process (Neisworth & Bagnato, 1987). Instead of comparing a child's performance to a normative group of peers, criterion-based tools allow for the comparison of a child to him- or herself (once baseline levels are established). Consequently, these tools are used to monitor progress via performance on a range of task analyses of basic developmental skills. Based on a child's progress, a specific treatment or teaching plan can be devised. White and Haring (1978) noted that norm-referenced tests are relatively insensitive to developmental changes in children with IQs below 35. Even assessment measures that employ normal developmental scales may be inappropriate for this population, because the development of children with severe or profound mental retardation does not necessarily proceed like that of typically developing children (White & Haring, 1978).

Neisworth and Bagnato (1987) divided criterion-based assessment tools into two categories: (1) developmental measures (in which the content and objectives are developmentally sequenced), and (2) specialized curriculum measures (in which content and objectives have been designed and field-tested for distinct groups of children with developmental disabilities).

Developmental Curriculum-Based Assessment Tools

A number of curricula have been developed and field-tested specifically for preschool programs serving children with developmental disabilities. For example, the Carolina Curriculum (third edition) is an assessment and intervention program designed for use among children from birth to age 5 years with mild to severe disabilities (Johnson-Martin, Attermeier, & Hacker, 2004; Johnson-Martin, Jens, Attermeier, & Hacker, 2004). An Infant/Toddler version is available, covering children from birth to 36 months of age, and a Preschool version covers the period of 24–60 months of age. Both curricula comprise five areas: Cognition, Communication, Social Adaptation, Fine Motor, and Gross Motor. Similarly, the Assessment, Evaluation, and Programming System for Infants and Children, Second Edition (AEPS; Bricker, 2002) is both an evaluation tool and a curriculum for children (from birth to 6 years of age) with disabilities. Six developmental areas are assessed, including Fine Motor, Gross Motor, Cognitive, Adaptive, Social-Communication, and Social. The Hawaii Early Learning Profile (HELP; Parks, 1992) comprises 685 skills and behaviors within six domains for children with developmental disabilities from birth to age 36 months. Finally, the Brigance Diagnostic Inventory of Early Development II (Brigance, 2004) is both a diagnostic instrument and a criterion-referenced classroom assessment. It provides criterion-referenced task analyses across 11 domains for children from birth to age 84 months. However, unlike the previously discussed tools, the Brigance is not a curriculum, in that it does not provide specific teaching strategies or activities based on the test results.

Specialized Curriculum Measures

Specialized measures have also been developed to assess and provide curricula for specific subgroups of children. For example, the Oregon Project Curriculum for Visually Impaired and Blind Preschool Children (Brown, Simmons, & Methvin, 1986) assesses children with both visual and other impairments from birth to age 72 months. The Developmental Assessment for Students with Severe Disabilities, Second Edition (DASH-2; Dykes & Erin, 1999) is a criterion-referenced instrument that assesses

performance in language, sensory–motor skills, activities of daily living, basic academic skills, and social–emotional skills in children whose developmental functioning falls between birth and 6 years, 11 months of age. It can serve as an initial assessment instrument, a tool for curriculum planning, and a means of monitoring progress. The Assessment of Basic Language and Learning Skills (ABLLS; Sundberg & Partington, 1998) is a language-based assessment tool and curriculum for young children with autism and other developmental disabilities. Twelve areas related to language are addressed, such as requests, motor imitation, labeling, and conversations. Finally, The Callier–Azusa Scale (Stillman, 1978; Stillman & Battle, 1985) was designed specifically for children who are deaf–blind, but it can also be used with most students with severe disabilities. The scale is based on direct observation of the child over a 2-week period and includes subscales assessing visual, auditory, and tactile development. Information on other specialized scales can be found in Bagnato, Neisworth, and Munson (1997).

Performance-Based Assessment Tools

Neisworth and Bagnato (2004) described a continuum of measurement contexts, including clinical (conducting the assessment in a highly scripted manner in a laboratory-like setting), simulated (using standardized administration, but in a setting that may better resemble the child’s natural environment), analogue (presenting materials in the child’s natural setting), and natural (observing play and learning behaviors in the child’s natural setting). Some tools that can be used within an analogue contact include the Communication and Symbolic Behavior Scales—Developmental Profile (CSBS-DP; Wetherby & Prizant, 2002), the Developmental Observation Checklist System (DOCS; Hresko, Miguel, Sherbenou, & Burton, 1994), and the Work Sampling System (WSS; Meisels et al., 2002). The CSBS-DP, a norm-referenced tool, helps assess the communicative competence (use of eye gaze, gestures, sounds, words, understanding, and play) of children with a functional communication age between 6 months and 24 months (chronological age up to about 6 years). The DOCS, a parent-completed checklist, has been normed for birth to age 6 years and assesses language, social, motor, and cognitive functioning. The

WSS, a curriculum-embedded, performance assessment for preschool to grade 5, is highly correlated with individually administered psychoeducational batteries.

Some options for use in more natural contexts include the DOCS, the Pediatric Evaluation of Disability Inventory (PEDI; Feldman, Haley, & Coryell, 1990) and the second edition of the Ages and Stages Questionnaire (ASQ; Bricker & Squires, 1999). The PEDI, a parent report questionnaire, evaluates functioning in children with disabilities ages 6 months to 7 years, 6 months, and includes both functional performance and capability in three domains: Self-Care, Mobility, and Social Function. The ASQ is a parent-completed questionnaire about communication, gross motor, fine motor, problem solving, and personal–social skills for children up to 5 years of age. Table 12.6 provides a summary of selected criterion- and performance-based assessment tools.

Task Analysis

Another way to conduct a performance assessment involves the use of a task analysis, which is the breaking down of a complex skill or sequence of behaviors into its component behaviors (Sulzer-Azaroff & Mayer, 1991). Each component is listed in the order of occurrence. For example, an eight-step task analysis for washing hands follows:

1. Turn on water.
2. Pick up soap.
3. Put hands under water.
4. Remove hands from water and rub hands with soap.
5. Put soap down.
6. Rub hands together.
7. Rinse soap off of hands.
8. Turn off water.

Once a task analysis is developed, individuals may be assessed on their level of independence for each step. Typically, a child’s or adolescent’s rating is based on the level of assistance required to complete a given step. Types of assistance include physical guidance, pointing, modeling, verbal cues, and visual cues. To conduct a skills assessment, an evaluator often uses a “least to most” prompting strategy. For example, the individual might simply be told to wash his or her hands. The evaluator waits a few seconds, and if the individual does not ini-

TABLE 12.6. Criterion-Based and Performance-Based Assessment Tools

Test	Age range	Description/comments
Ages and Stages Questionnaire, second edition (ASQ; Bricker & Squires, 1999)	Birth to 5 years	A parent-completed questionnaire on Communication, Gross Motor, Fine Motor, Problem Solving, and Personal–Social Skills.
Assessment, Evaluation, and Programming System for Infants and Children, second edition (AEPS; Bricker, 2002)	Birth to 6 years	An evaluation tool and curriculum for children with disabilities. Areas assessed include Fine Motor, Gross Motor, Cognitive, Adaptive, Social–Communication, and Social.
Assessment of Basic Language and Learning Skills (ABLLS; Sundberg & Partington, 1998)	NA	A language-based assessment tool and curriculum for young children with autism and other developmental disabilities.
Brigance Diagnostic Inventory of Early Development II (Brigance, 2004)	Birth to 84 months	Is both a diagnostic instrument and a criterion-referenced classroom assessment, but not a curriculum.
Callier–Azusa Scale (Stillman, 1978; Stillman & Battle, 1985)	NA	Designed for children who are deaf–blind, but can also be used with students with severe disabilities. Based on direct observation.
Carolina Curriculum (Johnson-Martin, Attermeier, & Hacker, 2004; Johnson-Martin, Jens, Attermeier, & Hacker, 2004)	Infant/Toddler version: birth to 36 months Preschool version: 24 to 60 months	Both curricula comprise five areas: Cognition, Communication, Social Adaptation, Fine Motor, and Gross Motor.
Communication and Symbolic Behavior Scales—Developmental Profile (CSBS-DP; Wetherby & Prizant, 2002)	6- to 24-month level of functioning (chronological age up to about 6 years)	A norm-referenced tool that assesses communicative competence (Use of Eye Gaze, Gestures, Sounds, Words, Understanding, and Play).
Developmental Assessment for Students with Severe Disabilities II (DASH-2; Dykes & Erin, 1999)	Birth and 6 years, 11 months (developmental functioning level)	A criterion-referenced instrument that assesses performance in Language, Sensory–Motor Skills, Activities of Daily Living, Basic Academic Skills, and Social–Emotional Skills.
Developmental Observation Assessment System (DOCS; Hresko, Miguel, Sherbenou, & Burton, 1994)	Birth to 6 years	A parent-completed checklist that assesses language, social, motor, and cognitive functioning.
Oregon Project Curriculum for Visually Impaired and Blind Preschool Children (Brown, Simmons, & Methvin, 1986)	Birth to 72 months	Assesses children with moderate to severe mental retardation.
Work Sampling System (WSS; Meisels et al., 2002)	Preschool to Grade 5	A curriculum-embedded performance assessment.
Pediatric Evaluation of Disability Inventory (PEDI; Feldman et al., 1990)	6 months to 7 years, 6 months	A parent report questionnaire of functional performance and capability in Self-Care, Mobility, and Social Function.

tiate the first step of the task analysis (e.g., turning on the water), the least intrusive prompt is given (e.g., “Turn on the water”). If the individual continues to require a greater level of assistance, a modeling or pointing prompt might be provided. Finally, physical guidance is given if less intrusive prompts are unsuccessful in assisting the individual to complete the step. This is repeated for every step of the task analysis.

Skills can also be broken down into more basic components, often in a developmental sequence. For example, the Carolina Curriculum for Preschoolers with Special Needs (second edition) (Johnson-Martin, Attermeier, & Hacker, 2004) provides curriculum sequences in a range of development areas, such as attention and memory, size and number concepts, and receptive language skills. Several published assessment tools and curricula provide task analyses for teaching a range of skills, such as preschool or preacademic skills (e.g., Johnson-Martin, Attermeier, & Hacker, 2004), language skills (Sundberg & Partington, 1998), and motor, cognitive, and adaptive skills (Bricker 2002).

Recommendations

It is difficult to provide specific recommendations or preferences regarding the previously mentioned alternative assessment methods. Most are used for assessment and educational planning. Choice of tool can be based on the age range covered and the desired response method. For example, the DASH-2 is appropriate for children 6–11 years of age, whereas many of the other scales focus on younger children. Some tools involve direct observation or assessment of the child (e.g., the Brigance); others rely on parental report (e.g., the DOCS). The ABLLS, which has become rather popular, can be extremely helpful in curriculum planning but is not norm based. Conversely, the Brigance, which is a popular, criterion-referenced assessment tool, does not provide a curriculum or educational guidance.

ASSESSMENT OF ADAPTIVE BEHAVIOR

Table 12.7 summarizes the most frequently used adaptive behavior scales. Adaptive behavior reflects an individual’s ability independently to meet the needs and social demands of the en-

vironment. Although the identification of deficits in adaptive functioning are a requirement for making a diagnosis of intellectual disability, there remains considerable disagreement within the field over what skills constitute adaptive behavior (AAMR, 2002). The current AAIDD definition of “intellectual disability” requires significant limitations in both intellectual functioning and adaptive behavior, as expressed in conceptual, social, and practical adaptive skills. This definition also focuses on an individual’s ability to perform these skills versus his or her acquisition of such skills. Furthermore, the operational definition of “limitations in adaptive behavior” is falling at least two standard deviations below the mean for (1) one of the three types of adaptive behavior or (2) an overall score on a standardized measure of adaptive behavior. Although many of the available tools for measuring adaptive behavior do not contain domain names that directly match the three areas encompassed in the AAIDD definition, most commonly used tools have empirically derived factors that correspond to the three dimensions of adaptive behavior.

A number of available scales have a history of use in intellectual disability. Most involve the use of a clinical interview of an informant who knows the individual well. Some also include options for a simple questionnaire format. The Vineland Adaptive Behavior Scales–II (Sparrow, Cicchetti, & Balla, 2005), perhaps the best known tool, has recently been revised. The survey and expanded interview forms utilize a semistructured interview format to gather information on adaptive functioning from a parent/caregiver. Teacher and caregiver rating forms are also available as an alternative to the interview. The Vineland assesses areas of communication, daily living skills, socialization, and motor skills (for ages 6–11 years and younger). Results can be expressed as a standard score ($X = 100$, $SD = 15$), percentiles, or age equivalents of each area, as well as an Adaptive Behavior Composite. The Interview Edition Survey and Expanded Form were standardized on 3,695 individuals (birth to age 90 years). Validity of the Vineland was also established for individuals with mild, moderate, and severe/profound mental retardation, as well as those with emotional disorders and other disabilities.

A second frequently used scale, the second edition of AAMR Adaptive Behavior Scale—School, last revised in 1993 (Lambert, Nihira,

TABLE 12.7. Tests Frequently Used to Assess Adaptive Functioning

Test	Age range	Description/comments
AAMR Adaptive Behavior Scale—School 2 (Lambert, Nihira, & Leland, 1993)	3 to 21 years	Assesses personal independence and personal responsibility in daily living as well as problem behavior. Both school/community and residential/community versions.
Adaptive Behavior Assessment System, second edition (ABAS; Harrison & Oakland, 2000)	Birth to 89 years	Assesses 10 adaptive skills domains. Infant/Preschool, School Age, and Adult kits available.
Adaptive Behavior Evaluation Scale—Revised (second edition) (McCarney & Arthaud, 2006)	4 to 12 years; 13 to 18 years	Includes both home and school versions.
Battelle Developmental Inventory II (Newborg, 2004)	Birth to 8 years	Assesses Personal–Social, Adaptive, Motor, Communication, and Cognitive. Assesses through interview, direct testing, or observation. Screening test also available.
Comprehensive Test of Adaptive Behavior—Revised (CTAB-R; Adams, 1999)	Birth to 60 years	Assesses Self-Help Skills, Home Living Skills, Independent Living Skills, Social Skills, Sensory and Motor Skills, Language Concepts, and Academic Skills.
Developmental Profile II (Alpern et al., 1989)	Birth to 12 years, 6 months	Well-standardized tool that covers a number of dimensions and contains 186 items.
Scales of Independent Behavior—Revised (SIB-R, Bruininks et al., 1996)	Birth through adult	Assesses Social Interaction and Community Skills, Personal Living Skills, Community Living Skills, Motor Skills, and Problem Behavior.
Vineland Adaptive Behavior Scales II (Sparrow, Cicchetti, & Balla, 2005)	Caregiver Survey Interview Form: 0 to 90 years Teacher Rating Form: 3 years to 21 years, 11 months	Assesses Communication, Daily Living Skills, Socialization, and Motor Skills (for ages 6–11 and younger). Caregiver survey and expanded interview forms and Teacher/Caregiver rating forms available.

& Leland, 1993), was normed on two groups: a sample of 2,000 students with intellectual disability and a sample of 1,000 typically developing students, ages 3–21 years. The scale should be completed by someone who knows the child or adolescent well; results are expressed as either standard scores ($X = 10$, $SD = 3$), percentiles, or age equivalents. There are nine skills domains and seven maladaptive behavior domains. The Scales of Independent Behavior—Revised (SIB-R, Bruininks, Woodcock, Weatherman, & Hill, 1996) contains a full-scale form, short form, and early development form, each of which also includes a Problem Behavior scale. Domains assessed include Social Interaction and Community Skills, Personal Living Skills, Community Living Skills,

and Motor Skills. The Comprehensive Test of Adaptive Behavior—Revised (CTAB-R; Adams, 1999) is normed for children and adults, covering areas such as self-help skills, home living skills, independent living skills, social skills, sensory and motor skills, language concepts, and academic skills. The teacher is typically the primary respondent, but information from other sources (e.g., a parent or guardian survey) can be used in order to complete the assessment tool.

The Adaptive Behavior Assessment System, Second Edition (ABAS; Harrison & Oakland, 2000) is a relatively new scale, based on the 10 adaptive skill domains identified in the 1992 AAIDD definition. Consequently, it is not possible to derive broader domains that corre-

spond to the 2002 AAIDD definition (requiring the evaluator to use only the total score). The ABAS is normed across the age span (birth to 89 years) and includes infant/preschool, school age, and adults kits. Parent, teacher, and day care forms are available.

A number of alternative adaptive behavior scales are also worth considering. One well standardized tool is the Developmental Profile II (Alpern, Boll, & Shearer, 1989), a 186-item inventory covering birth to 12 years, 6 months of age. Another option is the second edition of the Adaptive Behavior Evaluation Scale-Revised (McCarney & Arthaud, 2006). This recently updated scale comprises separate versions for 4- to 12-year-olds and 13- to 18-year-olds. The scale also includes both a home and school version. Finally, the Battelle Developmental Inventory II (Newborg, 2004), designed for children from birth to 8 years of age, covers five domains: Personal-Social, Adaptive, Motor, Communication, and Cognitive. Whereas the assessment takes 1–2 hours to complete, there is a screening test that requires 10–30 minutes. Ratings can be obtained via interview with parents, direct assessment of the child, or through observation of the child in the natural environment.

Recommendations

Although there are a number of options available for assessing adaptive behavior, the Vineland Adaptive Behavior Scales (Sparrow et al., 2005) remains that most frequently used tool. However, the Vineland is based on parent and/or teacher report rather than direct observation of an individual's skills by an independent evaluator. Clinicians who desire to conduct their own observations of adaptive behavior (in addition to obtaining parent-teacher feedback) may find the Battelle Developmental Inventory II (Newborg, 2004) to be of use. However, the scale only goes up to age 8 and can require a considerable length of time to complete.

ASSESSING PSYCHOSOCIAL FACTORS

As discussed previously, a range of psychosocial factors place an individual at risk for intellectual disability. The AAIDD (2002) divides psychosocial risk factors into three categories: social (e.g., poverty, maternal malnutrition,

lack of pre- and perinatal care), behavioral (e.g., parental substance abuse, domestic violence, child abuse and neglect), and educational (e.g., inadequate early intervention and special education services, impaired parenting). It is important to assess such factors, both to increase the understanding of potential contributions to intellectual dysfunction and to assist in development of recommendations for treatment. A considerable literature indicates that families of children with intellectual disability experience significantly more parental stress than other families (Baker, Blacher, Crnic, & Edelbrock, 2002; Nachsehn & Minnes, 2005). The level of stress perceived by families may be influenced by a number of factors, such as a child's diagnosis (Crnic, Friedrich, & Greenberg, 1983), severity of the handicapping condition (Donovan, 1988), severity of behavior problems (Baker et al., 2002; Hassall, Rose, & McDonald, 2005; Margalit, Shulman, & Stuchiner, 1989), a child's age (Bristol, 1979), race (Flynt & Wood, 1989), maternal age (Flynt & Wood, 1989), family socioeconomic status (Rabkin & Streuning, 1976) and parental marital status (Salisbury, 1987). The additional caregiving requirements for children with developmental disabilities are often a significant source of stress to families, with level of stress positively associated with the caregiving demands placed on mothers (Beckman, 1991). The availability of informal supports also has been found to be negatively associated with mothers' stress levels (Beckman, 1991).

Interestingly, siblings of children with intellectual disability appear to experience fewer adjustment problems than their parents. For example, Dyson (1989) compared 55 older siblings of young children with handicaps and 55 matched siblings of nonhandicapped children. Results indicated similar levels of self-concept, behavior problems, and social competence in the two groups. Hannah and Midlarsky (1999) also found no overall differences between siblings of children with intellectual disability and siblings of typically developing children on measures of internalizing disorders, externalizing disorders, and self-esteem. In a further examination of sibling functioning based on type of handicap, siblings of children with intellectual disability evidenced the best adjustment levels. These findings are consistent with other reports (e.g., Breslau, Weitzman, & Messenger, 1981; Lobato, Barbour, Hall, & Miller, 1987).

A number of structured questionnaires are available to assess family functioning. For example, the Parenting Stress Index—Third Edition (PSI; Abidin, 1995), a 120-item questionnaire, assesses family stress related to child characteristics, parent characteristics, and life stressors. The tool was normed with 2,633 parents of children 1 month through 12 years of age. Referenced group profiles are provided for families of children with autism, as well as with developmental disabilities. A short form comprising 36 questions is also available. The PSI has received considerable use by researchers examining stress in families of children with developmental disabilities. For example, Hassall and colleagues (2005) recently documented a positive relationship between level of parental stress (as measured by the PSI) and parental locus of control, parenting satisfaction, and child behavior difficulties in a group of 46 mothers of children with intellectual disability. Nachshen and Minnes (2005) also documented that parents of children with developmental disabilities reported more stress and less well-being, as measured by the PSI, than parents of typically developing children.

A number of other assessment tools have been used in studies of families of children with developmental disabilities. For example, the Questionnaire on Resources and Stress—Short Form (Friedrich, Greenberg, & Crnic, 1983) is a 52-item self-report questionnaire developed primarily for assessing stress in families who care for children with developmental or intellectual disability. It is a psychometrically derived version of the 285-item Questionnaire on Resources and Stress (Holroyd, 1974) and uses a true-false format. This tool was used by Dyson, Edgar, and Crnic (1989) to examine adjustment in siblings of children with developmental disabilities. The Family Impact Questionnaire (FIQ; Donenberg & Baker, 1993), a 50-item questionnaire that assesses parents' perceptions and of a child's impact on the family, has been used in recent studies of maternal well-being and parenting stress in families of preschoolers with developmental delays (Baker et al., 2002; Eisenhower, Baker, & Blacher, 2005; Nachshen & Minnes, 2005). The Family Member Well-Being Index (McCubbin, Pateron, & Glynn, 1982), an eight-item measure of family members' well-being, assessing health, tension, energy, cheerfulness, fear, anger, sadness, and general concern, was recently used in a study by Nachshen and Minnes (2005) to ex-

amine parental empowerment of school-age children with developmental disabilities. Finally, scales such as the Family Environment Scale (Moos & Moos, 1994) have a long history of use in family research, including studies of families with child or sibling with intellectual disability (e.g., Hannah & Midlarsky, 1999).

Recommendations

Despite the availability of a number of options to assess family functioning, the PSI, third edition (Abidin, 1995) is still used frequently with this and other pediatric populations. However, it fails to provide information regarding parental mental health and possesses only a limited number of items related to marital issues.

ASSESSING PSYCHIATRIC PROBLEMS

Conducting a psychiatric assessment for an individual with intellectual disability remains challenging for a number of reasons: (1) Language deficits often make it difficult for a child with intellectual disability to report internal and feeling states; (2) some behaviors may be maladaptive, yet developmentally appropriate (e.g., an adolescent with intellectual disability takes an item from a peer, but has no concept of "stealing"); (3) few available assessment instruments have been normed for this population; (4) sensory and/or physical impairments may complicate diagnosis; and (5) the presence of "diagnostic overshadowing" (Benson & Aman, 1999). Diagnostic overshadowing refers to situations in which the presence of intellectual disability decreases the diagnostic significance of a psychiatric disorder. In other words, behaviors that might be seen as evidence of psychopathology in typically developing children and adolescents are attributed to cognitive deficits in individuals with intellectual disability.

Proper diagnosis also often requires that clinicians rely on observable behavior rather than self-report (MacLean, 1993). As with typically developing children who require mental health treatment, parent/caregiver and teacher reports provide an invaluable source of information. Despite the aforementioned challenges, it is generally accepted that diagnostic criteria for psychiatric disorders, such as those found in DSM-IV-TR (APA, 2000), can be reasonably

applied to children and adolescents functioning at or above the mild range of mental retardation (IQs above 50). However, these criteria may be less appropriate or useful for those functioning within the severe to profound range of functioning (MacLean, 1993).

In assessing children and adolescents with intellectual disability, the clinician must be aware of certain symptom clusters that often may indicate the presence of a specific disorder associated with intellectual disability. For example, a child who exhibits regression in skills prior to 30 months of age, such as a loss of previously acquired language skills, along with unusual behaviors such as stereotyped hand movements, may be displaying symptoms consistent with Rett's disorder (APA, 2000). Lesch-Nyhan syndrome is often associated with severe self-injury (Nyhan, 1976). Children with Angelman syndrome typically display unprovoked laughter, hyperactivity, and sleep disorders, whereas children with Williams syndrome often have short attention spans but are quite social and often have strong musical skills (AAMR, 2002; Einfeld & Aman, 1995). Children with Smith-Magenis syndrome are often impulsive, have sleep disorders, and engage in stereotypical and self-injurious behaviors (AAMR, 2002).

Similarly, when evaluating a child or adolescent with a previously diagnosed medical disorder, it is important that the clinician be aware of any associated behavioral sequelae, because such behaviors are often the reason for referral. For example, when evaluating a child with intellectual disability secondary to lead poisoning, the clinician should ask questions regarding pica (the persistent eating of non-nutritive substances; APA, 2000). A child seen for evaluation with a diagnosis of Prader-Willi syndrome is likely exhibiting behaviors related to compulsive eating (Pueschel & Thuline, 1991).

Structured Diagnostic Interviews

To improve the reliability of open-ended psychiatric interviews, a number of structured psychiatric interview tools have been developed. Such interviews involve asking groups of questions in a standard manner and order. The rater indicates the presence or absence of each symptom, then tallies ratings at the conclusion of the interview and makes a diagnosis. Kamphaus and Frick (2002) reported a number of advantages to structured psychiatric interviews, in-

cluding (1) the ability to obtain important parameters of a child's behavior that are not typically assessed by most behavior rating scales, (2) the ability to provide temporal sequencing among behaviors (i.e., to determine whether a behavior suggestive of depression occurs contiguously with other behaviors associated with this diagnosis), (3) the ability to determine the level of impairment, (4) enhancement of the correspondence between the assessment technique and DSM diagnostic criteria, and (5) help in improving clinical assessors' competence in interviewing. Conversely, some specific weaknesses are also associated with structured psychiatric interviews: (1) the amount of time required to conduct such interviews, (2) the need to train interviewers to meet reliability standards, (3) lack of information from other sources (such as teachers), and (4) difficulty in accounting for age-related norms (i.e., being unable to account for age-appropriate differences in activity level between preschoolers and adolescents) (Kamphaus & Frick, 2002).

Three structured interview tools have received the most attention in the literature and have revised versions that include both DSM-III-R and DSM-IV criteria. Each has parent and child versions and takes up to 90 minutes to complete. None has been normed with children or adolescents with intellectual disability. The Schedule for Affective Disorder and Schizophrenia for School-Age Children—Present and Lifetime Version (K-SADS-PL; Kaufman, Birmaher, Brent, Rao, & Ryan, 1996), a semi-structured diagnostic interview, assesses past and present psychopathology in children and adolescents ages 6–18. It covers all major DSM-III-R and DSM-IV diagnoses applicable to this age group, with separate parent and child interviews. The Diagnostic Interview for Children and Adolescents-IV (DICA-IV) (de la Osa, Ezpeleta, Domenech, Navarro, & Losilla, 1997; Reich, 2000) was similarly developed for children and adolescents ages 6–18 and has a more structured format than the K-SADS. It, too, assesses all major DSM-III-R and DSM-IV diagnoses for children and adolescents. It also includes separate interviews for parents and children/adolescents and is available in a computerized form. The Diagnostic Interview Schedule for Children-IV (DISC-IV; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) is a highly structured, standardized interview schedule with versions for both children and parents. It is based on DSM-IV criteria cover-

ing children ages 6–17 years in the parent version and ages 9–17 in the self-report version. A computerized interview version (C-DISC) is also available. A couple of additional tools provide a similar interview format for both parent and child. The Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 2000), developed for individuals 8–17 years of age, and the Children's Interview for Psychiatric Symptoms (ChIPS; Weller et al., 2000), covering individuals 6–18 years of age, both offer possible alternatives to the K-SADS-PL, DISC-IV, and DICA.

Some of the available self-report interviews may be of particular interest to clinicians who assess children and adolescents with intellectual disability. However, none of these tools has been normed for individuals with developmental, cognitive, or learning disorders, and all appear to be based on DSM-III-R diagnostic criteria. The Dominic—Revised (Dominic-R; Valla, Bergeron, & Smolla, 2000), a structured pictorial questionnaire, assesses DSM-III-R–based diagnoses in children ages 6–11 years. A child is shown a number of drawings of a peer in situations associated with various childhood psychiatric disorders and is simply asked whether the same kind of thing has happened to him or her (“Are you like this?”). The reliability and validity data are promising. A recent article has been published with preliminary data on an adolescent version of the Dominic-R for 12- to 16-year-olds, also using DSM-III-R–based diagnostic criteria (Smolla, Valla, Bergeron, Berthiaume, & St. Georges, 2004). The third edition of the Pictorial Instrument for Children and Adolescents—Revised (PICA-III-R; Ernst, Cookus, & Moravec, 2000) comprises 137 pictures organized in modules that cover five diagnostic categories, including disorders of anxiety, mood, psychosis, disruptive behavior, and substance abuse. Although the standardization sample was drawn from individuals whose ages ranged from 6 to 16 years, limited data are available on the tool's psychometric properties. Like the Dominic-R, it uses DSM-III-R–based diagnostic criteria.

A few structured psychiatric interview schedules have been developed specifically for children and adolescents with intellectual disability. The Structured Clinical Interview (Spragg, 1988) was designed for individuals with intellectual disability. It uses simple language, relying on open-ended questions and items with choice formats. However, there are

limited available data on the scale's psychometric properties, and little evidence of its use for clinical or research purposes. The Schedule of Handicaps, Behaviour, and Skills (HBS)—Revised (Wing, 1982; Wing & Gould, 1978) was originally developed for children with intellectual disability or autism. Information is obtained from the caregiver in a semistructured interview. Although there are some psychometric data available (van Berckelaer-Onnes & van Duijn, 1993), it too does not appear to have received much attention in the literature.

Recommendations

The majority of tools reviewed here that were designed specifically for individuals with intellectual disability have seen limited use, and have minimal available data on psychometric properties. The clinical questionnaires with the strongest psychometric properties and history of use (e.g., K-SADS-PL, DISC-IV, DICA) require a greater amount of time to complete than is typically available within a clinical setting. Additionally, some require considerable training for staff to become skilled at proper administration (e.g., the K-SADS-PL). Consequently, most of these measures are used primarily for research purposes. Behavior problem checklists are an alternative option for assessing psychiatric problems in this population (discussed below).

Behavior Problem Checklists and Self-Report Scales

Behavior problem checklists have been used extensively to augment the diagnosis of psychiatric disorders in children with intellectual disability. Additionally, such tools have provided documentation of changes in behavior following a range of interventions, especially pharmacological treatment (e.g., Aman, De Smedt, Derivan, Lyons, & Findling, 2002; Handen & Hardan, 2006). Checklists can be completed by primary informants, such as teachers or parents, as well as by the child or adolescent. From an assessment standpoint, these tools allow one to obtain information from informants (e.g., teachers) who would otherwise not be available during the assessment. These tools also provide structure for informants and allow for comparison of the behavior of the child being evaluated with that of same-age and -gender peers.

The challenge facing the evaluator is whether to use a questionnaire that has been normed for children with intellectual disability or one that has been normed for typically developing children. From a diagnostic standpoint, the use of an appropriately normed tool is recommended. Such a tool takes into account population differences between typically developing individuals and those with intellectual disability. However, this is less of a concern for purposes of demonstrating a treatment effect (e.g., using either psychosocial or pharmacological treatment), because the individual can serve as his or her own control. However, the tool must be appropriate for individuals with intellectual disability. For example, a tool containing a high number of questions about con-

duct problems (e.g., swearing, threatening others with weapons) would be inappropriate for an adolescent with severe mental retardation and no language skills. I summarize some of the tools used in intellectual disability research, most of which have been normed with atypical populations.

Table 12.8 summarizes the most commonly used behavior problem checklists and self-report scales for children and adolescents with intellectual disability. Among the best-known checklists is the Conners Rating Scales (Conners, 1997), which have been used extensively as a supplemental data source for assessing ADHD and also the efficacy of a wide range of psychotropic medications in children with intellectual disability and/or autism

TABLE 12.8. Behavior Problem Checklists

Test	Age range	Description/comments
Aberrant Behavior Checklist (ABC; Aman & Singh, 1986) ^a	6 years to adult	Comprises 58 items and five factors: Irritability, Lethargy, Stereotypical Behavior, Hyperactivity, and Inappropriate Speech.
Conners Rating Scales (Conners, 1997)	3 to 17 years	Includes Parent and Teacher versions, including long and short forms. All forms include the ADHD Index.
Developmental Behaviour Checklist II (DBD-II; Einfeld & Tonge, 2002) ^a	Children and adults	A 96-item parent and 93-item teacher rating scale. Comprises five subscales: Disruptive/Antisocial Behavior, Self-Absorbed, Communication Disturbance, Anxiety, and Social Relating Disturbance. Norms for both parents and teachers.
Fear Survey for Children with and without Mental Retardation (Ramirez & Kratochwill, 1990) ^a	10 to 13 years	A 60-item, self-report questionnaire, appropriate for children with mild mental retardation. A self-report scale.
Nisonger Child Behavior Rating Form (Tasse et al., 1996) ^a	3 to 16 years	Includes parent and teacher forms. Comprises 66 items and five subscales: Conduct Problems, Hyperactivity, Self-Injury/Stereotypy, Insecure/Anxious, Self-Isolated/Ritualistic, Overly Sensitive (parent form), and Irritability (teacher form).
Reiss Scales for Children's Dual Diagnosis (Reiss & Valenti-Hein, 1990) ^a	4 to 21 years	Is a downward extension of the RSMB. Comprises 60 items with nine factors (e.g., Anger/Self-Control, Anxiety, Attention Disorder).
Reiss Screen for Maladaptive Behavior (RSMB; Reiss, 1988) ^a	Adolescents and adults	Comprises 38 items and seven clinical subscales: Aggressive Behavior, Psychosis, Paranoia, Depression (behavioral), Depression (physical), Dependent Personality Disorder, and Avoidant Disorder.
Repetitive Behavior Scale—Revised (RBS-R; Bodfish et al., 2000) ^a	NA	A 43-item rating scale with six factors: Stereotypical Behavior, Self-Injurious Behavior, Compulsive Behavior, Ritualistic Behavior, Sameness Behavior, and Restricted Behavior.

^a Normed or developed for individuals with mental retardation.

(Aman, Marks, Turbott, Wilsher, & Merry, 1991; Handen et al., 1992; Jaselskis, Cook, Fletcher, & Leventhal, 1992). The current revision of the checklist comprises a 59-item teacher version and an 80-item parent version. In addition, short forms for both teachers (28 items) and parents (27 items) are available. Each item is rated on a 4-point scale based on frequency of occurrence (from *Not at all* to *Very often*). The parent version comprises 10 subscales, whereas the teacher version has nine subscales. All four long and short versions include an ADHD Index.

Whereas the Conners Rating Scales are normed with typically developing children, they continue to be used as both a tool to establish research criteria for ADHD in children with intellectual disability and to document medication efficacy (e.g., Aman, Kern, McGhee, & Arnold, 1993; Handen et al., 1992). A 1994 study by Pearson and Aman compared the results of mental versus chronological age when using the Conners norms for children with intellectual disability. The study was prompted by the recommendation of some researchers and clinicians that mental rather than chronological age be used when comparing the score of a child with an intellectual disability with the normal group (Barkley, 1990). However, Pearson and Aman found significant correlations in only 4 of 27 comparisons between scale ratings and mental age, lending little support to guidelines stating that mental age be used to determine which norms should be applied when children with intellectual disability are evaluated.

A number of additional available behavior problem checklists have been developed and specifically normed for children, adolescents, and adults with intellectual disability. The reader is also referred to a 2004 chapter by Lecavalier and Aman, as well as an article by Aman (1994), that reviewed many of the available behavior problem checklists for use with this population.

The most extensively validated tool is the Aberrant Behavior Checklist (ABC; Aman & Singh, 1986). A Community Version of the ABC was validated in 1992 (Marshburn & Aman, 1992). The ABC comprises a list of 58 behavioral items, rated on a 3-point scale. The Community Version has been normed on a group of 666 children (ages 6–15) and 1,024 adults. The factor analysis resulted in five subscales: Irritability, Agitation/Crying, Lethargy/

Social Withdrawal, Stereotypic Behavior, and Hyperactivity. There are separate norms for children by both age and gender. The Community Version is completed by teachers or other staff who work with individuals with intellectual disability. The Nisonger Child Behavior Rating Form (Tasse, Aman, Hammer, & Rojahn, 1996) comprises a list of 66 behavioral items rated on a 4-point severity scale. The Nisonger was originally standardized on a sample of 369 children (ages 3–16) who were seen consecutively at an interdisciplinary clinic for children with intellectual/developmental disabilities. The majority of the sample functioned within the mild range of mental retardation. Both parent and teacher forms are available. Subscales include Conduct Problems, Hyperactivity, Self-Injury/Stereotypy, Insecure/Anxious, Self-Isolated/Ritualistic, Overly Sensitive (parent form), and Irritability (teacher form).

Another option for assessing mental health problems in adolescents and adults with intellectual disability is the RSMB (Reiss, 1994). It comprises seven clinical subscales, based on a factor analysis of data from a sample of 306 individuals with intellectual disability and mental health problems. An alternative for children is a downward extension of the RSMB, the Reiss Scales for Children's Dual Diagnosis (RSCDD; Reiss & Valenti-Hein, 1990). The original factor analysis was based on data from 313 individuals with intellectual disability (ages 4–21 years) seen at community-based agencies. Using a 3-point rating scale, the RSCDD comprises 60 items resolving into nine factors (e.g., Anger/Self-Control, Anxiety, Attention Disorder). However, because no "Depression" subscale was identified via the factor analysis, the authors selected a set of items from the DSM and other sources on an a priori basis to create such a subscale.

One of the most psychometrically sound behavior scales for children and adults with intellectual disability is the Developmental Behaviour Checklist II (DBD-II; Einfeld & Tonge, 2002). The authors have recently normed the scale (with a sample of 1,155 teachers and 1,536 parents), which was originally adapted from the Child Behavior Checklist (Achenbach, 1991). The scale seems to be particularly useful for individuals functioning within the moderate to severe range of mental retardation, but the recent revision includes a good number of items for individuals with mild

mental retardation (see Lecavalier & Aman, 2004). Utilizing a 3-point rating scale, the DBD-II comprises 96 items for the Parent version and 93 items for the Teacher version. Five subscales were derived from the most recent factor analysis: (1) Disruptive and Antisocial Behavior, (2) Self-Absorbed, (3) Communication Disturbance, (4) Anxiety, and (5) Social Relating Disturbance. A total behavior problem score may also be tabulated.

An assessment tool that may be useful for work with individuals with repetitive behaviors (a common problem among individuals with intellectual disability) is the Repetitive Behavior Scale—Revised (RBS-R; Bodfish, Symons, Parker, & Lewis, 2000). This empirically derived scale was developed by combining items measuring repetitive behaviors contained in other scales, along with clinical experience. The 43 items are rated on a 4-point scale, resulting in six factors: Stereotypic Behavior, Self-Injurious Behavior, Compulsive Behavior, Ritualistic Behavior, Sameness Behavior, and Restricted Behavior. Few self-report scales have been normed with individuals with intellectual disability. One of the obvious problems with such scales is the validity of the responses. One option is the Fear Survey for Children with and without Mental Retardation (Ramirez & Kratochwill, 1990), a simplified 60-item revision of the Children's Fear Survey Schedule (Ryan & Dietiker, 1979). The survey involves asking the child to indicate whether an item makes him or her scared, afraid, or nervous. Although it appears to be appropriate for children with mild mental retardation, the study sample included only children in the 10- to 13-year age range with intellectual disability.

Recommendations

In summary, for children and adolescents functioning within the moderate to mild range of mental retardation, scales such as those by Conners, may be useful but should be interpreted cautiously. Supplementing or replacing these scales with one that is normed and developed specifically for individuals with intellectual disability may be the best practice. For children and adolescents functioning within the severe to profound range of mental retardation, scales specifically developed for this population should be used. Obtaining information from multiple sources (e.g., parents and teach-

ers) is also recommended. Finally, one should be particularly cautious in using a self-report scale as the sole or primary source of information during an assessment.

BEHAVIORAL OBSERVATION

Direct behavioral observation provides an important part of a multimethod assessment of a child's strengths and weaknesses. When the referral question relates to specific behavior problems (e.g., self-injury, inattention), direct observation becomes paramount. Unfortunately, an outpatient clinic is not necessarily the best setting in which to observe a child. A child experiences considerable reactivity when first seen in a new and strange place. Therefore, when possible, home or school visits are an effective (although not necessarily efficient) means of obtaining valid information regarding a child's behavior. Because this is not always possible, researchers and clinicians have developed a number of different analogue, in-clinic situations that attempt to replicate home and school settings as closely as possible. In doing so, they hope to elicit behaviors similar to those observed outside the clinic.

Once the target behaviors have been identified (e.g., noncompliance, out-of-seat behavior, aggression), children may be observed in a variety of different situations within the clinic. However, it may require some ingenuity on the part of the clinician to provide a specific setting in which the target behaviors can be elicited and observed. For the child who is noncompliant, having the parent work with him or her on both easy and demanding tasks (e.g., simulate a homework session) may provide an opportunity both to see the behavior and to observe how it is handled by the parent. Sometimes, the assessment situation itself can elicit the behavior of concern. Such might be the case for a child who uses aggression or other disruptive behaviors to obtain attention. The youngster may attempt to interrupt or disrupt when the parent is talking with the clinician. Observing such interactions between parent and child provides a rich database from which to understand the problem and recommend solutions.

A variety of methods are available for quantifying direct observations of children alone or interacting with their parents. The most commonly used strategy is frequency recording,

which involves counting the number of occurrences of an event. For example, Kern, Mauk, Marder, and Mace (1995) examined the functional relationship between breath holding and various situations (e.g., being placed alone in a room, during play, being provided adult attention when breath holding) in a child with severe mental retardation and Cornelia de Lange syndrome. The dependent measure was the number of breath-holding episodes observed during each 10-minute observation. A second strategy involves recording the duration of an event. This might be useful when observing behaviors such as remaining seated or playing appropriately. The clinician simply records the total time a child engages in the target behaviors during the observation period. More complex observational strategies have involved the use of event sequences. For example, a clinician might track social interactions by scoring ongoing sequences of behavioral events, such as might occur during a mother-child interaction. Such data provide information on interactional patterns of behavior that can be used in treatment. Breiner and Forehand (1982) used such a tool to examine mother-child interactions in oppositional preschoolers with and without developmental disabilities. They found that mothers of the children with delays used significantly more commands, and the delayed children exhibited greater noncompliance than did the typically developing children. Similarly, Handen, Feldman, Lurier, and Husar (1999) observed mothers and their developmentally delayed preschoolers (all diagnosed with ADHD) during a clinic task, in which the mother asked the child to comply with 10 requests. Observations were conducted while the children were on both Ritalin and placebo. The preschoolers were found to be significantly more compliant and less disruptive during the Ritalin condition compared to the placebo condition.

A particular area of emphasis in behavior analysis has been to conduct a functional assessment of the target behaviors. Such an assessment can be done in a variety of ways. One strategy involves the taking data over a period of a few days or weeks (depending on the rate of the behavior of interest) by caregivers. When the target behavior occurs, information on possible antecedents (e.g., date, time, who was involved, what was occurring at the time), a description of the behavior, and the consequences

(i.e., how the behavior was managed) is gathered. With this information, the clinician can begin to develop hypotheses as to the function of the behavior and develop appropriate treatment interventions. Behavior analysts have typically divided the function of behavior into four categories: task avoidance, attention seeking, obtaining a tangible item, and obtaining sensory stimulation.

An alternative and more analytic approach is to conduct a functional analysis of a behavior. This involves the *direct manipulation of variables* to test the various functional relationships. One example is provided by Iwata, Dorsey, Slifer, Bauman, and Richman (1994), who used this model to better understand variables that either produced or maintained self-injury in nine children with developmental disabilities. Over a number of weeks, children were repeatedly observed for 15-minute periods in one of four experimental conditions: social disapproval for self-injury, academic demands in which the clinician turned away for 30 seconds following self-injury (with praise given for task completion), a no-demand play situation (with self-injury ignored), and an alone condition. Six of the nine subjects consistently evidenced higher levels of self-injury in specific stimulus conditions, suggesting that within-subject variability was a function of features of the environment. These findings have implications for the selection of appropriate treatment intervention. A number of other researchers have also used this model to assess children in a variety of settings. For example, Piazza and colleagues (2003) evaluated 15 children with feeding disorders (typically involving food refusal). Each child's behavior was observed under four different feeding conditions: (1) baseline: simply talking to the child throughout the meal and leaving a spoonful of food near the child's mouth; (2) attention: coaxing and other forms of adult attention following food refusal; (3) escape: removing the food following refusal to eat; and (4) tangible: providing tangible items (e.g., favorite toys, foods, or drinks) when the child refused to eat. Results found increased food refusal for 10 of the 15 children during one or more of the conditions, suggesting that environmental variables played a role in the feeding problem. Additionally, this information provided important information regarding possible treatment interventions for each child. Figure 12.1 shows in-

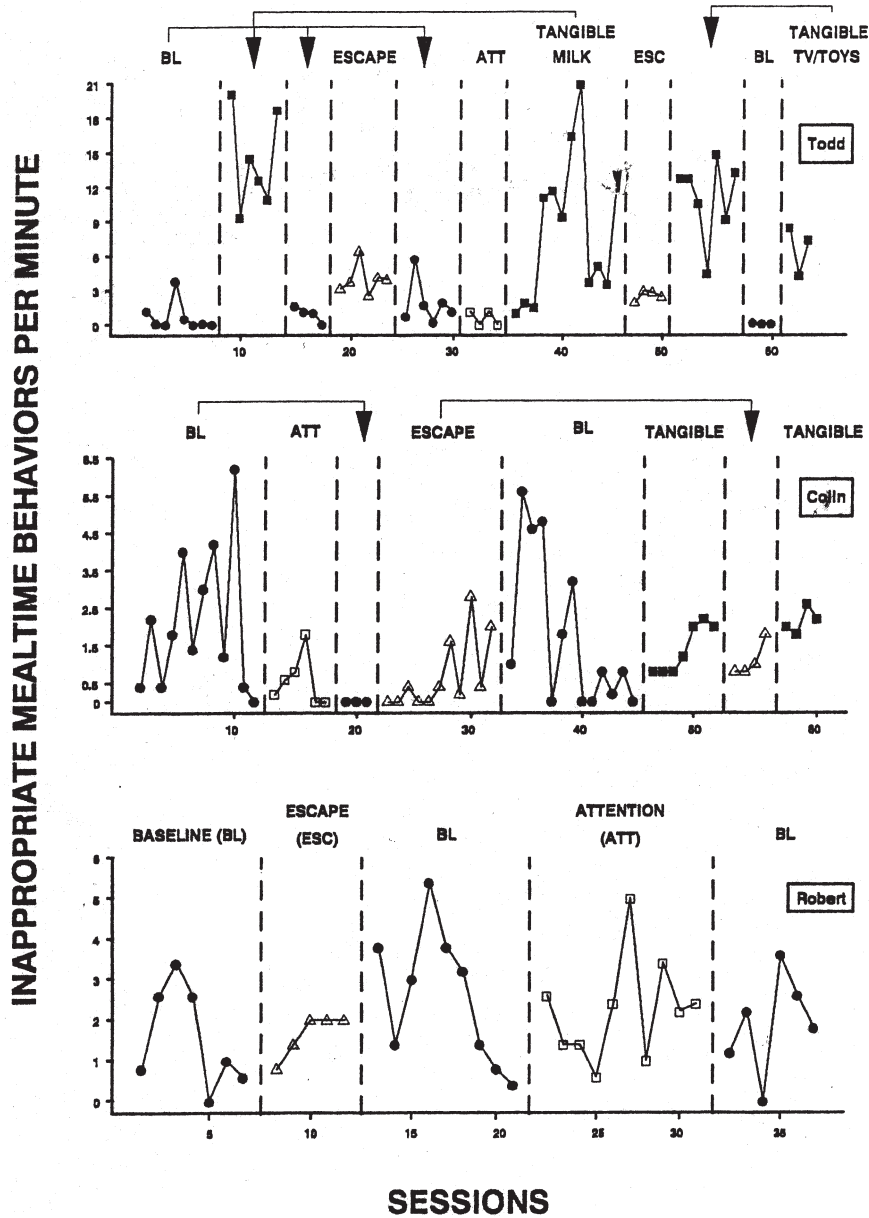

FIGURE 12.1. Inappropriate mealtime behaviors per minute for three children: Todd, Colin, and Robert. From Piazza et al. (2003). Copyright 2003 by the Society for the Experimental Analysis of Behavior. Reprinted by permission.

appropriate mealtime behaviors per minute in the attention and escape conditions for three children.

A number of clinicians and researchers have also developed complex observation systems to code behavior in the home or school. Such systems typically involve an interval recording strategy. This method divides time into small intervals (e.g., 10–15 seconds). Observers record as many as 25 possible behaviors (present-absent) during each interval. For example, Pierce and Schreibman (1997) used such a system to code social interactions between dyads of preschoolers with autism and typically developing peers. Daily sessions between two peers were videotaped and coded using 10-second intervals. Coded behaviors included maintaining interactions, initiating conversations, and initiating play. Computerized coding systems, such as the Social Interaction Code (SIC; Niemeyer & McEvoy, 1989), are also available. The SIC uses a laptop computer to code initiations, responses, and interactions of a target child with peers during play. A number of other software programs on the market allow clinicians/researchers to design their own coding schemes, depending on the target behaviors to be observed (e.g., The Observer XT, ProCoder for Digital Video).

Recommendations

The type of direct observational method to utilize depends on the specific behavior problem, as well as the resources available. Determining the function of the target behavior is the first priority if an appropriate treatment plan is to be developed. A clinician working within a school or home setting may observe the child directly. The clinician who is limited to seeing individuals in a clinical setting can still obtain outside data or observe directly through simulation of various conditions (e.g., a demand situation, play condition, attention condition). The ability to conduct abbreviated functional assessments within a clinic setting has been demonstrated by a number of researchers (e.g., Cooper et al., 1990; Wacker et al., 1994).

SUMMARY OF BEST PRACTICES IN ASSESSMENT

The choice of tools to be used for an assessment of a child or adolescent with intellectual

disability must match the question being posed. For example, a child who is referred for assessment and treatment of self-injurious behavior may not require IQ or achievement testing as part of the evaluation. Specific recommendations regarding assessment tools are provided at the end of each of the previous subsections. However, for a child referred for assessment of possible intellectual disability, a number of areas that represent current best practices should be thoroughly examined. These include a thorough developmental/medical history, use of a well-matched cognitive assessment tool, measurement of adaptive functioning, evaluation of achievement levels, assessment of related areas as appropriate (e.g., speech and language, motor, memory), the completion of behavior problem scale(s) (by both parent and teacher), and additional history and/or direct observation of behavioral concerns to assess the function of the behavior and to determine a possible comorbid psychiatric diagnosis. Referral to other specialists may also need to be considered (e.g., genetics, psychiatry, neurology, audiology, speech and language specialist, occupational therapy), depending on the possible role of other factors in the clinical picture (e.g., seizures, hearing loss, genetic disorder). Finally, the clinician needs to assess child and family strengths, and available resources to develop appropriate treatment recommendations.

INTEGRATING ASSESSMENT RESULTS

With data and information gathered from a wide array of sources, it may initially seem a formidable task to integrate the assessment results, let alone make treatment recommendations. Morgenstern and Klass (1991) suggest that the primary referral question should serve as a frame of reference for determining the answers to be provided during feedback to the family and in any subsequent report. Sattler (2001) recommends that a number of questions be considered that will guide the integration of information gathered during the assessment. Most important to consider is how the assessment results will help to answer the referral question and what questions remain. Once this is determined, the clinician must decide which major findings to interpret, which trends to develop in the feedback or report (i.e., Do the results suggest developmental delays across all areas? Do the results indicate consistent pat-

terns of errors or relative weaknesses?), and which recommendations to make. Crnic (1988) provides a list of six questions that may be useful in integrating assessment results.

1. Is there significant test scatter across skills areas?
2. How do the results compare with previous assessment?
3. Did changes in the structure of testing (e.g., testing limits or allowing the use of alternative strategies) affect performance?
4. What behavioral factors were problems and what factors were strengths? Did they affect the assessment outcome?
5. Did performance or behavior vary across settings?
6. Are historical variables (e.g., developmental, medical, behavioral) relevant to the child's performance?

In formulating specific recommendations following the assessment of a child with intellectual disability, Sattler (1988) suggests that a number of questions be considered:

1. Do the results indicate a diagnosis of intellectual disability?
2. Is the child eligible for special services?
3. What are the least restrictive options for programming?
4. If mainstreaming or inclusion is possible, what additional supports will be needed?
5. What are the child's social skills strengths and weaknesses?
6. What skills will be needed for productive employment (for adolescents)?
7. As the individual reaches adulthood, what types of supports will he or she require to live independently? If this is not possible, what type of living arrangement will be needed?

PROVIDING FEEDBACK

The success of the feedback session depends in large part on how the initial interview was conducted and on the development of a shared referral question between clinician and family. Assisting the family to frame the proper question early on sets the stage for productive and useful feedback. One should be careful not to have the feedback focus solely on a child's or adolescent's deficits. Instead, it will be impor-

tant to stress strengths, as well as areas in which interventions will be focused. Perhaps the most difficult feedback to offer a family is that of a diagnosis of intellectual disability. It is not unusual to find that others who have already evaluated the child and found identical results have never used the terms "intellectual disability" or "mental retardation" when talking with the family. This places the clinician in an awkward and in some ways unfair position. Yet it is important that this information be shared with the family.

The clinician should also offer to meet again with the family to process the information and to ensure that the recommendations have been followed. Specific recommendations should be provided in writing at the time of feedback whenever possible. These should include whom to contact regarding obtaining appropriate services, names of parent support groups, local and state resources for services such as respite, summer camperships, and so forth. Providing reading materials at the time can also be helpful. It is also important that families receive a copy of your report as soon as possible. Assessment results should not simply be exchanged among professionals and agencies, but should be shared with families. In fact, reports should be written with families in mind, so that they are clear and understandable, with as little jargon as possible. Often, when a family hears stressful news, it is difficult for them to hear the remainder of the findings and recommendations. Written reports provide another chance for family members to react to the results and recommendations.

SUMMARY

Assessment of the child or adolescent with intellectual disability is a considerable challenge. It requires a number of important skills on the part of the clinician, including the ability to work with families, knowledge of developmental and etiological issues, experience in using a range of standardized and criterion-based assessment tools, understanding of the service delivery system, knowledge of the law as it pertains to developmental disabilities, and experience in providing clinical interventions with this population. The heterogeneity of this group of children makes this a particularly daunting task. Consequently, the clinician needs to gather data from as many sources as

possible, assess a wide range of areas of functioning, and work closely with the family, as well as professionals from other disciplines. Finally, the clinician should work with the family to push the limits often placed upon individuals with intellectual disability. This means being open to suggesting the creative use of supports to enhance to the fullest the involvement of children and adolescents with intellectual disability in their schools, communities, and families.

Learning Disabilities

Deborah L. Speece
Sara J. Hines

It is an interesting and challenging time to consider the assessment of learning disabilities. The U.S. Congress recently passed legislation that modified regulations pertaining to identification of learning disabilities as part of the reauthorization of the Individuals with Disabilities Education Act (IDEA, 2004). Academics debate the merits of the changes and what they may portend for the field, while practitioners await state guidelines and, in some cases, apply new methods of identification. We assume that children and youth who struggle with learning the school curriculum continue to be identified and provided with services to assist their achievement despite the current ambiguity on identification procedures.

Our goal in this chapter is to identify, describe, and evaluate trends in the assessment of learning disabilities (LDs). The federal definition follows:

Sec. 602(30)(A)
SPECIFIC LEARNING DISABILITY.—

(A) IN GENERAL.—The term “specific learning disability” means a disorder in 1 or more of the basic psychological processes involved in understanding or in using language, spoken or written, which disorder may manifest itself in imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations.

(B) DISORDERS INCLUDED.—Such term includes such conditions as perceptual disabilities,

brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia.

(C) DISORDERS NOT INCLUDED.—Such term does not include a learning problem that is primarily the result of visual, hearing, or motor disabilities, of mental retardation, of emotional disturbance, or of environmental, cultural, or economic disadvantage. (IDEA Amendments of 2004, Sec. 602(30), p. 118)

This statutory definition has survived 30 years of scrutiny. Although modifications have been proposed, with some changes generally accepted by the field (Hammill, 1990), the central concepts of psychological processing problems coupled with academic difficulties remain intact. The recently passed regulations change the guidelines for implementing the statutory definition. It is here that the debate begins. There are two primary issues. The first is the possibility of not requiring an aptitude-achievement discrepancy. We view the discrepancy criterion as a proxy for psychological processing problems. The second is allowing a process called response to intervention (RTI) to be used as one means of documenting LDs. We provide more detail later on the changes, but it is this dynamic that sets the stage for most of our discussion. Although the regulations explicitly allow the possibility of using either a discrepancy formula or RTI, comments in the regulations by the U.S. Department of Educa-

tion suggest that RTI approaches are favored. In some sense, the train has left the station with RTI in the driver's seat. However, given the wiggle room in the current regulations and the need for any assessment to be valid regardless of backing by the federal government, we evaluate the merits (i.e., validity) of current identification standards. First we provide an historical perspective on LD assessment. A discussion of current issues that include overviews of exclusion factors, prevalence, and comorbidity follows this section. The primary emphasis in this section is the review of validity evidence for two major approaches to diagnosis: psychological/cognitive processing discrepancies and RTI. We end with recommendations and suggestions for future directions.

HISTORY OF LD ASSESSMENT

Historically the purpose of assessment of LD was not only to identify students with LDs but also to link assessment results to remediation. It seems that, over time, Federal involvement in the field resulted in an abandonment of the identification–assessment–remediation link. Therefore, we divide our analysis of historical issues into pre-Federal and Federal periods.

Hallahan and Mercer (2002) provide a detailed account of the history of LDs. Information for the current review relies heavily on that account, as well as those of Wiederholt (1974), Hammill (1993), Torgesen (1998, 2004), Shepherd, (2001), Hallahan and Mock (2003), and Lyon, Fletcher, and Barnes (2003).

Pre-Federal Involvement

Although the term “learning disabilities” was not coined until the 1960s, there is a long history of clinicians and researchers studying children and adults with related conditions. We highlight their major contributions to the identification and assessment of persons with LDs.

European Researchers

The contributions of Gall (ca. 1800) in Germany were integral to the development of the field of LDs (Hallahan & Mock, 2003; Hammill, 1993; Lyon et al., 2003). The systematic investigation of LDs began around 1800, with Gall's examination of adults who suffered head injuries resulting in loss of the ability to

speak (aphasia) but not the ability to write. Gall introduced the concept of relative strengths and weaknesses within an individual. He also focused on the related concept of specific rather than general cognitive deficits as the result of brain damage. Furthermore, for Gall it was critical that the patient's problems were not caused by other conditions, such as mental retardation or deafness, an exclusionary clause that continues in present definitions (Hammill, 1993).

Gall's discussions of the localization of brain functions stimulated and influenced the investigation of other European researchers concerned with spoken language disorders (Wiederholt, 1974). Specifically, the work of Bouillaud, Broca, Jackson, Wernicke, and Head established the occurrence of very specific types of mental impairment as a result of damage to isolated regions of the brain (Torgesen, 2004).

Hinshelwood, a French researcher, investigated not only individuals with head injuries, resulting in reading and language problems, but also children with what he referred to as “congenital word blindness” (Hallahan & Mercer, 2002). Kussmaul (1877) had previously used the term “word-blindness” to describe an adult patient with no apparent disability other than difficulty with reading (cited in Hallahan & Mercer, 2002). Hinshelwood was among the first to assert that congenital, rather than acquired brain defects, might cause children to have developmental reading problems and to speculate about effective remedial reading methods for such children. This concept of a specific reading problem that was not the result of a known head injury was significant to the conceptualization and assessment of LDs, as was Hinshelwood's linking of that condition to remediation. According to Wiederholt (1974), “Hinshelwood's landmark publications offered the first major detailed attempt to present the etiology of disorders of written language and to describe educational intervention techniques” (p. 117).

U.S. Researchers

READING-RELATED DISORDERS

European researchers in the 1800s who investigated the effects of brain injury or congenital factors on speech and language functions had a significant impact on research in the United

States. Several prominent physicians, psychologists, and educators used the findings of Gall, Hinshelwood, and other Europeans as a springboard for further research (Hallahan & Mercer, 2002). Specifically, Samuel Orton, Grace Fernald, Marion Monroe, and Samuel Kirk impacted the development of the LD field in the United States through their investigations of language and reading disabilities (Hallahan & Mercer, 2002).

Samuel Orton, in the 1920s and 1930s, relied heavily on Hinshelwood's prior work with individuals with "congenital word blindness." Orton's views differed from Hinshelwood's, in that Orton viewed the condition as more prevalent (over 10% of school population) than did Hinshelwood (less than 1 in 1000 students). Current estimates are more in line with Orton's view. Orton renamed the condition "strephosymbolia," which means mixed symbols, and hypothesized that inherited mixed cerebral dominance was the cause of many cases of the condition. He theorized that the nondominant hemisphere of the brain stored mirror images of those stored in the dominant hemisphere. In individuals with complete hemispheric dominance, the mirrored images were suppressed. However, in children with mixed dominance, the mirrored images emerged, causing reversals of letters and words, or strephosymbolia. Although Orton's ideas of mixed dominance are no longer popular in the field of LDs, Lyon and colleagues (2003) credit Orton with being the first to stress that reading disabilities were related to cerebral dysfunction and that they did not occur strictly in persons with low intelligence.

Orton was one of the first researchers to suggest direct instruction in phonics for students with reading disabilities, including instruction in sound blending. Furthermore, he was one of the first to suggest multisensory instruction for students with such disabilities. His ideas regarding phonics instruction were reflected in the work of Anna Gillingham and Bessie Stillman. In fact, the Orton-Gillingham method of phonics instruction is still used in practice. This technique uses a multisensory, direct instruction approach to teach phonics. Samuel Orton was prophetic in his emphasis on direct phonics instruction. Researchers over the last 20 years have linked phonological awareness deficits and poor grapheme-phoneme correspondence as the core issues underlying reading disabilities (e.g., Adams, 1990; Torgesen et al., 1999).

Marion Monroe, who served as Orton's re-

search associate, developed diagnostic tests based on the theories of Orton and Grace Fernald, and used the results to guide instruction. Monroe introduced two practices that are important in current theories of LD assessment (Hallahan & Mercer, 2002). First, she introduced the idea of discrepancy between actual and expected achievement as a means of identifying students with reading disabilities, calculating a reading index by comparison of the child's reading level (based on the average of four achievement tests) to an average of the child's chronological, mental, and arithmetic grades. Second, she advocated analyzing the specific types of reading errors children made on achievement tests to guide instruction, rather than focusing on the test scores. This practice introduced the notion of what would later be referred to as "diagnostic prescriptive instruction." Monroe also developed individual profiles of student errors to aid identification of students and selection of appropriate remedial tactics. The success of her instructional programs supported the optimistic belief that the reading problems of students could be remediated given the appropriate interventions based on diagnostic findings.

Influenced by Monroe's use of profiles, Samuel Kirk created the Illinois Test of Psycholinguistic Abilities (ITPA) as an instrument to provide profiles of intraindividual differences (Hallahan & Mercer, 2002). Results from the diagnosis of psycholinguistic strengths and weaknesses were used to inform remediation. Kirk's ITPA was the first formal attempt to measure cognitive processing and design remedial techniques based on the assessment findings. According to Barbara Bateman (2005), a student of Kirk in the 1960s, Kirk had a leading role in the field of LD as it emerged from its roots in language disorders, reading, and brain injury, because he distilled the three conceptual linchpins of LD: (1) the educability of intelligence; (2) pronounced intraindividual differences in cognitive abilities as the hallmark of children with LD, in contrast to the flat profiles of children with mental retardation; and (3) educational diagnosis of LD to inform recommendations of what and how to teach.

MORE GENERALIZED DISORDERS

The described work of Orton, Fernald, Monroe, and Kirk focused specifically on reading disabilities. It was the investigations of Heinz Werner and Alfred Strauss and colleagues dur-

ing the period after World War II that led to the emergence of the more generalized category of LD as a formally recognized field (Lyon et al., 2003). Kurt Goldstein's work in Germany with soldiers with head injuries influenced that of Heinz Werner and Alfred Strauss, who both emigrated from Germany to the United States and were simultaneously employed at the Wayne County Training School (Hammill, 1993). Together Werner and Strauss investigated whether children classified as mentally retarded who had suffered brain injury were different from those with congenital mental retardation. They wanted to determine whether the children classified as mentally retarded following brain injury were similar to Goldstein's nonretarded adults with brain injuries. They differentiated between children with brain injuries and retardation and those with congenital retardation, with a description of their correlated disorders, such as perceptual problems, impulsivity, disorganization, distractibility, disinhibition, and perseveration (Hallahan & Mercer, 2002; Hammill, 1993). Strauss and another colleague, Lehtinen, assessing the performance of these children with brain injuries and retardation, reported that they exhibited problems in the areas of figure-ground perception, attention, concept formation, as well as hyperactivity (Lyon et al., 2003). Strauss and colleagues used the term "minimal brain injury" (MBI) for these children. From their studies, the concept of MBI or dysfunction that emerged in the 1960s assumed that the condition could be identified by behavioral signs in the absence of physical or neurological evidence (Lyon et al., 2003).

The Wayne County research team recommended differentiated educational programming for the group with brain injuries. They suggested a distraction-free environment, and the diagnosis and remediation of perceptual disturbances (Hallahan & Mercer, 2002). According to Torgesen (1998, 2004) the effect of Werner and Strauss on the field of LD was profound, in that they crystallized three concepts used repeatedly by earlier researchers that provided a rationale for the field of LD as a separate entity, identifying a core about what was unique about children with LD. Those concepts were as follows: (1) individual differences in learning could be understood by examining how children approached learning tasks; (2) educational practices should be tailored to individual strengths and weaknesses; and (3) children with deficient learning processes could

be helped to learn normally, if those processes were strengthened (Torgesen, 1998, 2004). Werner and Strauss also suggested that standardized test scores be interpreted cautiously, advocating that clinicians dig deeper to determine why a particular error was made (Hallahan & Mock, 2003).

William Cruickshank extended Werner and Strauss's work with students with mental retardation to children with normal intelligence (Hallahan & Mercer, 2002). Cruickshank's instructional program focused on controlling the learning environment and providing readiness training in the form of perceptual and perceptual motor exercises, because he believed that deficiencies in those areas were responsible for the child's learning problems. The program paid little attention to reading or phonics instruction (Hallahan & Mercer, 2002). Results after the first year indicated that the program was only effective in improving perceptual motor abilities and reducing distractibility for the short term, and had no effects on achievement or IQ (Hallahan & Mercer, 2002).

A number of other individuals developed training programs in the 1960s for visual-perceptual and/or visual-motor skills; prominent among them were Newell Kephart, Marianna Frostig, Glen Doman, and Carl Delacato (Hallahan & Mercer, 2002). Their programs were also eventually found to be ineffective in improving academic performance. However, at this point in time, researchers had discovered tools they considered effective for identifying and educating students with disabilities, and they had sufficient knowledge to claim the existence of a specific construct, a construct not yet referred to as LD (Hallahan & Mock, 2003).

By 1963 the new LD field was moving toward the formal definition of LD as a handicapping condition (Lyon et al., 2003), based largely on the beliefs of the previously discussed pioneers in the field: that children with LDs learned differently than children with mental retardation, that their learning difficulties resulted from intrinsic (i.e., neurobiological) rather than environmental factors, that LDs were unexpected given the child's strengths in other areas, and that children with LDs required specialized education (Lyon et al., 2003). A further belief was that by examining a child's performance on formal (e.g., ITPA) and informal assessments, an appropriate and effective intervention plan could be developed.

Formal Definition and Federal Involvement

Creation of the Term "Learning Disabilities"

Samuel Kirk is generally credited with creating the term "learning disabilities." He originally defined the condition in his 1962 textbook *Educating Exceptional Children*:

A learning disability refers to retardation, disorder, or delayed development in one or more of the processes of speech, language, reading, writing, arithmetic, or other school subjects resulting from a psychological handicap caused by a possible cerebral dysfunction and/or emotional or behavioral disturbances. It is not the result of mental retardation, sensory deprivation, or cultural or instructional factors. (cited in Hallahan & Mercer, 2002, p. 22)

It is interesting to note that emotional-behavioral factors were possible causes of LDs according to Kirk's 1962 definition. However, he excluded children who were deaf or blind, mentally retarded, or who suffered from educational or cultural disadvantages.

The term "learning disabilities" was adopted in 1963 at a meeting of groups of parents and educators of children identified with a variety of names, including minimal brain injured, perceptually handicapped, and neurologically impaired. The parents and educators met in an attempt to unify their views. Kirk suggested "learning disabilities" at that meeting as a unifying term to define the children (Shepherd, 2001). That was the beginning of the group known today as the Learning Disabilities Association of America.

Bateman, a student of Kirk, redefined "learning disabilities" in 1965:

Children who have learning disorders are those who manifest an educationally significant discrepancy between their estimated potential and actual level of performance related to basic disorders in the learning process, which may or may not be accompanied by demonstrable central nervous system dysfunction, and which are not secondary to generalized mental retardation, educational or cultural deprivation, severe emotional disturbance, or sensory loss. (cited in Hallahan & Mercer, 2002, p. 23)

Bateman included in her definition Monroe's earlier IQ-achievement discrepancy concept as indicative of students with LDs. She also added emotional disturbance to the list of exclusionary factors. Both of Bateman's changes to

Kirk's definition were eventually incorporated into the Federal definition and regulations governing the identification of LDs, with far reaching consequences.

Federal Definition

In 1963, the U.S. government had convened three task forces to address issues related to LDs. Two of the task forces focused primarily on defining LD; they developed conflicting definitions on two controversial issues important to assessment: (1) whether or not nervous system dysfunction is a primary causal factor, and (2) whether an IQ-achievement discrepancy is a defining characteristic of LDs. As these two task forces were attempting to name and define the LD construct, the Education of the Handicapped Act was signed into law; the act did not extend Federal assistance and protection to students with LDs (Hallahan & Mock, 2003).

The United States Office of Education (USOE) asked the National Advisory Committee on Health and Disability (NACHD), headed by Samuel Kirk, to define LD. The NACHD definition was similar to that in Kirk's 1962 textbook; however, emotional disturbance was listed as an exclusionary condition in accordance with the Bateman definition (Hammill, 1990).

As a result of intense lobbying by professionals and parents with a stake in the field of LD, Federal legislation was passed to include students with LDs (Hammill, 1993). In 1969, the Elementary and Secondary Education Act of 1965 was amended to include students with LDs as a special education category.

In 1975, with the Passage of the Education for All Handicapped Children Act (Public Law No. 94-142), the Federal government mandated that school districts provide free and appropriate education to all children with handicaps, including those with LDs. During the House Subcommittee Hearing on Public Law No. 94-142, concern was expressed regarding the vagueness of the proposed definition. The Bureau of Education for the Handicapped was instructed to find a better definition that explained explicitly how children were to be identified. Consensus was not achieved, so the NACHD definition, with a few minor modifications, was adopted (Hammill, 1990).

The following definition was used in Public Law No. 94-142:

The term “specific learning disability” means a disorder in one or more of the basic psychological processes involved in understanding or using language, spoken or written, that may manifest itself in an imperfect ability to listen, read, spell, write, or to do mathematical calculations, including such conditions as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. The term does not include children who have learning problems that are primarily the result of visual, hearing, or motor handicaps, or mental retardation, or emotional disturbance, or of environmental, cultural, or economic disadvantage. (cited in Hallahan & Mock, 2003, p. 24)

The definition of learning disabilities that first appeared in 1975 in Public Law No. 94-142, the Education of all Handicapped Children Act, was also incorporated in revisions of that law (IDEA—1990, 1997, and 2004). The current revision of IDEA was reauthorized in December 2004.

IQ–Achievement Discrepancy

There is an operational definition in the Federal law, which first appeared in a separate set of regulations for children with LDs (USOE, 1977). These regulations, in accordance with the Bateman definition, state that a student has a specific learning disability if (1) the student does not achieve at the proper age and ability levels in one or more specific areas when provided with appropriate learning experiences, and (2) the child has a severe discrepancy between achievement and intellectual ability in one or more of seven areas (i.e., oral expression, listening comprehension, written expression, basic reading skills, reading comprehension, mathematics calculation, and mathematics reasoning). It is this operational definition that has resulted in reliance on evidence of an IQ–achievement discrepancy in LD diagnoses.

The focus in the regulations on a severe discrepancy resulted in a significant conceptual shift in LD from psychological processes to unexplained underachievement (Reschly, Hosp, & Schmied, 2003). This shift was in part a response to controversy about the psychological processing clause included in the definition (Torgesen, 2004). As discussed earlier, various programs to remediate specific processing deficits identified by assessment of processing abilities had not been proven effective for improv-

ing academic, cognitive, or even long-term perceptual–motor abilities. Although tests of specific processing abilities at that time (which often were focused on visual processing and visual–motor abilities) were ineffectual in determining appropriate intervention, they at least represented an attempt to link LD assessment to intervention. The shift to the IQ–achievement discrepancy criterion in the federal regulations abandoned this assessment goal. Discussion of psychological processes, as well as the use of the IQ–achievement discrepancy in assessment, is included later in this chapter.

In the 1976 Federal Register, the Bureau of Education for the Handicapped (USOE, 1976) suggested a formula for determining a severe discrepancy. The concept of “severe discrepancy” was defined as achievement 50% below expectations. This component, according to Hammill (1990), led to the development of state formulas for calculating a severe discrepancy between intellect and achievement. Opposition to the USOE formula approach was immediate; as a result, the formula was dropped from later regulations. However, although the USOE deleted the formula from its 1977 definition, many states seized on the idea of aptitude–achievement discrepancy, and designed and implemented their own formulas (Hammill, 1990). As of 2001, 48 of 50 states included the severe discrepancy between intellectual ability and achievement in their LD classification criteria (Reschly et al., 2003). No Federal guidance was provided regarding how the discrepancy was to be determined or what constituted a “severe” discrepancy. As a result, the definitions of and methods used to determine such a severe discrepancy vary dramatically across the states (Reschly et al., 2003).

There was another, practical rather than theoretical reason for the inclusion of discrepancy criterion in the regulations. According to Weintraub (2005), the question of whether to include students with LDs in Federal legislation was a major contention, because opponents argued that the proposed definition of LD was too vague and could possibly require services to millions of students. As a result, an amendment was agreed to on the floor of the House of Representatives, capping the number of students who could be served under the LD category at 2% (Reschly et al., 2003). This cap was subsequently lifted when the USOE adopted regulations for identification of students with

LDs, including the severe discrepancy requirement that would supposedly limit the number of students served to 1–3% of the total population (Weintraub, 2005). It is interesting to note that the current percentage of students classified as having LDs is almost double the higher limit of that estimate. Therefore, in addition to moving identification of LD away from assessment that informs instruction, the discrepancy criterion did not limit the identified population as intended. A more detailed discussion of the prevalence of LD is included later in this chapter.

The most recent edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; American Psychiatric Association, 2000) largely reflects the Federal perspective. Differences include use of the term “learning disorders” instead of learning disabilities and more emphasis on distinguishing among academic domains in diagnosis. The domains are reading, mathematics, and written expression, with an additional category for “learning disorder not otherwise specified.” The similarity is the embrace of a discrepancy model. Interestingly, there is no qualification associated with use of discrepancy despite an impressive body of research that calls its validity into question.

CURRENT ISSUES IN ASSESSMENT OF LDs

Other difficulties with the diagnosis of LD are the exclusion factors maintained in the statutory definition and the likelihood that an LD co-occurs with other conditions. On the one hand, the law seemingly ignores the possibility of comorbidity via the exclusions; on the other hand, research documents comorbidity. In contrast to Federal implications, DSM-IV-TR (American Psychiatric Association, 2000) guidelines support comorbid diagnosis including not only the co-occurrence of more than one academic difficulty but also cross-classification diagnosis with mental retardation, pervasive developmental disorder, and communication disorder. We next provide a brief overview of exclusion factors in the Federal definition and the most prominent comorbid conditions.

Exclusion Factors

The exclusionary factors in the Federal definition are retained in the latest reauthorization of

IDEA and include visual, hearing, or motor disabilities; mental retardation; emotional disturbance; and environmental, cultural, and economic disadvantage. Children cannot be diagnosed as having LDs if the cause of the learning problem is attributed to these sources. Fletcher and colleagues (2002) argued that the cognitive correlates of academic difficulties attributed to social, cultural, and economic disadvantage do not appear to be different from those associated with LD. Also, according to Lyon and colleagues (2001), a child’s intervention needs and response to intervention do not vary according to these distinctions. The exclusion of environmental factors is problematic, because such factors interact with and exacerbate LDs (Fletcher et al., 2002). Such factors need to be considered when evaluating a student and determining treatment, rather than discounted as not being the cause of the disability.

Comorbid Conditions

Social–Emotional Problems

Accumulating evidence indicates that a significant number of children with LDs are likely to have social–emotional problems. Students with LDs evidence problems in virtually every category of social well-being, that is, affective, self-concept and attributions, and social skills (Bryan, 1998). In a meta-analysis of 152 studies, Kavale and Forness (1996) found that on average about 75% of students with LDs manifest social skills deficits that distinguished them from comparison groups. The differences were consistent across different evaluators (peers, teachers, and the students themselves) and across major dimensions of social skills.

The results of several studies comparing students with and without LDs have consistently found that students with LDs are more likely to experience feelings of depression, anxiety, and loneliness (Bryan, 1998; Bryan, Burstein, & Ergul, 2004). Wright-Strawderman and Watson (1992) investigated the prevalence of depressive symptoms in elementary school children, ages 8–11, with LDs, and found that 35.85% scored in the depressed range on the Children’s Depression Inventory. Depression is not only a serious mental health issue but also an academic one. Negative affect depresses memory and produces inefficient information

processing; it affects the performance of complex cognitive functions that require flexibility, integration, and utilization of cognitive material (Bryan et al., 2004). The high percentage of children with LDs who reported depressive symptoms suggests that depression should be assessed in the diagnostic process (Wright-Strawderman & Watson, 1992). Maag and Reid (2006), however, caution that although researchers have found that students with LDs obtain statistically higher scores on measures of depression than their peers, it is not known whether the degree of difference is sufficient to place them in the clinical range. The authors stated that there are not unequivocal data to indicate that students with LDs are any more likely than their peers to have clinical depression.

Children with comorbid LDs and serious emotional disturbance are underidentified and underserved in special education systems (Handwerk & Marshall, 1998). A deterrent to such comorbid diagnosis is the stipulation in the Federal regulations that an LD cannot be caused by emotional factors. The exclusion of emotional factors in the LD definition is interesting, because for a child to qualify as emotionally disturbed, the impairment must adversely affect his or her educational performance (Handwerk & Marshall, 1998). Regarding the exclusion of students with emotional disabilities, Fletcher and colleagues (2002) state that early failure to achieve may be causally related to, and often precedes, the development of behavior problems and should be considered in evaluation.

In contrast to the Federal definition, past definitions of LDs have made either a direct or indirect connection between LDs and social-emotional deficits. The Learning Disabilities Association of America (formerly the Association for Children with Learning Disabilities), the Federal Interagency Committee on Learning Disabilities, and the National Joint Committee on Learning Disabilities all defined LDs as co-occurring with social and/or emotional problems (Elksnin & Elksnin, 2004). It should be noted that Kirk's original LD definition included emotional problems as a possible causal factor. However, the current Federal definition fails to consider the social-emotional deficits of children and adolescents with LDs. No changes in the LD definition referencing the effect of social problems were included in the recent reauthorization.

Attention-Deficit/Hyperactivity Disorder

LDs are often linked to attention-deficit/hyperactivity disorder (ADHD). Although ADHD is not a category under IDEA, children with ADHD are usually included under the other health impaired category if they do not qualify under any other category, such as LD or serious emotional disturbance (SED). Estimates of comorbidity between LD and ADHD vary considerably. Tabassam and Grainger (2002) stated that for students with LD, comorbidity with ADHD ranges from 40 to 80% across studies. Voeller (2004) reported that 80% of children selected because of severe phonological awareness deficits met criteria for ADHD. Children with a primary diagnosis of ADHD often have comorbid LDs as well. Voeller (2004) stated that it is rare to encounter a child with pure ADHD, without emotional or learning problems. Mayes, Calhoun, and Crowell (2000) analyzed data for 119 children ages 8–16, evaluated in a child diagnostic clinic, and found that an LD was present in 70% of the children with ADHD. Of interest is that children with both an LD and ADHD had more severe learning problems than children with an LD alone. Also children with an LD, but not ADHD, had some attention problems, and children with ADHD, but not an LD, had some degree of learning problems. The authors stated that results of their study indicate that learning and attention problems occur on a continuum, are interrelated, and usually coexist; therefore, psychologists should take these factors into consideration when assessing either condition.

Math Disability

It is increasingly common for researchers to specify the academic domain that is the target of the LD. Thus, comorbidity among academic disabilities requires consideration. Reading disability is the most frequently studied learning disability, followed by math, and there are a few studies of their co-occurrence. Light and DeFries (1996) reported that approximately 80% of students with LDs experience reading problems, and most of these students also evidence comorbid deficits in mathematics. In contrast relatively few children with LDs have problems restricted to mathematics and quantitative reasoning. These findings are contradicted by a recent epidemiological study,

wherein 35.0 to 56.7% of children with math disabilities (depending on formula used) did *not* experience a comorbid reading disability (Barbarese, Katusic, Colligan, Weaver, & Jacobsen, 2005). They also reported that the cumulative incidence of math disability ranged from 5.9 to 13.8%, and that boys were significantly more likely to experience a problem.

Investigations indicate that children with comorbid reading and math disabilities fare worse than children with a singular diagnosis. In the elementary school years, children with math difficulties (MD) who are good readers progress faster in mathematics achievement than do children with comorbid math and reading difficulties (MD/RD), independent of other factors (Hanich, Jordan, Kaplan, & Dick, 2001; Jordan, Hanich, & Kaplan, 2003). Specifically, children with MD evidenced an advantage over those with MD/RD in areas mediated by language (e.g., word problems and verbal counting), but not in areas associated with numerical understanding or rapid retrieval of math facts. According to Hanich and colleagues (2001), children with MD should be considered separately from children with MD/RD, because children with MD may have an advantage over children with MD/RD on skills that require or are mediated by language.

Comorbid Diagnosis

Despite evidence of comorbidity between LD and other conditions, Federal regulations and state guidelines discourage comorbid diagnosis (Handwerk & Marshall, 1998). Although not explicitly prohibited, Federal reimbursements are based on number of students identified, not number of handicapping conditions identified, resulting in states' reluctance to acknowledge comorbidity (Handwerk & Marshall, 1998). This may be particularly true of comorbid conditions requiring additional treatment, such as emotional disturbance, rather than of those requiring accommodations or pharmacological interventions, such as ADHD. Furthermore, because ADHD is not listed as an exclusionary factor in the LD definition, practitioners may be more willing to consider it in assessment.

Prevalence of LDs

Since the passage of Public Law No. 94-142, there has been a steady increase in the number of students identified as having LDs. The first

year the law was implemented (1977–1978) approximately 800,000 children, or 1.8% of the enrolled population, received services under the LD category. By the year 2002, the number had increased to 2.6 million, or 5.8% of the school-age population (U.S. Department of Education, 2002). State prevalence varied from a low of 2.96% in Kentucky to a high of 9.46% in Rhode Island during the 2001–2002 school year (Reschly et al., 2003). Also, 50% of all children served under IDEA are classified as learning disabled (U.S. Department of Education, 2002). Of those students classified as having an LD, 1.3% are Native American, 1.9% are Asian/Pacific Islander, 19.9% are African American (non-Hispanic), 14.5% are Hispanic, and 62.4% are white (non-Hispanic) (U.S. Department of Education, 2002).

The disproportionate representation of certain ethnic groups in the IDEA disability categories of mental retardation and behavior disorders is an urgent issue (Hallahan & Mock, 2003). Although the degree of representation is not as great as that for other categories, African Americans are slightly overrepresented in the LD category, because they constitute 14.8% of the school-age population but 19.9% of the LD population, as are Native Americans, who constitute 1.0% of the school-age population and 1.3% of the LD population. Furthermore, the overrepresentation of these two groups in the LD category in certain states is substantial (Hallahan & Mock, 2003).

Etiology

As our discussion on history attests, LDs have long been associated with cognitive processing difficulties considered constitutional in origin. Despite the difficulty of connecting poor academic performance and brain anomalies in children with no known tissue damage, early researchers continued to draw the inference. This inference is also reflected in the Federal definition of LD through subsuming the terms “perceptual disabilities,” “brain injury,” and “minimal brain dysfunction.” Lyon and colleagues (2003) noted that whereas early attempts to link brain and behavior in LDs were highly speculative, more recent work in neurobiology provides support for such a connection (e.g., Shaywitz et al., 2004; Simos et al., 2005; Temple et al., 2003). Lyon and colleagues are careful to point out that such linkages do not argue against environmental influences, and

that the evidence is limited to reading disability associated with word decoding difficulties (dyslexia). We believe most scientists and practitioners likely agree that the locus of LDs is suboptimal cognitive processing. A primary point of disagreement is the extent to which these processes can be measured reliably with valid connections to brain activity. This issue is elaborated in our review of assessment methods that follows.

OVERVIEW OF EVALUATION OF ASSESSMENT METHODS

The next sections of the chapter evaluate the validity of psychological–cognitive processing and RTI models of LD identification. Our use of the term “validity” is based on Messick’s (1989a, 1989b, 1995) broader conceptualization of test validity. In the current context the “test” to be considered includes procedures to operationalize LDs. Messick proposed that traditional methods of evaluating validity are too narrow, and that not only data associated with test scores but also consequences of applying test scores require examination. In our evaluation of LD assessment procedures, we focus on what Messick called “construct validity,” which comprises traditional ideas about types of validity: reliability, content, criterion and construct validity, and relevance. Relevance reflects users’ evaluations of usefulness (Good & Jefferson, 1998) and we interpret this to mean connections between assessment data and intervention. Other aspects of Messick’s view of validity include examining consequences of test use. We touch briefly on consequences, as appropriate. For each method reviewed, evidence for construct validity is presented, followed by evidence for relevance.

ASSESSING PSYCHOLOGICAL PROCESSING DISORDERS

The term “psychological processes” has been retained as part of the definition of LDs in every reauthorization of IDEA. This is so despite (1) early dissatisfaction with the term that led to the 1977 Federal regulations instituting intellectual ability–achievement discrepancies as a criterion for identification rather than psychological processes (Reschly et al., 2003; Torgesen, 2004) and (2) consistent research

findings from earlier eras that the psychological processing approach to assessment and intervention were not valid (e.g., Kavale & Mattson, 1983; Klenck & Kirby, 2000).

Present-day proponents of psychological–cognitive processing assessment for LD identification argue that past attempts using discrepancy were flawed, because the measure of intelligence (primarily the Wechsler scales) lacked a theoretical base (Kavale, Holdnack, & Mostert, 2005; Naglieri, 2003). They argue that its measurement rather than the conceptual base for IQ–achievement discrepancy is flawed. Although the number of professional writers who support this position is rather small, the number of supportive practitioners is potentially large. Machek and Nelson (in press) reported that 75% of the school psychologists they surveyed endorsed assessment of cognitive processes in diagnosing LDs and over 60% were endorsed using IQ–achievement discrepancies. We review and evaluate several processing approaches, including the Wechsler Intelligence Scale for Children–IV (Wechsler, 2003), the Woodcock–Johnson Tests of Cognitive Abilities–III (Woodcock, McGrew, & Mather, 2001), the Cognitive Assessment System (Naglieri & Das, 2005), and the Kaufman Assessment Battery for Children–II (Kaufman & Kaufman, 2004).

Wechsler Intelligence Scale for Children–IV

A method used historically by diagnosticians to identify a processing disorder is examination of subtest scores from intellectual assessments to determine patterns of cognitive strengths and weaknesses. Such an analysis determines whether the resulting pattern of subtest scores differentiates between students with LDs and other, low-achieving students (Kavale, 2002). Hale and Fiorello (2004) reported that 90% of school psychologists use factor or index scores, subtest profile analysis, or both, in interpreting IQ tests. Because intelligence tests are the basis of such assessments and the Wechsler Intelligence Scale for Children is often used, we present a description and evaluation of the latest edition developed for children.

Description

The Wechsler Intelligence Scale for Children–IV (WISC-IV), released in 2003, is the current version of Wechsler’s intelligence tests for chil-

dren and adolescents. It is an individually administered test for individuals ages 6 years to 16 years, 11 months. Each of the three Wechsler Scales (Wechsler Adult Intelligence Scales, WAIS; Wechsler Intelligence Scales for Children, WISC; and Wechsler Preschool and Primary Scales of Intelligence, WPPSI) originally provided three IQ scores: Full Scale IQ (FSIQ), Verbal IQ, and Performance IQ. Calculation of these three IQ scores was based on performance on individual subtest scores. The WISC is a downward extension of the WAIS, and the WPPSI is a downward extension of the WISC. In 1999, in addition to the three aforementioned scales, the Psychological Corporation published the Wechsler Abbreviated Scale of Intelligence (WASI) that comprises four subtests (Similarities, Vocabulary, Block Design, and Matrix Reasoning). Also available is the WISC-IV Integrated version, which can be

ordered as an upgrade and incorporates the core and supplemental subtests of the WISC-IV, along with 12 “process approach” subtests (McCloskey & Maerlender, 2005).

The WISC-IV has more changes than any previous model (Flanagan & Kaufman, 2004; Groth-Marnat, 2003), including the elimination of the traditional Verbal and Performance IQs. In place of the performance and verbal scores, the primary scores are now derivatives of four factor-based index scores: Verbal Comprehension, Perceptual Reasoning, Processing Speed, and Working Memory (Prifitera, Weiss, Saklofske, & Rolfhus, 2005). Table 13.1 lists these indices and describes the associated subtests. A detailed description of changes is provided by Prifitera and colleagues (2005). In general, subtests and indices were updated to reflect contemporary views of cognitive processes and achievement.

TABLE 13.1. Subtests of the Wechsler Intelligence Scales for Children—4th Edition (WISC-IV) Organized by Index

Index	Subtest
Verbal Comprehension	<ul style="list-style-type: none"> • Comprehension: The student is required to answer orally presented questions pertaining to social rules or problems. • Similarities: The student is required to explain the similarities between oral word pairs. • Vocabulary: The student is required to name pictures or provide definitions for words. • Information (Supplemental): The student is required to answer factual questions of learned content. • Word Reasoning (Supplemental): The student is required to identify a common concept based on successive verbal clues.
Perceptual Reasoning	<ul style="list-style-type: none"> • Block Design: The student is required to rearrange a set of blocks to match visual patterns presented on a card (timed). • Picture Concepts: The student is required to choose pictures from rows in an array to form a group with common characteristics. • Matrix Reasoning: The student is required to draw visual analogies and respond to multiple-choice questions. • Picture Completion (Supplemental): The student is required to identify missing element of picture of common object or setting (timed).
Processing Speed	<ul style="list-style-type: none"> • Coding: The student is required visually to match numbers with corresponding symbols and record appropriate symbols under numbers (timed). • Symbol Search: The student is required visually to scan an array and mark target symbols (timed). • Cancellation (Supplemental): The student is required to scan both a random and a nonrandom arrangement of pictures and mark target pictures (timed).
Working Memory	<ul style="list-style-type: none"> • Digit Span: The student is required to repeat orally presented numbers forwards and backwards. • Letter-Number Sequencing: The student is required to recode orally presented letter-number combinations, stating the numbers in ascending order and the letters in alphabetic order. • Arithmetic (Supplemental): The student is required to solve mentally and express orally the answer to orally presented arithmetic problems.

Use and Validity

The FSIQ and index scores are generally the first scores examined by the practitioner (Zhu & Weiss, 2005). The four WISC Index scores (Verbal Comprehension, Perceptual Reasoning, Working Memory, and Processing Speed) are often compared in the diagnosis of an LD to determine an individual's pattern of cognitive strengths and weaknesses. In fact, the primary level of interpretation of the WISC-IV is at the index score level (Weiss, Prifitera, & Saklofske, 2005). The diagnostician typically compares the index scores either to the mean of the index scores or among themselves to determine an individual's relative strengths and weaknesses (Prifitera et al., 2005). However, interpretations should be made cautiously, because moderate index differences are common to the general population (Groth-Marnat, 2003), indicating little empirical support for the practice.

Another traditional practice of psychologists is to interpret the pattern of WISC subtest scores and classify the patterns of cognitive strengths and weaknesses based on subtest analysis. Often WISC subtest scores are combined to establish a profile supposedly characteristic of students with learning disabilities. Bannatyne (1968, 1974) was one of the earliest to define such a profile. Bannatyne believed that the WISC's division of subtests into Performance and Verbal IQ measures was not diagnostically helpful in identifying students with LDs (Smith & Watkins, 2004). He recategorized the WISC subtest scores into those testing spatial abilities, conceptual abilities, sequencing abilities, and acquired knowledge. Bannatyne suggested that the performance of students with LD would demonstrate spatial abilities > conceptual abilities > sequencing abilities > acquired knowledge. The theory underlying Bannatyne's recategorization was that people with LDs would be expected to do better on spatial, holistic tasks that require simultaneous processing than on learning tasks that require sequential processing (Groth-Marnat, 2003). However, although more students with LDs exhibit the Bannatyne profile than do students in general, score differences are well below significance (Kavale, 2002). Also, the majority of students with LDs do not have the profile (Groth-Marnat, 2003; Smith & Watkins, 2004).

Others have attempted to define profiles of subtests on which students with LDs score

lower compared to their overall performance. Three such WISC profiles are the ACID, the ACIDS, and the SCAD. Originally developed for the WISC-R (Groth-Marnat, 2003), the ACID refers to the scores on Arithmetic, Coding, Information, and Digit Span subtests; the WISC-III's Symbol Search subtest was added to the ACID profile to create the ACIDS profile (Groth-Marnat, 2003); the SCAD profile comprises Symbol Search, Coding, Arithmetic, and Digit Span subtests. Children with LDs have been found to score poorly on the ACID, ACIDS, and SCAD subtests relative to their overall performance. Although these profiles occur more frequently in individuals with LDs than in the general population, other groups also have the same profiles, the frequency for students with LD is not that much higher, and the majority of individuals with LDs do not exhibit the profiles (D'Angiulli & Siegel, 2003; Groth-Marnat, 2003).

To investigate profile analysis and students with LDs, Mayes and colleagues (1998) compared the performance of 66 children with LDs and 51 children without LDs, ages 6–16, on the WISC-III. Analyses involving the younger children (6–7 years old) were conducted separately, because the authors determined that their age might have precluded identification as having LDs. Mayes and colleagues found that the only profile with statistically significant frequency differences between children ages 8–16 with and without LD on the WISC-III was the AD (Arithmetic, Digit Span). For children with LDs, 38% had Arithmetic and Digit Span as two of their three lowest subtest scores, whereas only 9% of students without LD exhibited that profile. It should be noted, however, that the majority of students with LD did not exhibit the AD profile. Furthermore, the authors found that for children age 6–7 years, there were no profile differences between students with and without LDs. According to Maller (2005), although the WISC-IV manuals promote the use of profile analysis for interpreting an examinee's strengths and weaknesses, practitioners should be wary that such an interpretation increases the likelihood of findings due to chance.

Another strategy frequently used in diagnosis of LDs is to determine the meaning of extremely high or low individual subtest scores. A common method of such subtest analysis is to compute ipsative deviation scores, comparing the individual's subtest scores and the mean to identify strengths and weaknesses (Robinson

& Harrison, 2005). However, according to Flanagan and Kaufman (2004), ipsative scores have poor reliability, are not stable over time, and do not add anything to predicting achievement beyond measures of general intelligence. Groth-Marnat (2003) cautions that such an analysis needs to be undertaken with care, because individual subtests are not sufficiently reliable or specific, and a high degree of subtest scatter is fairly common. Groth-Marnat recommends the following when interpreting subtest variation: (1) Statistical significance of the fluctuations should be ascertained; (2) hypotheses should be checked against performance on other subtests requiring similar skills; and (3) hypotheses should be confirmed with additional information, such as the student's motivation, school records, teacher reports, other test scores, and medical records.

The WISC is also frequently used as a measure of overall IQ (FSIQ) to identify children with IQ–achievement discrepancies that have long been considered a hallmark of LD diagnosis. This discrepancy is thought to indicate “unexpected” learning problems, presumably due to psychological or cognitive processing problems. Both logic and research have accumulated over the last 25 years, indicating that IQ–achievement discrepancies do not identify a unique group of children, they have a number of statistical and measurement problems, they require a history of failure before a discrepancy is apparent, and they do not inform instruction or prevention efforts (e.g., Fletcher et al., 1994; Share, McGee, & Silva, 1989; Stanovich & Siegel, 1994; Stuebing et al., 2002). This work is reviewed in a number of articles (e.g., Fletcher et al., 2002) and is not elaborated here. Our conclusion is that little evidence supports the use of intellectual–achievement discrepancies, and the burden is on its proponents to provide validity evidence.

Summary of Validity

The evidence supporting the construct and relevance validity of the WISC-IV is uneven. Some reviewers believe it is psychometrically sound (Groth-Marnat, 2003; Hale & Fiorello, 2004), whereas others do not (Maller, 2005). The previously mentioned review suggests that clinical practices such as profile analysis for identification of LDs are not valid. Furthermore, its usefulness in informing instruction for students with LDs is questionable. Braden and Niebling (2005) provided a detailed analysis of the valid-

ity of the WISC-IV and stated that “little or no direct evidence is provided for specific claims regarding treatment planning or links to neuropsychological foundations” (p. 620). Its usefulness as part of an index to measure discrepancy has been soundly rejected. So what conclusion should one draw then in terms of the role of the WISC-IV in the assessment of children with LDs? Should it be used under certain circumstances? In a particular way? Not at all? In summary, although the WISC has a historical role in the diagnosis of LDs, its validity or usefulness for that purpose has not been established. In our opinion its use should be reserved in LD diagnosis for measuring overall IQ to rule out the possibility of mental retardation. It should not be routinely administered as part of a diagnostic battery.

Woodcock–Johnson III Psychoeducational Battery

Description

The Woodcock–Johnson III Psychoeducational Battery (WJ-III) comprises two batteries: the Woodcock–Johnson III Tests of Cognitive Abilities (WJ-III-COG) and the Woodcock–Johnson III Tests of Achievement (WJ-III-ACH). The authors describe the WJ-III-COG as a comprehensive set of individually administered tests for measuring cognitive abilities, scholastic aptitudes, and oral language for individuals from age 24 months to 90 years, which is complemented by the WJ-III-ACH (Mather & Woodcock, 2001). The WJ-III Diagnostic Supplement to the WJ-III-COG includes additional subtests.

The WJ-III-COG is based on the Cattell–Horn–Carroll (CHC) theory of cognitive abilities, a hierarchical framework of human cognitive abilities that comprises three strata: general intelligence, broad cognitive abilities, and narrow cognitive abilities. Although the Woodcock–Johnson Achievement battery is one of the most frequently used measures of achievement, the Cognitive battery historically has not been used as frequently as the Wechsler scales. Recently there has been increased interest in the WJ-III-COG, because it is based on the CHC model of intelligence, which many believe to be the most empirically supported and theoretically sound model (Taub & McGrew, 2004). Cizek (2005) stated that the W-J-III (COG and ACH) is a comprehensive, norm-referenced, individually administered assessment of those cognitive abilities, skills, and ac-

ademic knowledge most recognized as constituting human intelligence, and routinely encountered in school and other settings.

The cognitive battery contains 20 subtests, 10 of which are part of the standard battery, and 10, part of the extended battery. The subtests are organized into the following broad

CHC cognitive ability clusters: Comprehension-Knowledge (*Gc*), Long-Term Retrieval (*Glr*), Visual-Spatial Thinking (*Gv*), Auditory Processing (*Ga*), Fluid Reasoning (*Gf*), Processing Speed (*Gs*), and Short-Term Memory (*Gsm*). The WJ-COG subtests organized by broad CHC factors are listed in Table 13.2.

TABLE 13.2. Subtests of the Woodcock–Johnson III Tests of Cognitive Abilities (WJ-III-COG) Organized by Broad Cattell–Horn–Carroll (CHC) Factor

Broad CHC factor	Subtest
Comprehension–Knowledge (<i>Gc</i>)	<ul style="list-style-type: none"> • Verbal Comprehension (Standard): The student is required to identify objects, provide antonyms and synonyms, and complete verbal analogies. • General Information (Extended): The student is required to explain where objects are found and how they are typically used.
Long-Term Retrieval (<i>Glr</i>)	<ul style="list-style-type: none"> • Visual–Auditory Learning (Standard): The student is required to learn and recall pictographic representations of words. • Visual–Auditory Learning–Delayed (Standard): The previous subtest is readministered after a time delay to measure ease of relearning. • Retrieval Fluency (Extended): The student is required to name as many examples as possible from a given category.
Visual–Spatial Thinking (<i>Gv</i>)	<ul style="list-style-type: none"> • Spatial Relations (Standard): The student is required to identify the subset of pieces required to form a target shape. • Picture Recognition (Extended): The student is required to identify a subset of previously presented pictures within a field of distracting pictures. • Planning (Extended): The student is required to trace a pattern without removing the pencil from the paper or retracing any lines.
Auditory Processing (<i>Ga</i>)	<ul style="list-style-type: none"> • Sound Blending (Standard): The student is required to listen to and blend phonemes or syllables to pronounce a word. • Incomplete Words (Standard): The student is required to identify words orally presented with missing phonemes. • Auditory Attention (Extended): The student is required to identify auditorily presented words amid increasingly intense background noise.
Fluid Reasoning (<i>Gf</i>)	<ul style="list-style-type: none"> • Concept Formation (Standard): The student is required to identify, categorize, and determine rules applied to visual information. • Analysis–Synthesis (Extended): The student is required to analyze puzzles to determine missing components. • Planning (Extended): The student is required to trace a pattern without removing the pencil from the paper or retracing any lines. (subtest also under Visual–Spatial Thinking Index)
Processing Speed (<i>Gs</i>)	<ul style="list-style-type: none"> • Visual Matching (Standard): The student is required to locate and circle two identical numbers in a row (timed). • Decision Speed (Extended): The student is required to circle the two pictures that are conceptually most similar in a row (timed). • Rapid Picture Naming (Extended): The student is required to recognize and name pictured objects (timed). • Pair Cancellation (Extended): The student is required to identify and circle a repeated pattern of pictures (timed).
Short-Term Memory (<i>Gsm</i>)	<ul style="list-style-type: none"> • Numbers Reversed (Standard): The student is required to repeat a series of numbers in reverse order. • Auditory Working Memory (Standard): The student is required to remember a set of numbers and letters and reorder them into the two corresponding sequences. • Memory for Words (Extended): The student is required to repeat lists of unrelated words in correct sequence.

Use and Validity

Mather and Woodcock (2001) stated that the goal of a learning disability assessment is to uncover the individual student's pattern of strengths and weaknesses to design an appropriate intervention and the W-J-III-COG battery provides such information. They further asserted that the use of the Cognitive battery in conjunction with the Achievement battery allows the practitioner to identify cognitive factors associated with achievement problems.

The WJ-III-COG's validity appears adequate (Salvia & Ysseldyke, 2004). Cizek (2005) stated that it is apparent that Standards for Educational and Psychological testing (Joint Committee on Standards for Educational and Psychological Testing of the AERA [American Education Research Association], American Psychological Association [APA], and National Council on Measurement in Education [NCME], 1999) informed the current revision of the WJ-III. He also reported that correlational evidence supports the validity of the WJ-III-COG, because the expected pattern of relationships among tests was observed; tests hypothesized to measure similar characteristics correlated more strongly than tests measuring dissimilar constructs, as hypothesized by CHC theory. Sandoval (2005) concluded that the WJ-III-COG has good concurrent validity overall, because the cognitive clusters intended to predict achievement correlate with the achievement clusters in the .70 range. Evans, Floyd, McGrew, and Leforgee (2002) examined relations between the WJ-III-COG and the CHC theory of cognitive abilities, and found that measures of CHC cognitive abilities obtained from the WJ-III were significantly related to components of reading achievement. They stated that the results supported the external validity for the WJ-III cognitive clusters. Other researchers have found links between the WJ-III-COG clusters and achievement in math (Floyd, Evans, & McGrew, 2003; McGrew & Hessler, 1995).

Hale and Fiorello (2004) described a model for developing and evaluating individual interventions using the CHC model. Fiorello and Primrano (2005) designed worksheets linking CHC abilities to specific achievement areas and derived programming recommendations from the cognitive processing findings. The authors recommended research or data collection to measure the effectiveness of the recommendations.

Fiorello and Primrano (2005) stated that collective research findings establish the differential diagnostic validity of the CHC-based WJ-III-COG. However, they caution that such links do not automatically lead to interventions. Braden and Niebling (2005), in a comprehensive analysis of validity evidence, stated that "no direct evidence to support claims of value for educational planning . . . is provided" (p. 626).

Summary of Validity

The WJ-III-COG has initial evidence of traditional validity (criterion related). A question to be considered is the extent to which this type of validity evidence is meaningful for an LD diagnosis. If achievement is the important validity criterion for cognitive processes, what is added by using cognitive processing scores? It would be more sensible to use the more direct measure (achievement) than a correlate (cognitive processes). This criticism applies to all processing tests in which achievement is viewed as the important criterion. Proponents of cognitive processing need to establish, at a minimum, that these scores provide more in-depth information about a child than can be derived from achievement scores. This may include identifying differential patterns of performance unique to children with LDs and connecting intervention plans with testing results.

Cognitive Assessment System*Description*

Designed for youth ages 5–17 years, the Cognitive Assessment System (CAS; Naglieri & Das, 1997) is an individually administered, norm-referenced test of cognitive processing. The CAS has four components derived from the PASS theory of intelligence (planning, attention, simultaneous, and successive cognitive processes) based on the theoretical work of Luria. Specifically, PASS processes were derived from Luria's 1973 neuropsychological theory of brain functions (Joseph, McCachran, & Naglieri, 2003; Naglieri & Reardon, 1993).

According to Naglieri and Rojahn (2004) the four separate dimensions of ability were developed as a modern approach to intelligence. Naglieri (2005) claimed that the PASS theory places emphasis on cognitive processes related to performance rather than on a general intelligence model. Naglieri (2001, 2005) suggested

that the CAS be used in the identification of students with LDs and that the four PASS processes represent the types of basic psychological processes described in IDEA. He claimed that the four basic psychological processes are used to design appropriate interventions to discover a child's strengths and weaknesses.

According to Naglieri and Das (1997), *planning* is the ability to formulate, execute, and judge the effectiveness of a strategy; *attention* is the ability to attend selectively to relevant versus irrelevant stimuli; *simultaneous processing* is the ability to survey and integrate elements into the whole; and *successive processing* is the ability to process information serially. Because the CAS subtests were developed specifically to operationalize the PASS theory of cognitive processing, the sole criterion for inclusion was each subtest's correspondence to the PASS the-

oretical framework (Naglieri, 2001). Table 13.3 summarizes the 12 CAS subtests organized by process. The CAS Standard Battery comprises all 12 subtests. The CAS Basic Battery comprises the first two subtests listed under each process.

Naglieri (2003, 2005) argued that all of the major intelligence tests except the CAS and the Kaufman Assessment Battery for Children (K-ABC) are biased in the assessment of minority children and children with limited English or limited academic skills, because the tests measure achievement rather than ability. Naglieri (2000) stated that removing verbal achievement from ability measures and focusing on cognitive processes increases fairness to minority populations. A study investigating the difference in performance on tests of ability by race found that the CAS test exhibited the

TABLE 13.3. Subtests of the Cognitive Assessment System (CAS) Organized by Process

Process	Subtest
Planning	<ul style="list-style-type: none"> • Matching Numbers: The student is required to identify and underline two identical numbers consisting of from one to seven digits (timed). • Planned Codes: The student is required to fill in code letters in accord with a legend (timed). • Planned Connections: The student is required to connect randomly ordered numbers, as well as numbers and letters, in sequential order (timed).
Attention	<ul style="list-style-type: none"> • Expressive Attention: The student (ages 5–7) is required to state whether a pictured animal is large or small in real life, ignoring the relative size of the picture. The student (ages 8 and older) is required to: (1) read color words, (2) name the color of a series of rectangles, and (3) name the color of ink a color word is printed in, ignoring the color word (timed). • Number Detection: The student is required to underline specific numbers printed in an outlined typeface (timed). • Receptive Attention: The student (ages 5–7) is required to (1) underline pairs of drawings that are identical in appearance, and (2) underline pairs of drawings that have the same name. The student (ages 8 and older) is required to do the same with letters (timed).
Simultaneous	<ul style="list-style-type: none"> • Nonverbal Matrices: The student is required to complete geometric matrices interrelated through spatial or logical organization. • Verbal–Spatial Relations: The student is required to select the appropriate spatial configuration in response to a verbal description. • Figure Memory: The student is required to identify a two- or three-dimensional figure (previously displayed for 5 seconds) embedded within a larger figure.
Successive	<ul style="list-style-type: none"> • Word Series: The student is required to repeat a series of single-syllable, high-frequency words. • Sentence Repetition: The student is required to repeat sentences composed of color words (e.g., <i>The blue is yellowing</i>). • Speech Rates (ages 5–7): The student is required to repeat a series of three one- and two-syllable words 10 times in a row (timed). • Sentence Questions (ages 8–17): Used instead of speech rate for older students. The student is required to respond after reading questions similar to those used in sentence repetition (e.g., <i>The blue is yellowing. Who is yellowing?</i>).

smallest difference between black and white participants (Naglieri, 2003).

Use and Validity

Naglieri and Sullivan (1998) suggested that identification of an LD begins with an examination of the PASS profile to identify intra- and interindividual weaknesses on the PASS processes. Then the student's academic achievement is evaluated for areas of low achievement. Thus, the determination of a cognitive weakness is based on dual processing criteria (a low score relative to both the child's mean and the norm group) and accompanied by a weakness in an achievement domain (Naglieri & Das, 2005). In interpreting the CAS, emphasis is placed at the PASS process level rather than at the specific subtest level (Naglieri & Das, 2005). The PASS scale scores are computed on the basis of the sum of subtest scaled scores included in each scale. These four scales, representing a child's cognitive processing in specific areas, are intended to be used diagnostically to examine cognitive strengths and weaknesses (Naglieri, 2005). Each of the 12 subtests measures the specific PASS process corresponding to the scale in which it is included; the subtests are not considered to represent specific abilities (Naglieri, 2005). Rather, subtests are intended as varying ways to measure each of the four processes and have less reliability than the composite scores for the PASS processes (Naglieri & Das, 2005).

To establish the construct validity of the CAS many researchers investigated the correlation between the CAS and achievement. Joseph and colleagues (2003) explored the relationship between the CAS performance of 62 primary grade children referred for reading problems, and their phonological processing and reading achievement. They hypothesized and found that some processes were strongly related both to phonological processes and reading performance. The strongest intercorrelation was between phonological memory and the successive processes composite on the CAS (.81). However, the best predictor of performance on word-level skills was the phonological awareness measure, not CAS scores.

Johnson, Bardos, and Tayebi (2003) explored the relationships between CAS performance and writing achievement in junior high school students with and without written expression disabilities. Ninety-six students were administered the CAS and the writing subtests

of the WIAT. Significant relationships were found between the planning and attention composites of the CAS and the WIAT writing scales in the students with writing disabilities. In contrast, simultaneous and successive composites of the CAS were significantly related to writing achievement in the students without writing disabilities.

Naglieri and Das (1997) investigated the predictive relationship between CAS performance and achievement compared to other tests of cognitive ability. The median correlation between the CAS Full Scale and the revised WJ-ACH was .70. The correlation with achievement was higher than coefficients obtained with the WISC-III (.59), the revised WJ-COG (.63), and the K-ABC (.63). Naglieri and Rojahn (2004) reported similar correlations between CAS performance and achievement. They interpreted these data as evidence of construct validity.

According to Naglieri (2001, 2003), the finding that the CAS had the highest correlation among the major intelligence tests with achievement was especially important for two reasons. First, one of the most important dimensions of validity for a test of cognitive ability is the relationship to achievement. Second, the CAS, unlike the Wechsler scales, does not include subtests that are highly reliant on acquired knowledge.

Kranzler and colleagues (Keith, Kranzler, & Flanagan, 2001; Kranzler & Keith, 1999) questioned the construct validity of the CAS, suggesting that the scales are more consistent with the CHC theory of intelligence than with the PASS theory based on the work of Luria. Therefore, they suggested that the CAS is not an appropriate tool for diagnostic or intervention purposes.

According to Salvia and Ysseldyke (2004), the validity of the CAS is problematic, because the underlying model of intelligence is so different from the models used by other tests of IQ. However, they stated that the CAS does correlate well with other tests of intelligence and does predict scores on standardized achievement tests. Thompson (2005), in a review of the CAS, stated that data presented by the authors in the interpretive handbook provide generally strong support for the construct validity. Furthermore, the criterion-related validity studies suggest that the CAS correlates highly with other measures of ability and achievement.

Naglieri (2000, 2001) believes data from CAS can inform instructional and intervention

needs, therefore speaking to relevance. Two approaches designed in accord with PASS theory are the PASS Remedial Program (PREP; Das, 1999), which targets reading decoding, and the Planning Facilitation Program (Naglieri, 1999), which originally targeted math calculation but has been used in other academic areas as well.

The focus of the PREP is primarily on successive processing. The program teaches children to focus on the successive nature of a variety of tasks, each of which has two forms, global and bridging (Naglieri, 2005). The global tasks are nonacademic in content and are designed to illustrate the underlying concept. The bridging tasks contain reading content and illustrate the same concept. For example, a global task of matching the head to the appropriate rear of an animal's body is paired with the bridging task of joining the beginning letters of a word to appropriate ending letters (Naglieri, 2001). Researchers found that students with decoding difficulties who were trained in the PASS-based PREP program made significantly greater gains than controls in word reading skills (Boden & Kirby, 1995; Carlson & Das, 1997; Das, Mishra, & Pool, 1995; Parrila, Das, Kendrick, Papadopolous, & Kirby, 1999).

The Planning Facilitation Program is based on the assumption that planning processes should be facilitated rather than directly instructed, so that children discover the value of strategy use (Naglieri, 2001). The approach, which was used in a number of research studies, varied from study to study but, in general, used a verbalization technique that encouraged a well-planned and organized examination of the demands of the task. Self-reflection and discussion were facilitated in all variations of the program (Naglieri, 2001, 2003). Naglieri and his colleagues (Haddad et al., 2003; Naglieri & Gottling, 1995; Naglieri & Johnson, 2000) reported that students with low planning scores on the CAS improved more following instruction targeting planning than did students with high scores. However, a study with a larger sample failed to replicate these findings (Kroesbergen, Van Luit, & Naglieri, 2003). The results of this line of research are tempered by the need for experimental designs that interpret intervention effects and have larger samples and testable hypotheses. For example, Naglieri and Johnson (2000) conducted an intervention with nine children, only three of whom evidenced a planning weakness, to ex-

amine the differential effectiveness of a version of the Planning Facilitation Program; Naglieri and Gottling (1997) conducted an intervention with eight children, with no experimental controls; and Kroesbergen and colleagues (2003) reported findings that contradicted the theoretical points made in the introduction to the study. Meikamp (2005) noted that few CAS intervention studies incorporated exceptional populations; therefore, caution should be used in prescribing PASS-based instruction for remedial students.

Summary of Validity

There appears to be general agreement on the criterion-related validity but some question regarding evidence for construct validity of the CAS. Studies of relevance are beginning to appear but have not yet met the burden of evidence required to link assessment with intervention.

Kaufman Assessment Battery for Children-II

Description

The Kaufman Assessment Battery for Children-II (K-ABC-II) is an individually administered battery of tests used to measure the IQ of children and adolescents. The first edition of the K-ABC was the first test to be influenced by Luria's cognitive processing model of human functioning (Naglieri, 2003). In developing the K-ABC, Kaufman and Kaufman departed from the common conception of intelligence as an overall global entity (Lichtenberger, 2001). Both the information processing approach of Luria and the cerebral specialization theory of Sperry, Bogen, Kinsbourne, Wada, Clarke, and Hamm provided the theoretical framework for the sequential and simultaneous process emphasis of the K-ABC (Lichtenberger, 2001).

The K-ABC-II, in contrast with the K-ABC, is based on a dual theoretical foundation: (1) Luria's processing model of human functioning, and (2) the CHC broad and narrow abilities model (Kaufman, Kaufman, Kaufman-Singer, & Kaufman, 2005). The K-ABC-II represents a substantial revision of the K-ABC, with a greatly expanded age range (3 years to 18 years, 11 months instead of 2 years, 6 months to 12 years, 6 months), the replacement of eight subtests, and the addition of a Delayed Recall scale. The K-ABC-II comprises core and supplemental subtests that are administered depending on the age of the child and

the model the examiner chooses to use. Change in the complexity of the theoretical structure of the test that is dependent upon the child's age is roughly consistent with milestones of intellectual development identified by other theorists, such as Piaget (Thorndike, 2005).

The KABC-II includes four or five broad ability scales depending on the model used. The CHC model organizes subtests into Short-Term Memory (*Gsm*), Visual Processing (*Gv*), Long-Term Retrieval (*Glr*), Fluid Reasoning (*Gf*), and Crystallized Ability (*Gc*) scales, and gives a Fluid-Crystallized Index composite score. The

Luria model renames the scales into Sequential Processing (Short-Term Memory, *Gsm*), Simultaneous Processing (Visual-Spatial Thinking, *Gv*), Learning Ability (Long-Term Retrieval, *Glr*), and Planning Ability (Fluid Reasoning, *Gf*) scales, and gives a composite Mental Processing Index score; the Crystallized Ability scale is not included in the Luria model. The test developers claim that the K-ABC-II can be interpreted using either the Luria model or the CHC model. Table 13.4 summarizes the K-ABC-II subtests organized by Fluid-Crystallized Index/Mental Processing Index.

TABLE 13.4. Subtests of the Kaufman Assessment Battery for Children—2nd Edition (K-ABC-II) Organized by Fluid-Crystallized Index/Mental Processing Index

Fluid-Crystallized Index/ Mental Processing Index	Subtest
Visual Processing (<i>Gv</i>)/ Simultaneous	<ul style="list-style-type: none"> • Triangles: The student is required to copy designs with plastic triangles or shapes. • Face Recognition: The student is required to identify a face that was shown earlier. • Conceptual Thinking: The student is required to identify a picture that does not belong in a group. • Rover: The student is required to select the shortest path on a checkerboard-like grid to move a dog toward a bone. • Block Counting: The student is required to visualize unseen blocks to determine how many are in a stack. • Gestalt Closure: The student is required to fill in gaps to complete an inkblot picture.
Short-Term Memory (<i>Gsm</i>)/Sequential	<ul style="list-style-type: none"> • Word Order: The student is required to touch silhouettes of common objects in correct sequence following examiner naming. • Number Recall: The student is required to repeat a series of numbers. • Hand Movements: The student is required to repeat a sequence of hand movements in response to examiner modeling.
Fluid Reasoning (<i>Gf</i>)/ Planning	<ul style="list-style-type: none"> • Pattern Reasoning: The student is required to select a missing shape in a series to complete a pattern. • Story Completion: The student is required to select a missing picture in a series of pictures that tell a story.
Long-Term Storage and Retrieval (<i>Glr</i>)/Learning	<ul style="list-style-type: none"> • Atlantis: After learning nonsense names for colorful pictures, the student is required to point to the appropriate picture in response to hearing its name. • Rebus: The student is required to learn words associated with simple line drawings, then read the drawings. • Delayed Recall: The student is required to recall paired associations learned earlier during the Atlantis and Rebus subtests.
Crystallized Ability (<i>Gc</i>): included in CHC model only	<ul style="list-style-type: none"> • Riddles: The student is required to answer riddles in response to a set of clues. • Expressive Vocabulary: The student is required verbally to identify objects represented in color drawings. • Verbal Knowledge: The student is required to point to a picture that corresponds to a vocabulary word or general information prompt.

Note. Different subtests are administered at different student ages (core or supplemental status also changes with age of student). Subtests are generally untimed for younger students, but they can be administered on a timed or untimed basis for older students.

Use and Validity

According to Kaufman and colleagues (2005), like the original K-ABC, the K-ABC-II was designed to assist in the identification of process integrities and deficits for assessment of individuals with specific LDs, among other purposes. The K-ABC-II assesses 15 of the approximately 70 CHC narrow abilities. The Broad Ability scales that comprise these narrow abilities are of primary importance for interpreting the child's cognitive profile (Kaufman et al., 2005).

The K-ABC-II also includes supplementary subtests (e.g., Delayed Recall, Hand Movements) that are not included in the computation of standard scores but are intended to allow the examiner to follow up hypotheses suggested by the profile of scores on the Core Battery (Kaufman et al., 2005). For example, Delayed Recall measures the evaluation of a child's recall of paired associations learned 20 minutes earlier.

Because the K-ABC-II utilizes a dual theoretical approach, it permits alternate interpretation of the scales based on either the examiner's orientation or the specific individual being evaluated. For example, the index containing the Word Order, Number Recall, and Hand Movements subtests may be interpreted as Sequential Processing Skill (problem solving based on linear input) under the Luria model or Short-Term Memory (ability to apprehend and briefly hold information) under the CHC model.

The CHC is ordinarily the model of choice, particularly when assessing children with known or suspected LDs (Kaufman et al., 2005). However, the Luria model is recommended when exclusion of measures of acquired knowledge from the global scale promotes fairer assessment, for example, with individuals who have a receptive or expressive language disability or come from a bilingual background (Kaufman et al., 2005). Similar to the K-ABC, the K-ABC-II also provides a Non-verbal scale, with subtests that can be administered in pantomime and require a motor response.

Braden (2005) stated that although the manual justifies why crystallized ability knowledge is omitted from the Luria model, it does not justify why the same subtest scores can be interpreted in two different ways (e.g., why the same subtest reflects sequential processing in one examinee but short-term memory in an-

other when interpreted under a different model). Kaufman and colleagues (2005) explained that the change in the two models was in response to criticism that the K-ABC interpreted mental processing scales solely from the sequential-simultaneous perspective. Braden (2005), in his review, concluded that the absence of direct evidence to support one model over another leaves the examiner wondering what the K-ABC-II actually tests.

Braden (2005) further stated that although the K-ABC does not explicitly use the current measurement standards to organize and evaluate validity evidence, it presents substantial evidence of validity in three domains (i.e., content validity, relationships within the test, and relationships to other tests). However, there is little evidence that K-ABC-II score patterns or profiles effectively discriminate among individuals with different types of LDs or ADHD. Another criticism is that there is no evidence that derived test data are useful in designing interventions. According to Thorndike (2005), in a review of the K-ABC, an important piece of validity evidence was not presented by the test's authors. Because the CAS was explicitly designed to assess the Luria processing model and extensive work has been done to validate the CAS, Thorndike suggests that the CAS should have been used to validate the K-ABC's use of the Luria model. Also, although most of the clinical studies reported in the manual in support of the K-ABC-II reveal mean differences between groups with disabilities and the norm group, the pattern of differences for the various scales for students with LDs is relatively flat, suggesting little diagnostic utility.

Summary of Validity

The K-ABC-II has evidence of content and criterion validity. Reviewers question the strength of the evidence to support the construct of intelligence, as defined by the selected processes. Most critical to this chapter is the need for an assessment to distinguish between children with LDs and the general population, and provide information to guide intervention. Currently the K-ABC-II cannot be recommended for these purposes.

Summary of Psychological Processes

Many professionals believe in the existence of intrinsic processing weaknesses as a construct underlying LD (Torgesen, 2002). The direct di-

agnosis of students with LDs through analysis of processing weaknesses potentially has several advantages over the IQ discrepancy approach, including early identification, inclusion of students without discrepancy between IQ and achievement, and the potential to focus instruction in areas of greatest need.

Similar to Torgesen (2004), we conclude that whereas psychological processing differences likely underlie the condition we call LDs, current understanding of processing operations and their relationship to learning are not sufficiently developed for either diagnosis or intervention. This conclusion does not mean it will never be possible to assess cognitive processes in a meaningful way, only that the necessary evidence is not currently available. The issue of diagnostic relevance is essential when evaluating measures of cognitive processing. Two questions arise: Are measures of psychological processing effective in diagnosing students with LD, and are they helpful in designing interventions? It seems that there is not solid evidence to support their relevance in either area. Fletcher, Coulter, Reschly, and Vaughn (2004) stated that “anecdotal links between cognitive processing and instruction are at best appealing experimental hypotheses that have not been validated despite extensive efforts over the past 30 years” (p. 321).

Certainly there are those who disagree with this conclusion. Kavale and colleagues (2005) argue that the negative perceptions regarding intellectual assessment/psychological processing and the development of useful diagnostic profiles from such assessments is a result of the strong influence of the *g* factor (general intelligence) implicit in the Wechsler scales. Kavale and colleagues suggested that newer tests of cognitive abilities (e.g., CAS) that have moved away from the *g* factor and are theory based will result in better individualized interventions.

Although these authors are appropriately impressed with the importance of theory, what seems to be missing in their formulations is the realization that a theory is important because one can generate and test hypotheses based on it. Theory in and of itself does not buy much if it is not used this way. It would seem that relevant propositions could be developed and tested (Fletcher et al., 2004).

A major hurdle to overcome is the lack of consensus on the meaning of the term “processing.” Are the processing abilities to be evaluated those proposed by, for example, Naglieri,

those examined by indexes of the WISC or the WJ-COG, or those at the sublexical level, as in phonological processing? The issue is more than semantic, and research comparing the hypothesized processes across measures and perspectives would be valuable as one step toward consensus. Evidence of relevance to instruction needs to follow.

RESPONSE TO INTERVENTION

Background and Definition

RTI has gained favor as an important element in Federal regulations that govern the identification of LDs. The essence of RTI models is that evidenced-based instruction is provided with fidelity, progress is monitored frequently, and the child’s responsiveness is evaluated (Batsche et al., 2005; Vaughn & Fuchs, 2003). In the context of the regulations for the implementation of IDEA (2004), there is a two-pronged test for LD eligibility: (1) The child does not achieve commensurate with peers in one of eight domains despite appropriate instruction, and (2) the child fails to make sufficient progress in meeting state-approved results. One of two methods can be used to judge the latter criterion. The first, an RTI method, was clearly favored in the discussion that accompanied the *proposed* regulations (wrightslaw.com/ideallaw.htm). The second criterion requires a pattern of strengths and weaknesses either alone or in conjunction with intellectual ability that the multidisciplinary team believes is relevant for an LD diagnosis. The approved regulations maintain the exclusionary clauses that include sensory impairments, mental retardation, and economic and cultural differences. In addition, IDEA specifically states that a child may *not* be identified as having an LD if there was a lack of appropriate instruction in reading or math, or if the child has limited English proficiency.

It was anticipated that the regulatory language specifying a severe discrepancy between achievement and intellectual ability as a defining characteristic of LD would be altered. However, the final regulations for IDEA 2004 retained both RTI and IQ–achievement discrepancies, the latter a hallmark of LD identification since the first regulations were put in place in 1977.

In any event, the new emphasis in diagnosis is clearly on instruction. Although “failure to

learn despite adequate instruction” has always been part of the Federal regulations for learning disabilities, documentation of “adequate instruction” never received serious consideration as part of a diagnostic workup (Speece & Shekitka, 2002). In schools, diagnostic information may include both classroom observations and prereferral activities designed to improve teaching and learning by making changes in the general education classroom prior to an eligibility decision. However, our experience suggests that the decision largely rests on data derived from published, norm-referenced tests, and not on observation, regardless of whether the school or a private practitioner makes the diagnosis.

RTI is an umbrella term encompassing a variety of different assessment and instructional approaches (e.g., D. Fuchs, Mock, Morgan, & Young, 2003; Marston, Muyskens, Lau, & Carter, 2003). However, there is some consensus on conceptualizing RTI as three tiers of increasingly intense instruction, with ongoing monitoring of progress. Tier 1 is general education instruction in which all children are receiving instruction deemed to be effective. Prior to the new regulations, general education was assumed to be effective without any substantiation. The thrust of the new regulations is a more rigorous approach to documenting the quality of general education, emphasizing instruction and curricula that have scientific support. Another proposal for assessing quality is monitoring student progress. When most students are making progress, the instruction is presumed to be effective (L. S. Fuchs, 1995; Fuchs & Fuchs, 1998). The extent to which this will mean monitoring all children is not clear, but several authors urge universal screening at a minimum, if not regular monitoring of all children (e.g., L. S. Fuchs, 1995; Speece & Case, 2001).

Tier 2 instruction may occur in the general education classroom (e.g., Fuchs & Fuchs, 1998; O'Connor, 2000; Speece & Case, 2001) or as an extra classroom supplement (e.g., Vaughn, Linan-Thompson, & Hickman, 2003; Vellutino et al., 1996). Tier 2 often includes two learning trials for a child considered at risk for learning problems, each lasting between 8 and 10 weeks. If the first trial does not result in improved learning, instruction is further modified and a second trial is undertaken. Tier 3 is associated with assessment for eligibility as an LD diagnosis, as well as more intensive instruc-

tion and continued monitoring of progress. Tier 3 is the most poorly defined of the three tiers, with no clear consensus on what further assessment may include or how an LD will be defined.

An RTI approach to diagnosis contains many moving parts, and a lack of integrity in any one part greatly damages the validity of the system. Elements include screening, research-based instruction, fidelity of implementation, valid progress monitoring, and interpretation. The inseparable linkage between instruction (research-based, fidelity) and assessment (screening, progress monitoring, interpretation) complicates the diagnostic process. The most fully developed model of RTI was presented by Fuchs and Fuchs (1998; L. S. Fuchs, 1995; Fuchs, Fuchs, & Speece, 2002). Originally called “treatment validity,” Fuchs and Fuchs (1998) credited Messick (1984) with laying the groundwork for a special education diagnostic system that would result in more accurate identification of children from minority groups. In their initial four-phase model, all children receive frequent (e.g., weekly) assessments with curriculum-based measures (e.g., reading, math) in Phase 1. Within-classroom (or grade level) progress is quantified by two indices: level of performance at the end of the measurement period and slope reflecting growth across the measurement period. Children who deviate from the class level and slope by some amount (e.g., 1 *SD* below classroom means) are considered at risk for academic problems and are identified at the end of Phase 1. Fuchs and Fuchs (1998) referred to deficiencies on both level and slope as “dual discrepancies.” In Phases 2 and 3, the general educator, continuing with progress monitoring, provides interventions to at-risk (dually discrepant) children. If after these two phases, a child’s performance has not improved to acceptable standards, he or she would then proceed to Phase 4 to receive a trial placement in special education to determine whether the placement resulted in better learning.

Several nuances in this system deserve mention (Fuchs & Fuchs, 1998). First, general education instruction is considered adequate if level and slope data indicate that most children are profiting from the instruction. Classrooms with low performance compared to others would receive intervention at the classroom level to improve the overall learning trajectory of all children before identifying an individual

child as being at risk. This procedure acknowledges the potential problem of poor instruction confounding risk status. Second, Fuchs and Fuchs specify that the first round of interventions occurs in general education, not in a separate setting with a different teacher. Fuchs (2002) makes a convincing case that to do otherwise blurs the distinction between general and special education. For example, what does it mean, diagnostically, when a child responds well to small-group instruction delivered by a specialist (or a paraprofessional for that matter)? Is the child remediated and ready to return to the general education classroom? Or does it mean the child should receive special education in which reduced teacher-child ratios are common? Fuchs argues that if the instruction needed to enhance a child's response cannot be implemented reasonably in general education, then the child likely needs special education.

Third, special education placement is not automatic. The same interpretation rules that apply at other phases remain in place; that is, the child must demonstrate a positive response to special education instruction for it to be considered a valid treatment. Holding special education accountable for progress is noteworthy and an aspect that should not get lost in transition to new systems. This requirement is not without problems, many of which have been discussed with recommendations (Fuchs, Fuchs, & Speece, 2002). The major issue is, what happens if special education is not successful? Returning the child to the general education environment is not reasonable, because it was a source of initial failure. Fuchs and colleagues (2002) suggested that educators and parents consider an alternative curriculum that may be better suited to the child's needs.

Validity of RTI Frameworks

Of importance to our consideration in this chapter is the extent to which treatment validity/RTI systems have demonstrated validity. Establishing validity for complex systems is daunting but no less a requirement than for single tests. It is certainly true that there are more published opinions than published evidence about RTI, a fact that gives us some pause. Two studies indicate that both academics and practicing professionals are in favor of an RTI approach to identifying reading disabilities. These data can serve as one piece of evidence in

Messick's validity matrix (values). Speece and Shekitka (2002), in a study that predated the acceptance of the RTI term, surveyed editorial board members of LD and related journals on criteria that should be used to identify reading disabilities. Two-thirds of respondents were in favor of RTI (treatment validity) as a criterion, with 30% endorsing IQ-achievement discrepancies and almost 50% selecting cognitive processing as a criterion. Whereas only 42% of respondents would include intelligence cutoff scores, 72% believed mental retardation should be retained as an exclusionary criterion. Because IQ tests would be required to rule out mental retardation, this result suggests that there is some ambivalence about the role of IQ tests in the identification of LDs.

Machek and Nelson (in press) (reviewed earlier in the chapter) replicated the Speece and Shekitka (2002) study with practicing school psychologists. This group also was in favor of RTI as a criterion (over 80% agreed or strongly agreed). Interestingly, over 60% also endorsed IQ-achievement discrepancies, and over 75% endorsed cognitive processing. The findings from both studies suggest that whereas RTI holds considerable appeal and acceptance, it is not unanimous. Considerable work in establishing relevance that also translates to training is needed, if RTI is to replace long-held beliefs about the roles of intelligence tests, achievement discrepancies, and cognitive processes in LDs.

A handful of studies address different validity questions. They are primarily concerned with construct validity—determining whether nonresponsive children are different from other children (Fuchs, 2003; Fuchs et al., 2005; McMaster, Fuchs, Fuchs, & Compton, 2005; Speece & Case, 2001; Speece, Case, & Molloy, 2003). There also are analyses of relevance based primarily on longitudinal outcomes (Case, Speece, & Molloy, 2003; Vaughn et al., 2003; Vellutino et al., 2003), with some attention to social-consequential validity (Speece & Case, 2001; Vaughn et al., 2003). These studies are reviewed to assess the extent to which evidence for validity is obtained.

Construct Validity

Speece and Case (2001) assessed the validity of three methods of identifying reading disability: (1) curriculum-based measurement (CBM) dual discrepancy on level and slope of oral

reading fluency (ORF) performance compared to classmates (RTI), (2) IQ–reading achievement discrepancy, and (3) low reading achievement. From a population screen of 694 first- and second-grade children, they identified an epidemiological sample of at-risk and not-at-risk children based on performance early in the academic year on letter–sound fluency (LSF; first grade) and ORF (second grade). In this study, responsiveness was measured in relation to peers receiving general education instruction over most of the school year. The CBM dual-discrepancy group was compared to both IQ–reading discrepancy and low achievement groups on a battery of reading, reading-related, and behavioral measures. Although there were no differences on word-level reading skills, the CBM dual-discrepancy group was younger, more impaired on reading processes (phonological awareness and rapid automatic naming [RAN]), and was rated lower by teachers on academic competence. Furthermore, the CBM dual-discrepancy group reflected the gender and ethnic/racial distributions of the population. The IQ–reading discrepancy group was disproportionately white. Differences were larger for the comparisons between the CBM dual-discrepancy and IQ–reading discrepancy groups than for the CBM dual-discrepancy and low achievement groups. These findings were interpreted as providing evidence of both construct and social consequential validity in support of one aspect of RTI (identification in general education). CBM dual-discrepancy criteria (1 *SD* below classroom means for level and slope) identified 8% of the population *before* any specialized intervention, which is close to the 5% prevalence of LDs. However, the three identification methods were not distinct. There was a 25% overlap between CBM dual discrepancy and IQ–reading discrepancy, and a 60% overlap between CBM dual discrepancy and the low achievement criterion.

Interestingly, measures administered in the beginning of the academic year were not sensitive indicators of which children would experience reading problems at the end of the year. Neither of the two CBM measures nor phonological awareness fared well in the prediction of year-end reading status. These findings held for the classification of the CBM dual-discrepancy group and the entire pool of poor readers (Speece & Case, 2001). This suggests that more time-consuming methods that incorporate growth in learning may be necessary for

valid classification. Speece, Case, and Molloy (2003) further investigated the relative merits of a static versus a growth view of identification with respect to classification accuracy. First- and second-grade children who scored above a standard score of 90 on the Basic Reading Skills cluster score (WJ-R) were examined with respect to their oral reading fluency skill and status as CBM dually discrepant to determine who might be missed if a static low achievement criterion was used to identify early reading failure. Twenty percent of first-grade children and 25% of second-grade children who scored above 90 also scored *below* the 25th percentile on ORF (15 words per minute [wpm], first grade; 51 wpm, second grade), indicative of severe reading difficulty. Thus, the Basic Reading Skills cluster score was not sensitive to poor oral reading fluency and would result in missing children who were deficient in a critical reading skill. Of the 48 first- and second-grade children who were above 90 on Basic Reading Skills but below the 25th percentile on CBM ORF, 12 were also identified as CBM dually discrepant. Not only were their levels of fluency discrepant from peers, but also their rate of growth. These and other findings support the inference that the addition of growth measures to an identification formula may assist in the identification of true-positive cases (Compton, Fuchs, Fuchs, & Bryant, 2005; Fuchs et al., 2005; Speece, 2005).

L. S. Fuchs and colleagues (Fuchs, 2003; D. Fuchs, Fuchs, & Compton, 2004; Fuchs et al., 2005) also examined the validity of different RTI identification strategies. Their general approach was to apply a variety of identification criteria to a sample and compare them on relevant measures. Methods that identify larger between-group differences on relevant measures and a reasonable number of children with problems are viewed more favorably. For example, Fuchs (2003) compared CBM level, CBM slope, and CBM dual discrepancy to see which would function as the best identification method (number of children identified, size of group differences). Second-grade children comprised the sample. Performance level and slope estimates were based on the first 10 weeks of school. Outcomes included end-of-year level and across-year slope on word identification, word attack, and comprehension. CBM dual discrepancy yielded the smallest number of nonresponsive children (5%) compared to CBM slope (15%) and CBM level (16%). Both

CBM level and CBM dual discrepancy yielded significant and large differences on the word measures but not comprehension. Although obtaining CBM dual discrepancies requires more time devoted to identification, in this analysis, it was the superior method.

Using the same approach with first-grade children, McMaster and colleagues (2005) examined nonresponsiveness to Tier 2 reading interventions. Tier 2 children were those who showed lower rates of response to a validated general education reading program. Five definitions of nonresponsiveness to Tier 2 interventions were analyzed: dual discrepancy; level on either published, norm-referenced measures or a CBM benchmark; and either no growth or limited growth on published, norm-referenced word-level measures. The percentages of nonresponders based on the total Tier 2 sample as defined by each definition were 70, 45, 100, 7, and 39, respectively. These figures illustrate how dramatic the differences may be with various criteria. Although there is no consensus on how to evaluate these Tier 2 percentages given that they do not represent population prevalence, the CBM benchmark definition (< 40 wpm) that yielded 100% nonresponders is likely too high, because no child is identified as responsive. Other researchers have reached the same conclusion regarding this criterion (D. Fuchs et al., 2004; Speece, 2005).

In a rare study of identification of math disability and response to intervention, Fuchs and colleagues (2005) compared 17 definitions that included IQ–achievement discrepancy, low achievement–average IQ, normalized achievement RTI, and slope RTI (including dual discrepancy on level and slope). The validity of each method was judged positively if it produced a prevalence rate of math disability between 4 and 7% and an effect size of 0.50 or better on one of several math outcome measures. Several approaches met the validity criteria: IQ–achievement discrepancy with untimed math concepts and applications as the achievement measure; normalized achievement on either untimed math concepts and applications or basic addition fact fluency, and CBM dual discrepancy based on math computation fluency. The authors noted that the IQ–achievement discrepancy method may produce valid findings, because the achievement measure was sensitive to performance differences at the low end of the achievement range, a fact that may not be true of published, norm-referenced mea-

asures such as the WJ-III-ACH. The study by Speece, Case, and Molloy (2003) reviewed earlier also supports this insight.

SUMMARY OF CONSTRUCT VALIDITY

The bulk of the evidence suggests that some RTI methods identify a group of children who experience serious learning problems. Methods that include slope as a criterion, in addition to level of performance, identify a reasonable number of children (i.e., 4–10%) who differ significantly, and often substantially, from children who do not have academic growth and level deficits. These studies provide evidence of construct validity. Whether these children should be labeled learning disabled is open to debate and further inquiry. The database is limited to early elementary school children and reading, with few exceptions. This limited coverage of developmental levels and academic domains is of concern given Federal initiatives to support RTI approaches to the identification of LDs. Studies are needed that incorporate larger and more diverse samples and a wider array of measures and domains. Another issue that hinders evaluation is that RTI criteria are arbitrary. For example, to identify students for further intervention, Speece and Case (2001) defined “dual discrepancy” as 1 *SD* below the mean level and slope of classmates who were not considered at risk for reading problems. McMaster and colleagues (2005), however, defined “dual discrepancy” as .5 *SD* below the mean level and slope of all average achieving students in the study. Thus, the case for RTI construct validity is positive but limited in scope to children in early elementary school and reading.

Relevance

Relevance, in terms of RTI, is interpreted as an evaluation of the extent to which the procedures produce meaningful outcomes. This criterion might include consumer satisfaction, the extent to which children were over- or under-identified, and longitudinal outcomes. As with construct validity, the data are limited but interpreted as promising.

Compton and colleagues (2005) investigated the usefulness of slope as a predictor of reading status for 206 children at risk for reading problems. The focus of their study was to identify effective screening procedures to identify which

children should receive a Tier 2 intervention. Slope was based on CBM word identification fluency (WIF) across 5 weeks in first grade, signifying responsiveness to general education instruction. Other predictors included WIF level, phonemic awareness, rapid naming, and oral vocabulary. A composite measure of reading based on the end of second grade performance was used to classify children as reading disabled. Several models were evaluated for their classification sensitivity (correct identification of at-risk children with RD) and specificity (correct identification of children without RD). The first model, which included all variables except WIF level and slope, resulted in reasonable classification rates. The addition of WIF initial level, WIF slope, and WIF 5-week level resulted in much better classification accuracy, with 90% sensitivity and 83% specificity in one case, and 100% sensitivity and 93% specificity in another model. Although the classification approaches tested require statistical sophistication, the results indicate that fluency growth measures, which are often used in RTI models, provide important information to identify children in need of more intensive instruction.

Case and colleagues (2003) asked if persistent nonresponsiveness to classroom literacy instruction over time identified a unique group of poor readers. In addition to the screening procedures and classification of poor readers (CBM dual discrepancy) used by Speece and Case (2001), the investigators worked with 25 general education teachers across 3 years to develop reading interventions that the teachers then implemented in their classrooms for children classified as poor readers. Dual-discrepancy status was assessed two to three times per year. The longitudinal sample comprised 36 first- and second-grade children identified as being at risk on Fall screening measures in one school. These at-risk children were placed into one of three groups based on their responsiveness to instruction across 3 years: never dually discrepant (NDD; $n = 12$), infrequently dually discrepant (IDD, $n = 17$), and frequently dually discrepant (FDD; $n = 7$). The IDD group was identified one to three times and the FDD group was identified four or more times as dually discrepant. Case and colleagues hypothesized that the FDD group should be more impaired on reading, reading-related, behavioral, and school attention measures if responsiveness to instruction is a valid indicator

of child status. School attention was the sum of extra classroom assistance (e.g., reading specialist, special educator) and services (e.g., parent meetings, IEP meetings) received by the child. There were clear and significant differences between FDD and NDD (word reading, pseudoword reading, word reading fluency, academic competence, problem behavior, school attention) and between FDD and IDD (Word Reading, Word Reading Fluency, Academic Competence, Problem Behavior, School Attention). In all cases cited, the FDD group performed less well than the comparison group. The sensitivity of these groupings was reflected by one NDD-IDD difference (Problem Behavior) and small to moderate effect sizes (ESs) on other measures (e.g., ES = 0.25 for phonological awareness, -0.60 for problem behaviors). Contextual measures (classroom observations of instruction, teachers' years of experience, classroom reading slopes) did not produce differences between the groups, but the effect size for classroom slope (NDD-FDD ES = -0.42) suggested that the FDD group might have experienced stronger instructional environments.

The Case and colleagues (2003) study spanned 3 years but RTI models in practice would identify children for more intensive instruction within one school year, as was done by Vaughn and colleagues (2003) in a study of Tier 2 interventions. They provided small groups of at-risk second-grade readers with daily supplemental reading instruction and evaluated their progress every 10 weeks. Children who met the criterion were dismissed from the instruction, whereas the others continued to receive instruction for up to 30 weeks. Regardless of status, children continued to receive assessments. Children who responded quickly to the instruction (after 10 weeks) were more likely to maintain progress in general education than were children who needed 20 weeks of supplemental instruction. This finding suggests that Tier 2 instruction defined as a pullout service may differentiate between students who need a short-term "boost" and those students who need more intensive and long-term support. However, whereas all children in the 10-week exit group continued to make good progress after 10 weeks in the general education curriculum, 30% were making *minimal* growth after 20 weeks. Thus, quick response is not synonymous with a "quick fix," and the finding emphasizes the importance of constant progress monitoring. The

researchers also reported that the children who met the criterion at 10 or 20 weeks differed from children who never met the criterion on passage comprehension, passage reading fluency, and rapid naming of letters and digits measured at baseline. Thus, children who were persistently nonresponsive did experience more serious problems.

Vellutino and colleagues (1996) provided individual reading tutoring to at-risk first-grade children for one or two semesters and assessed differences between groups defined by their responsiveness to the tutoring. Participants had to be nominated by their first-grade teachers, have either a performance or verbal intelligence test score of 90 or above, and score at or below the 15th percentile on a word-level test. The study was framed to differentiate between reading problems due to educational experience and those due to within-child deficits, a basic tenet of RTI frameworks (Fuchs & Fuchs, 1998). The authors concluded that the primary difference between at-risk children who had higher and lower responsiveness rates was skill with phonological measures when compared to normal readers. Interestingly, and similar to Vaughn and colleagues (2003), phonological measures did not distinguish between the very high- and very low-growth tutored children, but rapid naming tasks did. Vellutino, Scanlon, and Jacard (2003) provided a follow-up report on the tutored children at the end of third and fourth grades. The percentage of children in the very high-growth group who scored above the 25th percentile was similar at the end of second, third, and fourth grades, 95–100%, as was the percentage of very limited-growth readers, 10–16%. The authors do not state whether the same children were in the normal range at each assessment point, an important consideration in determining if the low-growth students who did respond to the tutoring maintained their advantage. In any event, these data suggest that children who do not respond to a very structured and intensive intervention in first and second grades will likely require special education and could conceivably be considered reading disabled.

SUMMARY OF RELEVANCE VALIDITY

All four studies provide evidence that children identified by RTI approaches have meaningfully different outcomes over time. This conclusion holds whether instruction reflects usual

general education instruction, modified general education instruction, or small-group or individual tutoring. The Case and colleagues (2003) study also showed that teachers across 3 years viewed the persistent nonresponders as less academically competent, and the school provided these children with more resources. The implication is that children who do not respond to instruction represent a meaningful and recognizable group to practitioners. A major methodological issue is the small sample sizes associated with these studies; thus, replication and extension are required to elaborate the case for validity.

Measuring Responsiveness

Academic Domains

CBM is by far the most frequently used measurement system to document response to intervention. CBM represents a set of measures with multiple alternate probes (test forms) in the basic academic domains of reading, math, spelling, and writing. They are designed to be brief, time-based assessments that measure fluency (accuracy and rate). Importantly, they are general outcome measures and, because of this feature, can be distinguished from other types of curriculum-based assessment (CBA) procedures such as mastery measurement (Fuchs & Deno, 1991; Hintze, Christ, & Methe, 2006). The distinction is that general outcome measures assess progress toward a goal (e.g., proficiency in end-of-year reading curriculum), whereas mastery measures assess what was taught. Mastery measurement is based on a task-analysis conceptualization of learning in which discrete skills are taught and assessed. The assumption is that the accumulation of such activities represents progress monitoring (Fuchs, 2004). In contrast, items for CBM probes are sampled randomly from the entire curriculum, or from the part of the curriculum that represents goal material (e.g., books that represent end-of-year reading). Thus, each probe is a parallel form that either represents the entire curriculum or the goal curriculum.

For example, the familiar weekly spelling test is a mastery measurement assessment. Typically each lesson contains a specific grapheme or grapheme–phoneme convention (e.g., silent *e*, double vowels, consonant blends). Children study a list of words, take a test on Friday, and begin again with a new list

the following Monday. In contrast, CBM spelling begins with defining the curriculum (all words in the second-grade spelling text), randomly selecting 20 words from the pool of all words for each probe, and repeating the selection process to have enough probes for weekly assessment. The advantage of CBM for RTI is sensitivity to growth in the curriculum.

The research that supports CBM reflects the validity issues emphasized by Messick (1989, 1995): technical adequacy (construct validity), treatment validity (consequences), and feasibility (relevance) (Deno, Fuchs, Marston, & Shin, 2001; Fuchs & Fuchs, 1998). A number of reviews of this voluminous literature confirm excellent reliability and validity, the connection between growth on CBM and achievement, and usefulness for teachers (Fuchs & Fuchs, 1986; Hosp & Hosp, 2003; Madelaine & Wheldall, 1999; Shinn, 1989; Stecker, Fuchs, & Fuchs, 2005). The Research Institute on Progress Monitoring identified over 500 documents devoted to CBM, with 141 representing published studies (Espin & Wallace, 2004). Reading was the most frequent content area reflected in the articles (58%), followed by math (18%), writing (5%), and spelling (4%). A searchable database for these documents may be accessed online at progressmonitoring.org.

Administration of CBM is relatively easy, especially for professionals who are proficient with timing responses, and who understand the importance of standard administration and scoring. The several sources for probes include the World Wide Web (e.g., www.aimsweb.com and www.dibels.uoregon.edu) and educational publishers (e.g., *Monitoring Basic Skills Progress*; Fuchs, Hamlett, & Fuchs [1998]). The website for the National Center on Student Progress Monitoring (www.studentprogress.org) is recommended as the first stop for the examiner interested in training, evaluation of the available instruments, and further information on probe availability that includes no-cost options.

Examples of an examiner protocol and child copy for passage reading fluency (PRF) are shown in Figures 13.1 and 13.2, respectively. The examiner reads the directions at the top of the protocol; the child reads for 1 minute while the examiner marks errors. The measure of interest is the number of words read correctly in 1 minute. The time varies depending on measure and academic domain. Figure 13.3 illustrates first- and second-grade PRF progress

monitoring data for a child. The graphs were produced with the software available from Fuchs and colleagues (1998). The vertical lines indicate that a change of instruction occurred; “G” represents the goal established for the child, and “T” is the child’s trend (average) line. In Janis’s case, three interventions were attempted in her first (Reading 1) and second (Reading 2) general education classrooms, because she demonstrated a dual discrepancy relative to her classmates. There were not enough data points to establish a trend line for the last intervention, but it is evident that Janis was not making sufficient progress to meet the goal. These data illustrate a possible scenario for Tier 3 assessment and intervention when general education is not effective.

Although there are many reasons to recommend CBM as a progress monitoring tool, there are limitations. The lack of national norms makes it difficult to interpret data outside the local context. There are several sources that compile benchmarks and growth rates from the available literature (Deno et al., 2001; Fuchs & Fuchs, 2004; Hosp & Hosp, 2003), and the DIBELS website (www.dibels.uoregon.edu) provides benchmarks based on extensive, unpublished data. These sources provide guidelines that can be supplemented with school system norms. Another drawback is the primary focus on measures for the elementary school years. Progress monitoring measures for secondary students are in development, but the research base is in its early stages (e.g., Espin & Foegen, 1996; Espin et al., 2000). Finally, results from CBM progress monitoring data with decision rules indicate whether an instructional change is required, but not necessarily what the instructional change should be. There is some work in this area (Fuchs, Fuchs, & Hamlett, 1994) that requires elaboration. We find that analysis of several probes (e.g., PRF) provides sufficient clinical information upon which to offer instructional ideas, but systematizing an approach would be of benefit to most users.

Preacademic Skills

The strength of CBM research and practice coupled with national interest in early reading assessment, prevention, and intervention (e.g., National Reading Panel 2000; Snow, Burns, & Griffin, 1998) spawned the development of prereading and premath fluency tasks that mir-

CBM #1/Grade 1

# attempted	# of errors	# read correctly	

Instructions

You are going to read this story titled *Frog Feels Sick* out loud. This story is about when Toad tried to make his friend Frog feel better. (*Place the reading passage in front of the student, face down.*) Try to read each word. You can use your finger to keep your place. If you come to a word you don't know, I'll tell it to you. You will read for one minute. Be sure to do your best reading. Do you have any questions? (*Turn the passage right-side up.*) Put your finger on the first word. Begin.

Frog Feels Sick

One day in summer Frog was not feeling well.	9
Toad said, "Frog, you are looking quite green."	17
"But I always look green," said Frog. "I am a frog."	28
"Today you look very green even for a frog," said Toad.	39
"Get into bed and rest."	44
Toad made Frog a cup of hot tea. Frog drank the tea, and	57
then he said, "Tell me a story while I am resting."	68
"All right," said Toad. "Let me think of a story to tell	80
you."	81
Toad thought and thought. But he could not think of a	92
story to tell Frog.	96
"I will go out on the front porch and walk up and down,"	109
said Toad. "Perhaps that will help me think of a story."	120

FIGURE 13.1. Example of an examiner's protocol for a curriculum-based measurement probe of passage reading fluency.

Frog Feels Sick

One day in summer Frog was not feeling well.
 Toad said, "Frog, you are looking quite green."
 "But I always look green," said Frog. "I am a frog."
 "Today you look very green even for a frog," said Toad.
 "Get into bed and rest."
 Toad made Frog a cup of hot tea. Frog drank the tea, and
 then he said, "Tell me a story while I am resting."
 "All right," said Toad. "Let me think of a story to tell
 you."
 Toad thought and thought. But he could not think of a
 story to tell Frog.
 "I will go out on the front porch and walk up and down,"
 said Toad. "Perhaps that will help me think of a story."

FIGURE 13.2. Example of a child's protocol for a curriculum-based measurement probe of passage reading fluency.

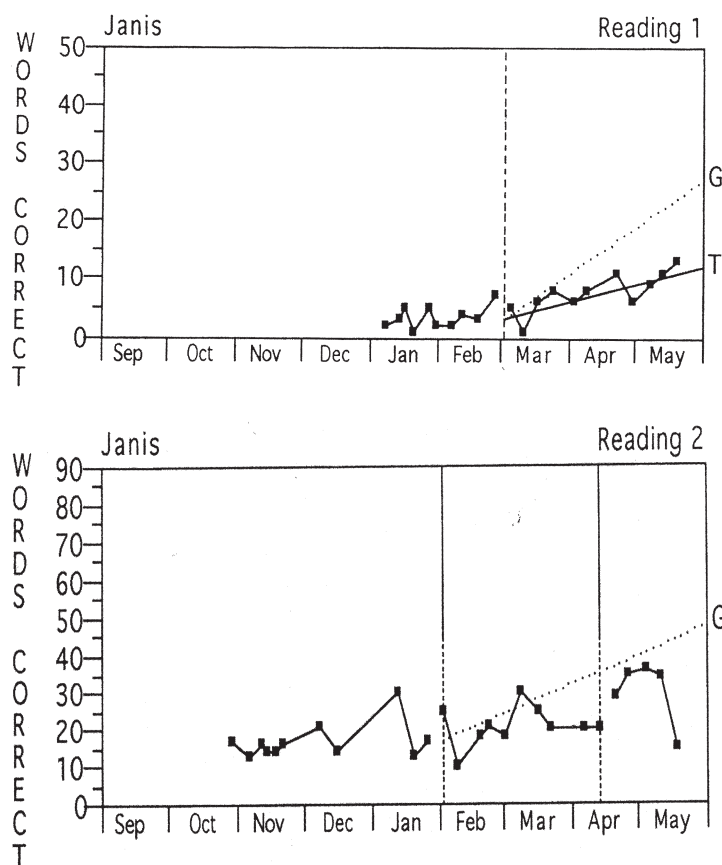

FIGURE 13.3. Graph of passage reading fluency performance for a child in first (top panel) and second grade. G, goal; T, trendline; vertical lines signal a change in instruction.

ror CBM tasks. The best known effort is the Dynamic Indicators of Early Literacy (DIBELS; 2001) system, in which fluency of sublexical skills such as letter names, initial sounds, and phonemic segmentation are measured (Good, Simmons, & Kame'enui, 2001; Kaminski & Good, 1996). This is a new area of research and as such, most of the validity data reflect that of construct validity in Messick's terms (1995). Researchers also have investigated the validity of letter-sound fluency (Ritchey & Speece, 2006; Speece, Mills, Ritchey, & Hillman, 2003; Stage, Sheppard, Davidson, & Browning, 2001) and premath skills (VanDerHeyden et al., 2004; VanDerHeyden, Witt, Naquin, & Noell, 2001).

Although these preacademic tasks are often called "CBM," there are important distinctions (Fuchs & Fuchs, 1999). Prereading fluency measures assess a single skill that does not rep-

resent the general outcome of word recognition and reading comprehension. In contrast, PRF reflects word recognition and comprehension processes (Jenkins, Fuchs, van den Broek, Espin, & Deno, 2003), the goals of reading instruction. There is concern that single-skill measurement may narrow the range of skills teachers may teach, and that the measures may not adequately model growth in the curriculum (Fuchs & Fuchs, 1999). Ritchey and Speece (2006) reported that letter-sound fluency slope predicted word reading at the end of kindergarten, suggesting some relation between sublexical growth and reading outcomes. The DIBELS website provides benchmarks that could be construed as evidence of growth. However, several research reports indicate that the benchmarks yield too many false-positive cases (Fuchs, 2003; Hintze, Ryan, & Stoner, 2003; Speece, 2005). Further work along the

lines of the research program that guided CBM is required to understand the full range of validity questions. Construct validity is established for several of the measures, so they can be viewed as predictors of literacy outcomes, but their use as progress monitoring or diagnostic measures is premature.

RECOMMENDATIONS AND FUTURE DIRECTIONS

Although our own work focuses on RTI, not psychological processes, and, accordingly, we view RTI as more viable for the identification of LDs, examination of validity indicates both approaches require more work to claim the high ground. There is evidence of construct validity for each. It is true that RTI has a stronger hold on relevance given the direct tie to instruction and child outcomes (e.g., Speece & Case, 2001; Vaughn et al., 2003; Vellutino et al., 1996), but there remain a large number of questions to be examined, such as validity for older children, academic domains beyond reading and math, applicability to children in kindergarten and preschoolers, methods to ensure fidelity of treatment as RTI goes to scale in schools, and methods to reduce the cumbersome nature of the RTI enterprise. Major issues for psychological processing methods include demonstrating a contribution beyond what is learned from achievement tests and evaluating instructional relevance through tighter research designs that include experimental control and larger samples. Both methods need to be more definitive about the criteria for diagnosing a learning disability.

Obviously, clinicians and practitioners do not have the luxury of waiting for definitive answers if, indeed, any are forthcoming. Current best practice is to implement an RTI system with all the components (increasingly intensive instruction across three tiers, progress monitoring, and fidelity of instruction). In line with IDEA, Tier 3 must include a multifaceted assessment in relevant domains *as needed*, in addition to continued progress monitoring. This *may* mean an intellectual assessment, if mental retardation is suspected, but this assessment would not be routine. We advocate greater sensitivity to potential comorbid conditions, including social emotional functioning, ADHD, and academic domains other than that cited in the referral. There is a great deal of evidence that chil-

dren's attention to task predicts academic performance (e.g., McKinney, Mason, Perkinson, & Clifford, 1975; McKinney & Speece, 1983; Speece & Cooper, 1990; Stage et al., 2003; Torgesen et al., 1999). This general conclusion holds whether behavior is measured directly through observation or inferred from behavior ratings by teachers. A number of instruments are available to assess attention and should be incorporated as indicated in a comprehensive assessment. Our preference is to conduct minimalist assessments beyond the information on discrepant learning levels and rates provided by RTI. Selected measures should emphasize informing instruction and not comparisons with a norm group.

As the foregoing suggests, RTI is a school-based process. This raises the question of how private practitioners will participate in LD identification if RTI holds sway. If a state educational agency decides that an RTI process is required as part of the diagnostic process, then nonschool practitioners will need to develop additional procedures to work in schools. The proposed regulations, however, provide leeway for a business as usual approach (i.e., testing to document discrepancy and psychological processing difficulties). This flexibility will likely lead to conflict between school systems that adopt RTI and outside practitioners who base diagnosis on a different set of criteria. States will need to consider this possibility and be clear on what counts as evidence. One possible resolution may be the development of dynamic assessment procedures in which test-train-test paradigms administered in single sessions or over a brief amount of time assess responsiveness (e.g., Speece, Cooper, & Kibler, 1990; Swanson & Howard, 2005). Dynamic assessment connected to academic learning holds promise as an efficient approach to RTI and is in development (D. Fuchs, personal communication, October 2005).

Advances in the neurosciences also hold promise for informing psychological processing methods of assessment. Recent work documenting changes in brain activation patterns as a result of reading interventions may ultimately assist in linking these patterns with behavioral measures (e.g., Shaywitz et al., 2004; Simos et al., 2005; Temple et al., 2003). It will be important to expand the behavioral measures to include newer versions of intellectual assessment (i.e., CAS, K-ABC-II) to further assess construct validity.

Although it is unsettling to have such ambiguity in definition and identification for a construct with a long history, as Doris (1986) noted, the LD field actually has a short scientific past. Assessment of LD is more a clinical than a statistical enterprise. Paul Meehl (1954) urged us to put more work in the latter to achieve the validity that the LD field demands.

ACKNOWLEDGMENTS

Work on this chapter was supported by Grant No. H325D020040 from the Office of Special Education Programs, U.S. Department of Education. The opinions expressed here are not necessarily those of the funding institute. We acknowledge with appreciation the contributions of Ming-yi Cho and Caroline Walker.

PART VI

Children at Risk

Child Abuse and Neglect

Claire V. Crooks
David A. Wolfe

In this chapter we present a comprehensive update and review of the major findings on child abuse and neglect to formulate a multi-level framework for psychological assessment. Because of the advances in theory and research since the last edition of this volume, new information has led to considerable changes and refinements in our assessment strategy. Most notably, assessing the child is much more detailed due to the sizable number of new instruments and approaches that have been investigated; previously, the parent was the focus of the lion's share of assessment procedures, and little information was available as to either the effects on or the needs of the children. Although physical abuse continues to receive more coverage than child neglect, many recent studies' added specificity to their procedures has allowed for better discrimination among factors relevant to assessment. In particular, specific measures of neglect have been developed since the previous edition of this volume.

Child abuse and neglect occur within ongoing relationships that are expected to be protective, supportive, and nurturing. Children from abusive and neglectful families grow up in environments that fail to provide consistent and appropriate opportunities that guide develop-

ment; instead, these children are placed in jeopardy of physical and emotional harm. Because their ties to their families, even to the abuser, are very important, child victims may feel torn between a sense of belonging and a sense of fear and apprehension. For this and many other reasons discussed in this chapter, the assessment of abused children, their caregivers, and their family environment is fraught with challenges.

The chapter begins with an overview of the types of child maltreatment, epidemiological findings, and developmental consequences, all of which are important for formulating an assessment strategy. This overview is followed by a comprehensive look at the state of assessment approaches for this multidimensional problem. Our assessment strategy incorporates procedures for assessing many areas of emotional and behavioral development of maltreated children; moreover, it addresses critical areas associated with parent and family functioning that affect maltreatment, such as parental history, childrearing skills, stressful events, and so on. The approach to assessment, derived from research and clinical literature, involves a multi-stage process that profits from advances in observational and self-report assessment strategies.

TYPES OF CHILD ABUSE AND NEGLECT

Many societies are struggling to balance parental rights (e.g., parents' rights to discipline their children) and the rights of children to be safe and free of harm. Consequently, a significant shift is underway in how child maltreatment is defined and in how its effects are studied. In the past, abuse was defined primarily by visible physical injuries. However, physical injuries are only one of many consequences; maltreatment can also damage individuals' developing relations with others and their fundamental sense of safety and self-esteem.

At its most basic level, "child maltreatment" is a generic term describing volitional or neglectful acts on the part of a child's caregiver that result in, or have the potential to result in, physical injuries and/or psychological harm. Maltreatment includes four primary acts of commission or omission: (1) *neglect* (failure to provide care in accordance with expected societal standards for food, shelter, protection, affection); (2) *emotional abuse* (verbal abuse, isolation, exposing children to violence); (3) *physical abuse* (nonaccidental bodily injury); and (4) *sexual abuse* (sexual contact, including attempts or threats). Importantly, most child maltreatment occurs in the context of the caregiver-child *relationship*, which has significance because this relationship is central to the child's ongoing sense of safety, trust, and fulfillment of needs. Although there are other forms of maltreatment that are not caregiver- or family-based (e.g., child sexual exploitation/prostitution, child labor, abuse/assault by non-family persons known to the child), we limit our discussion herein to physical abuse and neglect by a child's primary caregiver (interested readers on these other forms of exploitation are referred to Cooper, Estes, Giardino, Kellogg, & Vieth [2005]). Thus, from a psychological perspective, maltreatment is harmful or potentially harmful to the child's immediate and future well-being not only because of physical injuries, but also because of what it often represents in terms of interfering with the child's ongoing social, cognitive, and behavioral development (Wekerle, Miller, Wolfe, & Spindel, 2006).

Physical abuse is the deliberate application of force to any part of a child's body, which results, or may result, in a nonaccidental injury. It may involve hitting a child a single time, or it may involve a pattern of incidents. Physical

abuse also includes behaviors such as shaking, choking, biting, kicking, burning, or poisoning a child, holding a child under water, or any other harmful or dangerous use of force or restraint (e.g., locking a child in a closet or tying him or her to a chair). Child physical abuse is often connected to physical punishment or may be confused with child discipline. *Neglect* occurs when a child's parents or other caregivers are not providing essential requisites for a child's emotional, psychological, and physical development. Physical neglect involves inadequate provision of a child's needs for food, clothing, shelter, cleanliness, medical care, and protection from harm. The determination of child abuse and neglect typically requires consideration of cultural values and standards of care, as well as recognition that some forms of maltreatment may be bound by poverty.

In addition to these more clearly defined forms of abuse and neglect, the definition of "child maltreatment" for purposes of assessment and intervention often includes cases of high-risk parenting practices that may fall short of documented injuries. Rather than a dichotomous definition (abusive-not abusive), such a view considers the full continuum of childrearing acts, which may range from appropriate and developmentally sensitive behaviors to physically and verbally abusive ones (Wolfe, 1999). Examples of family problems that are addressed by this assessment strategy include reliance upon high-intensity physical punishment, use of excessive criticism and verbal harassment, use of unorthodox disciplinary techniques, lack of physical or verbal affection toward the child, failure to provide developmentally appropriate stimulation or opportunities to the child, exposure to domestic violence, and similar trauma-inducing experiences caused directly or indirectly by caregivers. These and many similar instances of parental inadequacy or ineffectiveness often warrant professional involvement. Because determination of such events involves professional judgment, definitions of child abuse and neglect vary somewhat in accordance with the purpose of the assessment and intervention concerns. This ambiguity is considered necessary and acceptable in view of the current state of knowledge and the presumed advantage to the child and family in seeking assistance for wide-ranging problems (as opposed to labeling or punishing individual family members).

Legal definitions of abuse and neglect emphasize parental deviance and wrongdoing,

thereby focusing on the implicit intent to harm or the parent's inability to protect the child from harm. In contrast, social science definitions allow greater recognition of the individual, family, and social context of maltreatment, because most incidents involve non-life-threatening injuries rather than major acts of assault. The social science perspective, reflected herein, places primary importance on the relational context of maltreatment, because the child's short- and long-term adjustment following incident(s) of abuse or neglect are highly dependent on the overall quality of this relationship. In other words, a parent who is abusive on some occasions may be a source of support and nurturance for the child at other times; thus, the overall psychological impact of abuse may be tempered by other aspects of the relationship (although this process does not negate the significance of the act or the parent's responsibility).

The most distinguishing aspect of parents who have been reported for abuse, compared to their socioeconomically matched counterparts, is the chronic and escalating pattern of parent-child conflict, culminating in more and more serious harm over time. Neglectful parents are usually distinguished by the chronicity and severity of their behavior rather than by single events (Hildyard & Wolfe, 2002; Slack, Holl, McDaniel, Yoo, & Bolger, 2004). Furthermore, both abuse and neglect are most detrimental when they occur in the absence of compensatory factors, such as positive interactions or a strong social support network, which are crucial to facilitating a child's social, cognitive, and emotional development. Thus, rather than being categorically distinct from other parental actions, childhood maltreatment is best understood in terms of a continuum of parenting behaviors. At one extreme on the continuum are those practices considered to be most harmful and inappropriate; at the other extreme are methods that promote the child's social, emotional, and intellectual development. From this perspective, "child abuse and neglect" can be defined in terms of the degree to which a parent uses aversive or inappropriate control strategies in an attempt to inflict physical or emotional pain upon a child, and/or fails to provide minimal standards of caregiving and nurturance (Wolfe, 1999). Furthermore, abuse and neglect often involve a negative and rejecting stance toward the child, which translates into limited opportunities for the child to re-

ceive positive attention and nurturance, or to develop a sense of trust in relationships.

INCIDENCE AND PROFILE

Every week, more than 50,000 children are reported as victims of suspected child abuse and neglect in the United States alone (U.S. Department of Health and Human Services [USDHHS], 2005). This weekly toll translates into an annual rate of about 3 million reports of *suspected* child abuse and neglect cases each year, a figure that has changed very little over the last decade (USDHHS, 2004). About one-third of these reports end up as *substantiated* cases by child protective services, yielding a rate of 12.4 per 1,000 children in the population. Child neglect (including medical neglect) continues to be the most common form of maltreatment, accounting for close to 60% of all documented cases in the United States. Almost one-fifth of the children suffered physical abuse, and nearly 10% were sexually abused. In addition, about one-fourth of these children suffered more than one type of maltreatment.

By comparison, Canada's substantiated incidence of maltreatment was 9.7 per 1,000 children based on a 1998 sample (Trocmé et al., 2001). However, Canada's incidence rate more than doubled in the more recent 2003 study (21.71/1,000 children), mostly because the latter survey included children exposed to domestic violence (as a category of neglect) (Trocmé et al., 2005). Notably, almost two-thirds of the families in the Canadian Incidence Study were known previously to child protective services, underscoring the chronicity and repetitive nature of most forms of maltreatment.

Lifetime prevalence estimates of maltreatment are derived by asking adults if they ever experienced particular forms of maltreatment as children. For example, the Ontario Health Supplement, a general population survey of nearly 10,000 residents of Ontario, Canada, asks people 15 years and older about physical and sexual abuse in childhood (MacMillan et al., 1997). A history of child physical abuse was reported more often by males (31.2%) than by females (21.1%), whereas sexual abuse during childhood was more commonly reported by females (12.8%) than by males (4.3%). Retrospective reports of childhood experiences are inexact, and it is rarely possible to corroborate episodes of maltreatment to get

precise accounts (Hardt & Rutter, 2004). Nevertheless, on the whole, these incidence and prevalence data indicate a substantial problem affecting a sizable proportion of the child and adult population.

Child abuse and neglect occur in all societies, and more and more countries are committed to an ongoing surveillance of reported cases for better awareness and planning. Cross-culturally, the World Health Organization (WHO; 2002) estimates that 40 million children ages 0–14 are victims of child abuse and neglect annually around the world, confirming suspicions that child abuse is found in all societies and is almost always a highly guarded secret.

Certain child characteristics identified through incidence studies help to identify the overall probability and type of maltreatment. Incidence studies have consistently found that children's age and sex are related to risk of maltreatment but that ethnic identity is not, once other factors such as poverty and homelessness are taken into account (Trocmé et al., 2001; USDHHS, 2003). Younger children, who have the greatest need for care and supervision, are the most common victims of physical neglect. Along with young adolescents, toddlers and preschoolers are the most common victims of physical and emotional abuse, which corresponds to the emergence of greater independence and parental conflict at these developmental periods. Sexual abuse, in contrast, is relatively constant from age 3 on, which attests to children's vulnerability from early preschool years throughout childhood. Although both boys and girls are more likely to be sexually abused by someone they know and trust, boys are more likely to be abused by male *nonfamily* members (e.g., camp staff, teachers, scout leaders), whereas girls are more likely to be sexually abused by male *family* members (Berliner & Elliott, 2002; Wolfe, Jaffe, Jetté, & Poisson, 2003).

Abuse and neglect are more common among the poor and disadvantaged, although they also occur among higher income families. This socioeconomic connection is not likely accounted for by reporting bias, as it has not changed for the past 30 years despite increased awareness and reporting (USDHHS, 2003). Family structure is also connected to the probability of child maltreatment. Children living with a single parent are at significantly greater risk of both physical abuse and neglect. Those living

in father-only homes are almost twice as likely to be physically abused as those living with mothers alone (Sedlak & Broadhurst, 1996; Trocmé et al., 2001). The majority of child victims are maltreated by one or both parents (85%) across all forms of maltreatment. However, there are important exceptions, as well as key sex differences in the nature of abuse or neglect. Child neglect is committed predominantly—about 90% of the time—by mothers, which fits with the fact that mothers and mother substitutes tend to be primary caretakers and are more likely to be charged with child neglect, even when a father figure is present in the family. In contrast, sexual abuse is committed more often—about 90% of the time—by males, about half of whom are the child's father or father figure. Although males are the dominant perpetrators in sexual abuse, the most common perpetrator pattern overall is a female parent acting alone, who is typically younger than 30 years of age (USDHHS, 2003). The finding that a single mother is the most frequently identified perpetrator of child abuse is to some extent a reflection of the number of single-parent families headed by mothers.

DEVELOPMENTAL CONSIDERATIONS AND IMPAIRMENTS

The development of the abused child seldom follows a predictable course, because child abuse is characterized by many other negative socialization forces, including family instability, parenting inconsistency, and socioeconomic disadvantage. Information about the developmental sequelae of abuse has gradually grown from its early beginnings (i.e., case histories, clinical interventions, comparative studies of abused and nonabused children) to include more sophisticated longitudinal investigations. These studies continue to suggest that maltreated children, as a group, do not reveal characteristic adjustment patterns or long-term developmental problems that clearly distinguish them from nonabused children. At the same time, the range and extent of problems in this population implicate abuse as a contributory factor in a wide range of child (e.g., delinquency, school problems, speech and language delays) and adult (e.g., criminal behavior, marital conflict, childrearing problems) developmental impairments (Trickett, Kurtz, &

Pizzigati, 2004). This wide range of possible developmental trajectories poses a challenge for assessment due to the number of areas that are potentially affected by child abuse and neglect. A developmental psychopathology perspective of abuse views the emergence of maladaptive behaviors, such as peer aggression, school failure, and delinquency, within a longitudinal and multidimensional framework (Cicchetti, Toth, & Maughan, 2000). This perspective facilitates an ongoing investigation of the *changes over time* observed among samples of abused children, and attempts to account for these changes on the basis of both global (e.g., socioeconomic and normative factors affecting all children) and more specific (e.g., type of maltreatment, child and family resources) intervening variables.

Because child abuse and neglect are the result of adult actions and not child disorders, it is important for assessment purposes to examine the major developmental impacts that have been linked to these phenomena. These developmental impairments show up in children from infancy through adolescence, and can have consequences throughout adulthood. Some of the effects on development lead to mental disorders in childhood or later life, such as posttraumatic stress disorder (PTSD), mood disorders, substance abuse, and so on, whereas others affect ongoing relationships, educational attainment, criminal behavior, and many other aspects of personality and adjustment. Below is a snapshot of the major developmental processes most affected by child physical abuse and various forms of child neglect, followed by discussion of major disorders often associated with longer-term outcomes. Assessment implications and approaches for these impairments follow in subsequent sections.

Episodes of child abuse and neglect, whether chronic or sporadic, can disrupt the important process of early childhood attachment, and interfere with children's ability to seek comfort and to regulate their own physiological and emotional processes. As a result, young maltreated children are more likely than other children to show an absence of an organized attachment strategy (Lyons-Ruth, Yellin, Melnick, & Atwood, 2003). Without consistent stimulation, comfort, and routine to aid in the formation of secure attachments, maltreated infants and toddlers have considerable difficulty establishing a reciprocal, consistent pattern of interaction with their caregivers. In-

stead, they may show a pattern described as *insecure-disorganized attachment*, characterized by a mixture of approach and avoidance, helplessness, apprehension, and a general disorientation (Barnett, Ganiban, & Cicchetti, 1999). The lack of a secure, consistent basis for relationships places maltreated children at greater risk of falling behind in their cognitive and social development, and can result in their having problems regulating their emotions and behavior with others (Sroufe, Carlson, Levy, & Egeland, 1999).

Parent-child attachment and the home climate also play a critical role in emotion regulation, another early developmental milestone. "Emotional regulation" refers to the ability to modulate or control the intensity and expression of feelings and impulses, especially intense ones, in an adaptive manner (Cicchetti, Ganiban, & Barnett, 1991; Maughan & Cicchetti, 2002). Because maltreated children live in a world of emotional turmoil and extremes, it is very difficult for them to understand, label, and regulate their internal states (Shipman, Zeman, Penza, & Champion, 2000). Expressions of affect, such as crying or signals of distress, may trigger disapproval, avoidance, or abuse from caregivers, so maltreated youngsters have a greater tendency to inhibit their emotional expression and regulation, and remain more fearful and hypervigilant (Klorman, Cicchetti, Thatcher, & Ison, 2003). Similarly, they show increased attention to anger- and threat-related signals, such as facial expressions, and less attention to other emotional expressions (Pollak & Tolley-Schell, 2003). Difficulties modulating emotions can be expressed as depressive reactions, as well as intense angry outbursts (Wekerle & Wolfe, 2003). Accordingly, as they grow older and are faced with new situations involving peers and other adults, poor emotional regulation becomes more and more problematic. Over time, this inability to regulate emotions is associated with both internalizing symptoms, such as depression and fearfulness, as well as externalizing symptoms, such as hostility, aggression, and various forms of acting out (Burack et al., 2006; Éthier, Lemelin, & Lacharité, 2004).

Neuroscientists have connected the behavioral signs of poor emotional regulation among maltreated children to alterations in the developing brain. Studies with maltreated children and adults with a history of childhood

abuse show long-term alterations in the hypothalamic–pituitary–adrenal (HPA) axis and norepinephrine systems, which have a pronounced affect on one’s responsiveness to stress (Bremner & Vermetten, 2001; Nemeroff, 2004). Brain areas implicated in the stress response include the hippocampus (involved in learning and memory) the prefrontal cortex, and the amygdala. The impact of child abuse on these areas of the brain may lead to long-term mental health problems (Bremner, 2003). In effect, acute and chronic forms of stress associated with maltreatment may cause changes in brain development, resulting in changes in structure and function. Due to prolonged and unpredictable episodes of abuse or neglect, cortisol levels become depleted, and the feedback systems that control hormone levels in the brain may become dysfunctional. As a result, the neuroendocrine system becomes highly sensitive to stress (De Bellis, Keshavan, Spencer, & Hall, 2000). These neurobiological changes that occur in response to untoward early-life stress may partially account for the psychiatric problems that emerge throughout the lifespan among individuals who were maltreated in childhood.

Maltreated children may also lack core positive beliefs about themselves and their world, because their negative experiences in relationships are carried forward to new situations (Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003). They may develop negative representational models of themselves and others based on a sense of inner “badness,” self-blame, shame, or rage that further impairs their ability to regulate their affective responses (Feiring, Taska, & Lewis, 2002). The child’s developing sense of personal self-efficacy can be undermined by physical and verbal abuse, as well as by physical and emotional neglect, because such maltreatment devalues the child as a person. Feelings of betrayal can also challenge an individual’s sense of self, because a person on whom the individual was dependent violated that trust and confidence.

Maltreated children’s relationships with their peers and teachers typically mirror the models of relationships they know best. Instead of a healthy sense of autonomy and self-respect, their models of relationships have elements of being both victim and victimizer—those who rule and those who submit—and during interactions with peers, maltreated children may alternate between being the aggressor

and being the victim (Dodge, Pettit, & Bates, 1994). Their adaptation strategies, such as hypervigilance and fear, evolve to become highly responsive to threatening or dangerous situations. These strategies conflict, however, with the new challenges of school and peer groups. As a result, children with histories of physical abuse and neglect may be more distracted by aggressive stimuli and misread the intentions of their peers and teachers as being more hostile than they actually are (Dodge et al., 1994). Given their propensity to attribute hostile intent to others and their lack of empathy and social skills, it is not surprising that abused and neglected children are rejected by their peers (Bolger & Patterson, 2001; Burack et al., 2006; Shields, Ryan, & Cicchetti, 2001), and have severe and wide-ranging problems in school and interpersonal adjustment (Egeland, Yates, Appleyard, & van Dulmen, 2002). This pattern of poor adjustment often persists, leading to higher rates of personality disorders in early adulthood, especially among neglected children (Johnson, Smailes, Cohen, Brown, & Bernstein, 2000).

LIFE COURSE

As children approach adulthood, the developmental impairments stemming from child maltreatment can lead to more pervasive and chronic psychiatric disorders, including anxiety and panic disorders, depression, eating disorders, sexual problems, and personality disturbances (Brown, Cohen, Johnson, & Smailes, 1999; Edwards, Holden, Felitti, & Anda, 2003; Felitti et al., 1998). Four of the prominent developmental outcomes of abuse and neglect discussed herein include mood and affect disturbances, substance abuse, posttraumatic stress-related problems, and antisocial or abusive behavior in relationships.

Symptoms of depression, emotional distress, and suicidal ideation are common features of individuals of all ages with histories of physical as well as sexual abuse, especially in the absence of positive relationships and opportunities to develop healthy coping strategies and social supports (Leifer, Kilbane, Jacobsen, & Grossman, 2004). Symptoms of depression and mood disturbance often increase during late adolescence and adulthood, especially among those who were abused since childhood (Brown et al., 1999; Kolko, 2002), and can

lead to life-threatening suicide attempts and self-mutilating behavior (Kaplan, Pelcovitz, Salzinger, Mandel, & Weiner, 1997).

Similarly, teens with histories of maltreatment have a much greater risk of substance abuse (Kilpatrick et al., 2003), which in turn increases the risk of other adjustment problems. Perhaps as a result of chronic emotional pain, some teens and adults attempt to cope with unpleasant memories and current stressors by abusing alcohol and drugs, in a futile effort to diminish their distress. Substance abuse may also bolster self-esteem and temporarily reduce feelings of isolation (Bensley, Eenwyk, & Simmons, 2000). Thus, drug and alcohol use may function as a coping mechanism for increased stress brought on by childhood abuse. Alcohol and other illegal drug use may reduce symptoms of hyperarousal and unpleasant emotions, and produce emotional numbing and euphoria.

A significant number of men and women who have been subjected to severe physical or sexual abuse during childhood suffer long-term stress-related disorders. Between 20 and 50% of children and adolescents with histories of maltreatment involving sexual abuse or combined sexual and physical abuse meet criteria for PTSD (McCloskey & Walker, 2000; Scott, Wolfe, & Wekerle, 2003). The prevalence among adults is equally disturbing: About one-third of the childhood victims of sexual abuse, physical abuse, or neglect meet criteria for lifetime PTSD (Kilpatrick et al., 2003; Widom, 1999). Because of the emotional and physical pain of abusive experiences, children may voluntarily or involuntarily induce an altered state of consciousness known as “dissociation,” which can be adaptive when neither resistance nor escape are possible (Herman, 1992). The process allows the victim to feel detached from the body or self, as if what is happening is not happening to him or her. Child abuse victims may come to rely on this form of psychological escape to the extent that profound disruptions to self and memory can occur (Macfie, Cicchetti, & Toth, 2001).

Finally, although most child victims of abuse and neglect do not grow up to be perpetrators of violence, a disturbingly high number, approximately 30%, carry the pattern into adolescence and adulthood (Kaufman & Zigler, 1987). Growing up with power-based, authoritarian methods of asserting power, even if they do not result in physical injuries or identified

maltreatment, can be toxic to relationship and social patterns (Straus, 2001). For example, youth who have learned to adapt to violence and intimidation as a way of life, and who lack suitable alternative role models or experiences, are more likely to approach dating with inappropriate expectations about relationships. Youth (girls as well as boys) who grow up in violent homes report more violence, especially verbal abuse and threats, both toward and from their dating partners (Wolfe, Scott, Wekerle, & Pittman, 2001; Wolfe, Wekerle, Scott, Straatman, & Grasley, 2004). Dating violence during adolescence, combined with a past history of violence in their own family, are strong prerelationship predictors of intimate violence in early adulthood and marriage (O’Leary, Malone, & Tyree, 1994; White & Widom, 2003).

SUMMARY

The perspective on abused and neglected children presented herein has focused on knowledge of the wide range of developmental changes and deviations that have been documented in this diverse population. This developmental viewpoint embraces the subtly interacting conditions that work in combination either to attenuate the effects of powerful traumatic events or to turn a minor developmental crisis into a major impairment. Accordingly, maltreatment during infancy is strongly associated with characteristics of both anxious and disorganized attachments that may, over time, adversely affect the child’s intellectual and socioemotional development. Preschool-age abused children are more difficult to manage and have more marked developmental delays in language, self-control, and peer interactions than do nonabused children. As they reach school age, these children continue to have significant learning and motivational problems at school, and higher rates of aggressive and destructive behavior with peers. Finally, as abused children reach adolescence and adulthood, they are likely to continue this pattern of altered development, manifested by elevated symptoms of mood and affect disorders, substance abuse, posttraumatic stress, and abuse and violence in their close relationships.

Despite the potential for these serious consequences, child maltreatment, like other forms of adversity and trauma during childhood,

does not affect each child in a predictable or consistent fashion. To the contrary, the impact of maltreatment depends on not only the severity and chronicity of the events themselves but also how such events interact with the child's individual and family characteristics (Felitti et al., 1998). Accordingly, because of the wide-ranging causes and effects of maltreatment, a comprehensive assessment framework must be followed that includes child, parent, family, and cultural influences. We describe the global and specific aspects to such a framework for assessing these areas in the sections to follow.

ETIOLOGY

Physical abuse, in particular, may be understood as a special case of aggression in which child behavior often represents an immediate aversive stimulus that precipitates adult aggression. This perspective also recognizes the significance of contextual factors, such as crowded housing, ambient noise level, and socioeconomic disadvantages that contribute to the uncontrolled expression of aggression in the family. Although such precursors to abuse are highly relevant to our understanding of the problem, the question remains as to why only a relatively small percentage of adults exhibit such behavior in the presence of these common aversive events. To answer this question, a consideration of parent, child, and situational characteristics that may serve to accent or buffer the impact of such events is required.

Child physical abuse and neglect are often considered *relational disorders*, because they occur in the context of critical relationship roles. These relationships are particularly salient during periods of stressful role transitions for parents, such as the postnatal attachment period, the early childhood and early adolescence "oppositional" periods of testing limits, and times of family instability and disruption. Caregivers' failure to provide nurturing, sensitive, available, and supportive care, especially during critical periods, is a fundamental feature of maltreatment.

Abuse and neglect are rarely caused by a single risk factor, notwithstanding the critical role of the adult offender. In addition, even though risk signs and indicators may be present, it is still very difficult to predict who may become abusive and who will not. Because child maltreatment is an event, not a uniform disorder, it

is necessary to consider multiple interactive causes. The presence of stress can convert static conditions into dynamic, chaotic patterns. For example, physical abuse and neglect occur most often in the context of social and economic family deprivation, which can transform predisposed, high-risk parents into abusive or neglectful ones. The greater degree of stress in the social environment of the abusive parent increases the probability that violence will surface as an attempt to gain control or cope with irritating, stressful events. In the case of neglect, stress may be so great that parents withdraw from their child care responsibilities.

For many parents, childrearing is a difficult and aversive event that can escalate unpredictably into a sudden abusive incident, or more gradually turn into avoidance and neglect. Lacking experience and guidance in childrearing, and faced with overwhelming stress, these parents cannot think of ways to handle a situation. Instead, they are often hypersensitive to perceived child misbehavior or have unrealistic expectations of child behavior, and respond overaggressively. Many abusive and neglectful parents have had little past or present exposure to positive parental models and supports. Their own childhoods were often full of difficult, sometimes very traumatic episodes of family violence, alcoholism, and harsh family circumstances related to frequent moves, unemployment, and poverty (Wolfe, 1999). As adults, they find daily living stressful and irritating, and they prefer to avoid potential sources of support, because it takes additional energy to maintain social relationships. Chronic physical ailments and a pervasive mood of discontentment, both common complaints, are understandable in light of the circumstances and limited coping resources.

Offender Characteristics

Because abuse and neglect usually occur in relation to childrearing demands, it is not surprising that both neglectful and abusive parents interact less often with their children than other parents during everyday activities. In general, neglectful parents actively avoid interacting with their child, even when the child appropriately seeks attention, most likely because social interaction is unfamiliar and even unpleasant. Physically abusive parents, in contrast, tend to deliver to their children a lot of threats or angry commands that exceed the de-

mands of the situation, rather than positive forms of guidance and praise (Azar & Wolfe, 2006). Because of hostile information-processing biases, maltreating parents may misperceive or mislabel typical child behavior in ways that lead to inappropriate responses and increased aggression (Azar, 2002; Milner, 2003). They are unfamiliar with what is developmentally appropriate for a child at a given age. Some parents apply the same faulty reasoning to themselves as well, which results in lowered self-efficacy (“I’m not a good mother; other mothers can get their children to do these things”) and greater interpersonal dependency (Bornstein, 2005). Unrealistic expectations and negative intent attributions can lead to greater punishment for child misbehavior and less reliance on explanation and positive teaching methods (Azar & Wolfe, 2006). Children are seen as deserving of harsh punishment, and its use is rationalized as a way to maintain control (Bugental, Blue, & Cruzcosa, 1989).

Neglectful parents have received far less research attention than physically abusive ones, perhaps because *omissions* of proper caretaking behaviors are more difficult to describe and detect than *commissions*. Although personality characteristics and lifestyle choices of abusive and neglectful parents overlap considerably, as a group, neglectful parents have more striking personality disorders and inadequate knowledge of children’s needs, and they suffer more chronic patterns of social isolation than both abusive and nonabusive parents (Hildyard & Wolfe, 2002). Furthermore, neglectful caregivers typically disengage when under stress, whereas abusive parents become emotionally and behaviorally reactive (Azar, 2002). Neglectful parents try to cope with the stress of childrearing and related family matters through escape and avoidance, which can lead not only to severe consequences for the child but also to higher risk of substance abuse and similar coping failures for these parents (Crittenden & Claussen, 2002).

Child and Family Influences

Even though children might do things that are annoying, adults are fully responsible for abuse and neglect. Children’s behavior or developmental limitations may increase the potential for abuse, but only if accompanied by the other critical factors noted previously. Unintentionally, however, the child may still play a role

in the continuation or escalation of an abusive or neglectful relationship. For example, children with disabilities such as mental retardation or physical impairments were three times more likely to be abused than were their non-disabled peers based on a large population-based sample (Sullivan & Knutson, 2000).

Abusive incidents occur most often during difficult to manage, but not uncommon, episodes of child behavior such as disobedience, fighting and arguing, accidents, and dangerous behavior, which may produce anger and tension in some adults. Circumstances surrounding incidents of neglect, in contrast, relate more to chronic adult inadequacy, which spills over into daily family functioning (Herrenkohl, Herrenkohl, & Egolf, 1983). Neglected children’s early feeding problems or irritability may place an increased strain on the parents’ limited child care abilities, again setting in motion an escalation in the child’s dependency needs and demandingness, accompanied by further parental withdrawal (Drotar, 1999).

Family circumstances, most notably conflict and marital violence, also have a causal connection to child maltreatment. In about half of the families in which adult partners are violent toward one another, one or both parents have also been violent toward a child at some point during the previous year (Edleson, 1999). Domestic conflicts and violence against women most often arise during disagreements over childrearing, discipline, and each partner’s responsibilities in child care (Edleson, Mbilinyi, Beeman, & Hagemester, 2003). Children may be caught in the crossfire between angry adults, or in some cases, they might instigate a marital conflict by misbehaving or demanding attention. In either case, an escalating cycle of family turmoil and violence begins, whereby children’s behavioral and emotional reactions to the violence create additional stress on the marital relationship, further aggravating an already volatile situation.

Child maltreatment usually occurs in the context of multiproblem homes and neighborhoods, where poverty, social isolation, and wide acceptance of corporal punishment exert major influence on child development. Perhaps as a result of cultural and social factors, maltreating families often lack significant social connections to others in their extended families, neighborhoods, and communities, as well as to social assistance agencies (Korbin, 2003; Thompson & Flood, 2002). Unfortunately,

maintaining family privacy and isolation may come at the cost of restricted access to healthier childrearing models and social supports. Neglectful families are especially prone to such isolation and insularity, which may be tied to the parents' significant interpersonal problems (Gaudin, Polansky, Kilpatrick, & Shilton, 1996).

In summary, abusive and neglectful parents may be characterized as coming from multi-problem families of origin, in which they were exposed to traumatic or negative childhood experiences, such as family violence and instability. As adults, they often are incapable of managing the levels of stress found in their environment, and tend to avoid social contacts that they may perceive as additional sources of stress. Inadequate or inappropriate exposure to positive parental models and supports (both in the present and the past), coupled with limited problem-solving skills and ability to make appropriate judgments during childrearing situations, may serve to make childrearing a difficult and aversive event. Consequently (or concomitantly), such parents may report symptoms indicative of health and coping problems that further impair their ability to function effectively as parents. As a result, strategies for assessing parents must balance between screening for a wide range of possible difficulties without being cumbersome in an attempt to be exhaustive.

ASSESSMENT OF CHILD ABUSE AND NEGLECT

The preceding overview has emphasized the interplay of a constellation of factors that involve the entire family, including the parent's childhood and early adult history, childrearing skills, recent stressful events, social relationships, and features of the child, among others. We have also seen that the causes and outcomes of abuse are entwined with general background factors that may impair child development, such as socioeconomic disadvantage, health status, and family instability. In view of the complexity of this problem, several implications for the assessment of maltreating families emerge. Whereas home and clinic observations of behavior have demonstrated their value for pinpointing specific problem areas, by themselves such observations may be insufficient to reveal the range and significance of contextual events that may be dramatically influencing

parent and child behavior. Therefore, indirect assessment methods (e.g., self-report and collateral report instruments, interviews, and standardized psychological tests) that assess such things as parental attitudes, perceived social supports, and physical and emotional health are important methods for examining low-frequency behaviors and qualitative factors that relate to parental competence and possible marital, social, or financial problems.

Another assessment issue that deserves emphasis relates to the extremely wide range of behaviors that may be shown by abused children. Typically, functional components of the abuse process, such as marital conflict, family instability, and elevated expressions of anger, are associated with an unusual pattern of child behavior. However, it is not uncommon to find maltreated children who either lack any signs of overt problems or distress or exhibit very self-defeating behavior with no obvious function. Rather than assuming that an apparent absence of distress is indicative of the benign effects of abuse, other alternatives must be carefully considered. Therefore, the ongoing assessment of abused children's development and behavior over an extended time period may be necessary both to understand the relationship of their behavior to previous and current experiences, and to determine the (possible) adaptive nature of their coping and adjustment patterns at different developmental periods.

Referral Questions

Assessing child abuse and neglect is a complex undertaking, in part because there are many different assessment purposes. Unlike assessing pathology such as depression or anxiety, in which the assessment questions tend to be more consistent, there is a range of referral reasons for an assessment evaluating child maltreatment. It is critical to have a clear understanding of the parameters and focus of the assessment at the outset, because child maltreatment assessments range on a variety of dimensions, including the likelihood of becoming part of a court proceeding. Because child maltreatment occurs within a system rather than an individual, evaluation typically includes an assessment of the parent(s), child(ren), and/or the parent-child relationship. A comprehensive assessment almost always includes all three elements. Some common referral purposes include the following.

Assessment of Risk of Abuse and/or Competence of Parenting

One of the most common purposes of referral, assessment of risk for abuse and/or parenting capacity, is often ordered to assist child protective services or the court in making placement decisions. The importance of a clear referral purpose cannot be overstated. Even within this particular type of assessment, the more focused the purpose of referral the better, because vague or global reasons for referral (e.g., “to evaluate this mother’s parenting ability”) are likely to lead to vague and global reports (Budd, 2001). These assessments may be very labor intensive, because they often include a review of significant amounts of collateral information and require interviews with many individuals who have been involved with the family. Assessing allegations about parenting capacity and/or abuse occurs with higher frequency in high-conflict custody cases than in the general public (see Box 14.1).

Assessment of a Family Where Child Maltreatment Has Been Identified for the Purposes of Intervention Planning

General treatment planning for various members of a family is another common purpose for assessment. In these cases, maltreatment has already been substantiated in the child protection system (or the family has been identified as high risk) and the purpose of the referral is to identify appropriate intervention(s). Although protocols related to mandatory reporting of child abuse still apply, there is less focus on whether an incident did or did not occur and more emphasis on identifying strengths and weaknesses of the family. In these assessments, recommendations typically focus more on identifying required interventions and supports than on specific placement decisions.

Assessment of the Adult Perpetrator of Child Maltreatment for the Purposes of Intervention Planning

In some cases, an adult perpetrator of child abuse is referred for an assessment to assist intervention planning. Although the focus is the adult perpetrator, an understanding of the parent–child dynamics associated with child abuse is critical for conducting these assessments. Because these assessments are more typically the domain of child protective services or

adult forensic work, and less likely to be part of general psychological practice, they are not covered in great detail in this chapter.

Assessment of Child Victim for the Purposes of Intervention Planning

Social workers and psychologists are often called upon to assess child victims of abuse to evaluate the extent of trauma and other difficulties that have arisen due to the abuse. These assessments provide a critical basis for intervention planning. The assessment may include overt symptomatology (e.g., trauma symptoms, depression and anxiety, behavioral problems), more subtle attitudinal components (e.g., attributions about blame, attitudes about acceptability of violence), and deficits in interpersonal and academic functioning.

Screening for Child Abuse in a General Clinical Setting

Sometimes a child or family that has come into contact with professionals for reasons other than child maltreatment may evidence a “red flag” for neglect or abuse. Situations in which abuse might be suspect include the following: (1) The history of the child’s injury given by the parent is incompatible with the present injury; (2) the parent’s account of the “accident” changes during the course of questioning; (3) repeated episodes of trauma or accidents are known to the agency, setting, or interagency records; and (4) there is an inexplicable delay in seeking treatment for the child’s injury or illness. Typically, such assessment or screening is done by emergency care staff in hospitals and child protection agencies, although any professional who comes into contact with families may be called upon to offer his or her opinion about the nature and probable cause of an atypical pattern of child injuries, delays, or behavior.

Victim Impact Assessment of Adults Who Were Victims of Child Abuse

A final, highly specialized focus is assessment of the impact of historical child abuse on individuals who are now adults. These assessments, conducted for the purpose of criminal or civil litigation, document the severity and pervasiveness of the effects of the abuse. In some of these assessments there is a vocational component to highlight the gap between possi-

BOX 14.1. Legal Issue: Assessing Child Abuse Allegations in the Context of High-Conflict Custody Cases

Psychologists and social workers who conduct custody assessments for the court are often presented with competing claims of child maltreatment by divorcing parties (Jaffe, Crooks, & Bala, 2006). One California-based study of high-conflict separation cases in the family courts found that more than half involved an allegation of spousal or child abuse (Johnston, Lee, Olesen, & Walters, 2005). Allegations in the context of high-conflict divorce might be dismissed by professionals as symptoms of the parental conflict, and child protective services often want the matter settled in civil or family court. However, the results of the California study suggest that these allegations should be taken seriously and evaluated on their own merit. In this sample, about one-half of the abuse allegations were substantiated, and in about one-fourth of the cases some form of child or spousal abuse was perpetrated by both parents. Professionals may be (understandably) suspicious about the timing of child abuse allegations in the context of custodial proceedings and worry that a parent is making unfounded allegations to gain the upper hand in the civil proceedings. However, there may be other good reasons why allegations are made at the point of separation. In some cases, the child or parent feels too intimidated or guilty to disclose the abuse until after separation; in other cases, child abuse may not begin until after separation. Nonetheless, false allegations remain a weighty concern for mental health and justice system professionals.

What is the incidence of false allegations in child custody proceedings? It is impossible to say definitively, and it may be more useful to think about unfounded allegations (rather than maliciously false). Overall, in the few empirical studies that have been conducted, there is a significantly higher incidence of unfounded allegations of child abuse in the post separation context than in other situations (Bala & Schuman, 1999; Trocmé & Bala, 2005). However, it is important to note that a relatively small number of the unfounded postseparation allegations of child abuse in these studies were deemed to be due to deliberate or malicious fabrication. More common are cases of unfounded postseparation allegations, in which the accusing parent has an honestly held (albeit erroneous) belief about abuse based on numerous factors. For example, children's vague descriptions or symptoms, the parent's own abuse history, their poor view of the other parent, and lack of trust between parents may well contribute to the unfounded belief that abuse occurred.

In some cases, the accusing parent's erroneous beliefs about the other parent perpetrating child abuse are held so strongly that he or she will reject repeated independent, professional opinions refuting the allegations. In these cases, courts and community service providers have to manage their limited resources to ensure that repeated assessments and the litigation process are not harming the children. The fact that a parent continues to hold unfounded beliefs about child abuse perpetrated by the other parent in the face of clear refutation by investigating professionals may be symptomatic of serious emotional problems and require intervention.

Implication for Assessment

Regardless of the particular context, allegations of child abuse require thoughtful and thorough assessment. Custody proceedings tend to be conceptualized by the parties as having a winner and a loser, and there is an implicit assumption that at least one of the parents can provide safe and adequate parenting. In reality, both parents may have significant parenting deficits and/or engage in child abusive behaviors, requiring assessors to make a report to child protective services. Custody assessments in general tend to trigger the highest number of complaints about practitioners to licensing boards across jurisdictions. Assessors are cautioned to undertake these assessments with great care, and to ensure adequate supervision and professional development before entering into this area of practice.

ble career success and the individual's actual path. Similar to parenting capacity assessments, victim impact assessments are conducted with the understanding that the report will become part of a settlement or trial proceeding, and the assessor may be called to testify. These assessments may focus on historical familial abuse but, increasingly, they relate to historical institutional abuse (Wolfe et al., 2003).

Although the basic standards of good assessment apply to all of the preceding referral issues, there are additional considerations for assessments relating to child maltreatment. The American Psychological Association (APA) has published guidelines to assist psychologists who engage in child protection evaluations (APA Committee on Professional Practice and Standards, 1998). These guidelines address numerous areas, including orientation, preparing for a child protection evaluation, and procedures. Although not intended to be binding standards, they are highly recommended for any professional undertaking these assessments. Also, there are additional considerations specific to the broader area of child maltreatment assessments (over and above child protection evaluations). These considerations provide a critical context for the entire assessment process, and competent assessment of child maltreatment is grounded in an appreciation of these factors.

1. *Child maltreatment encompasses a range of behaviors.* As noted in the first section of this chapter, there is a wide range of patterns that span the subject of child maltreatment, from the legal definition of child abuse to a more encompassing clinical concept of maltreatment. Generally, it is recognized that officially documented cases of legal child abuse represent only the "tip of the iceberg" (Trocmé, et al., 2001). The legal definition of child abuse is predicated on whether or not a specific event occurred, but beyond these discrete incidents that have met the legal threshold, there may be ongoing toxic and coercive parent-child interactions that do not meet the legal definition. It is important for an assessor to be clear about whether he or she is documenting child abuse in the formal, legal sense or maltreatment in a broader sense. Regardless of the parameters of the referral question, inclusion of subabusive violence directed toward children in the assess-

ment process is key (Graziano, 1994). Furthermore, as difficult as it is to measure physical child maltreatment, neglect and emotional abuse are even more complicated due to differences in definitions and conceptualizations (see Straus & Kantor [2005] and Hamarman, Pope, & Czaja [2002], respectively).

2. *Families are typically seeking service involuntarily or with significant coercion.* Families undergoing assessment for child abuse and neglect often have been referred for psychological services involuntarily or under duress. This referral pattern has implications in terms of both eliciting the necessary, accurate information from the parents and establishing credibility and rapport that will increase clients' motivation to change their parenting style. In general, such clients are more reserved and defensive than self-referred clients in terms of acknowledging their need for mental health services. In addition, there are specific concerns with respect to response patterns for well-established standardized measures (Carr, Moretti, & Cue, 2005). These response patterns are discussed in more detail in the section of this chapter on assessing adults. Assessing defensiveness is an important piece of a comprehensive assessment, because readiness to change has been found to predict improvement and recidivism in a child welfare sample (Littell & Girvin, 2005). Finally, it is important to be aware that informed consent in these cases may have a coercive element.

3. *Child abuse represents an entrenched style of interaction with many barriers to change.* The task of learning unfamiliar child management procedures may appear overwhelming to parents, strengthening their desire to adhere to more familiar, aversive control methods. This "resistance to change" is also embedded in cultural and familial factors (e.g., proclivity toward physical punishment and rigid control) that may conflict with the therapist's style of assistance and intended goals for the family. In our parenting program for abusive fathers, men typically begin by saying that they are simply "not going to do it again"; however, even with the desire to change, these men face significant challenges associated with altering overlearned patterns of relating (Crooks, Scott, Francis, Kelly, & Reid, 2006).

4. *Abusive families are a heterogeneous group of multiproblem families.* Abusive families are a heterogeneous group of multiproblem families that possess unique combinations of

assets and liabilities. Recent research efforts have begun to identify profiles or types of parents who are abusive (Haskett, Scott, & Ward, 2004; Herron & Holtzworth-Munroe, 2002), but the reality remains that each family is idiosyncratic in terms of its own strengths and weaknesses. Thus, each family requires a uniquely tailored, ongoing assessment strategy that is sensitive to its particular needs. It is a widely recognized clinical principle that the likelihood of positive treatment outcomes is maximized when interventions are matched to specific targets on the basis of an appropriate assessment. A mismatch of intervention and needs is at best inefficient, and at worst dangerous, particularly in families where child maltreatment is an issue (Saunders, Berliner, & Hanson, 2003).

General Assessment Methods and Process

Assessment for all comprehensive child abuse referral questions involves assessing parents, children, and parent-child dynamics separately. The overall options for data collection are the same as for other types of assessment (i.e., interview, self-report, administered tests, and observation) and the general principles of competent assessment still apply (i.e., multimethod, multi-informant approaches). However, there are many additional considerations unique to the nature of the problem being assessed.

In the next sections we discuss assessment of parents, followed by children, and finally parent-child abuse-related dynamics. In the parent and child sections, our focus is on specific abuse assessment considerations and concerns rather than reiteration of basic assessment principles. Where specific measures have been researched more carefully with a child abuse population, we describe the findings. We highlight recent innovations and include comments on feasibility of measures and approaches throughout.

STEP 1: ASSESSING PARENTS

Issues in Assessing Maltreating Adults

The assessment of abusive parents must be tailored to the needs of the referral source, as well as those of the particular family. The complex array of factors that contribute to abuse and neglect requires an assessment approach that attends to the major problem areas in an orga-

nized and progressive fashion, without becoming overburdened by the number of potential concerns.

Because the possible consequences associated with the family's participation during assessment and issues of confidentiality are often initially unclear, parents may behave in a cautious or defensive manner. It is important that the interviewer explains his or her professional role (i.e., to assess areas in need of change) and standards concerning client confidentiality; however, it is equally important to clarify for the parents the assessor's legal obligation to report any suspicions of child maltreatment to protective services. Usually this can be done in a matter-of-fact manner as the session begins:

"I'll be asking you to tell me a lot of detail concerning your child's behavior and your feelings and actions related to your child. My role is to find out whether the problems you are having can be lessened in any way. Please understand that I'm not here to make any judgments about your parenting ability without your agreement and understanding. I am under no obligation to report to anyone outside of this room about what we discuss unless there is a risk of your child or another child being at risk for harm. This means that if you tell me that you hurt your child or may hurt him/her I must notify your caseworker (or protective services). Beyond the immediate safety of children, I will not discuss anything with your worker unless we have both agreed to this beforehand. If you have any other concerns about your situation and my role, let's discuss them now before proceeding with the interview."

Mental health professionals who have been asked by the court to prepare a written report on parental competence and risk will have to modify this statement to clarify for the parent exactly what the court is asking, and what does and does not need to be reported.

A wide range of assessment domains may be pertinent for a particular adult, and the breadth of the assessment, of course, stems from referral concerns. There has been a move away from extensive personality testing, in part because there is not an "abusive personality" for which to assess. At the same time, a general measure of personality (e.g., the Personality Assessment Inventory, the Minnesota Multiphasic Personality Inventory—Second Edition)

may be incorporated to help develop an overall pattern of strengths and weaknesses. Typically, an assessment includes a general evaluation of psychosocial functioning and possible symptomatology, emotional functioning and regulation, social support, life stress, and the marital relationship or other intimate partner relationships. Additional indicated areas, such as a more in-depth mental health or substance abuse assessment, are included on an as-needed basis.

Interview

Initial information concerning both parent and child functioning is typically obtained from a semistructured interview with the parent, as well as reports from others. To assist in organizing the material in a comprehensive fashion, a Parent Interview and Assessment Guide, presented in Table 14.1, provides an overview of the major issues that we address below.

TABLE 14.1. Parent Interview and Assessment Guide: Abuse and Neglect

The following is a selected summary of the major factors associated with child abuse and neglect, requiring further interviewing and assessment of the parent, as indicated. The framing and emphasis of each question are left up to the discretion of the interviewer.

- I. Identifying general problem areas
 - A. Family background
 1. Early rejection or abuse during own childhood; relationship with biological and/or psychological parents
 2. Methods of punishment and reward receiving during own childhood
 3. Family planning and effect of children on the marital relationship
 4. Preparedness for and sense of competence in childrearing
 5. Early physical, emotional, behavioral problems of child (i.e., illnesses, trauma, temperament)
 - B. Marital relationship
 1. Length, stability, and quality of present relationship
 2. Examples of conflict or physical violence
 3. Support from partner in family responsibilities
 4. Substance abuse
 - C. Areas of perceived stress and supports
 1. Employment history and satisfaction
 2. Family income and expenses, chronic economic problems
 3. Stability of occupation, income, and living arrangements
 4. Perceived support from within or outside of the family
 5. Daily/weekly contacts with others (e.g., neighbors, social workers)
 6. Quality of social contacts and major life events (i.e., positive vs. negative influence on the parent)
 - D. Symptomatology
 1. Recent or chronic health problems; treatment; drug and alcohol use
 2. Identifiable mood and affect changes; anxiety; social dysfunction
 3. Previous psychiatric evaluations of treatment
- II. Assessing parental responses to childrearing demands
 - A. Emotional reactivity
 1. Perception of how particular child differs from siblings or other children known to the parent
 2. Feelings of anger and loss of control when interacting with child (describe circumstances, how the parent felt, how the parent reacted)
 3. Typical ways of coping with arousal during/following stressful episodes
 - B. Childrearing methods
 1. Parental expectations of child (i.e., accuracy of expectations for child behavior and development, in reference to child's actual developmental status)
 2. Examples of recent efforts to teach new or desirable behavior to child
 3. "Preferred" and "typical" manner of controlling/disciplining child
 4. Attitudes toward learning different or unfamiliar childrearing methods
 5. Perceived effectiveness of parent's teaching and discipline approach
 6. Pattern of child behavior in response to typical discipline methods (i.e., accelerating, decelerating, manipulative, responsive)

Family Background

The importance of careful investigation of parents' previous childhood experiences that may affect current behavior cannot be overstated. Abusive parents can often relate to the examiner several significant events, such as early rejection or abuse during childhood, or strong cultural values, such as adherence to corporal punishment and disavowal of "bribery methods," that have influenced or guided their behavior within the family. Although these events and perceptions may have little to do with changing current behaviors per se, they may suggest to the examiner the type of treatment approach that might be most effective (emphasis on cognitive and attitudinal change, modeling, problem solving, etc.). Most importantly, knowledge of the parent's history enables the therapist to develop an intervention plan that is most likely to succeed in relation to the parent's expectations, abilities, and needs.

The interview should trace the origins and development of significant areas of stress within the family system, beginning with family planning and the effects of children on the marital relationship. This discussion includes, for example, whether the child was planned, the effect of the pregnancy on parental attitudes and lifestyle, support of the biological father, the mother's/father's preparedness and sense of competence in childrearing (i.e., emotional maturity, family support, peer influences), and early childhood problems (e.g., illnesses, trauma, and temperament). It is often useful to allow time for general discussion of the child throughout the interview, because the parent may have justified or rationalized his or her actions based on the child's "difficult behavior." The parent can be encouraged to describe the child's desirable and undesirable behaviors, and to discuss how he or she would like to see these changed.

Marital and Family Adjustment

Because the parent's childrearing effectiveness and appropriateness is often related to his or her interactions and experiences with other significant adults, the interviewer should be careful to assess areas of non-child-related stress within the family. In many instances of child maltreatment, the marital (or common-law) relationship is a primary source of added conflict and stress that interferes with childrearing. A

discussion of the length, stability, and quality of the present relationship may provide insight into the manner in which adult conflict may influence parent-child interactions, such as tolerance for child misbehavior, noise, and interruptions. Interestingly, family functioning may be an area where there are different risk factors for men and women. In one study of military parents, depression, parental distress, and family conflict predicted child abuse potential scores for both mothers and fathers, whereas low family expressiveness was predictive only for fathers, and marital dissatisfaction, low social support, and low family cohesion were predictive only for mothers (Schaeffer, Alexander, Bethke, & Kretz, 2005).

In addition, the interviewer should be sensitive to other signs of major distress or conflict in the family system that may play a major role in the perpetration of child maltreatment, especially physical violence between partners, extramarital relationships, substance abuse, interference from relatives, and lack of spousal assistance in handling family affairs. These topics may need to be addressed during private, individual sessions with each partner as circumstances require.

Areas of Perceived Stress and Support

The major purpose of assessing the family's or individuals' degree of stress and support is to locate areas that are perceived as highly stressful and to determine what resources family members use to manage these areas of stress, either effectively or ineffectively. Assessment of highly stressful socioeconomic factors can be accomplished during the interview by discussing employment history and satisfaction, family income and expenses, housing and living arrangements, and similar circumstances that may be contributing to family problems.

Parental Emotional Regulation and Functioning

The parent's reactivity to unpleasant or aversive environmental events is an important factor believed to mediate anger and aggression (Wolfe, 1999). Because emotional reactivity involves involuntary somatic responses (e.g., changes in cardiovascular function, temperature of peripheral organs, muscle tension) that are very difficult to observe or measure under realistic conditions, self-report ratings of annoyance, anger, or unpleasant changes in affect

have most commonly been used. Abusive parents are often willing to describe their feelings of anger and “loss of control” when provided with distinctive cues or examples, such as interacting with their child in a high-conflict situation or discussing a recent conflict (e.g., Koverola, Elliot-Faust, & Wolfe, 1984); that is, feelings of anger, tension, and frustration can be identified by asking parents to provide recent examples of irritating child behaviors, the circumstances in which they occurred, how they felt, and how they reacted. At the same time, the clinician can ask parents to identify fluctuations in mood (especially depression, anxiety, and agitation) that precede or follow incidences of parent–child conflict (MacMillan et al., 1991).

Throughout the interview it is important for the clinician to attend to the process as well as the content relayed by the parent’s responses. By attending to *how* responses are given and looking for patterns, an understanding of the parent’s worldview will begin to emerge. Do they see authority figures and helping professionals as trustworthy or do they feel hostile towards people in general? Do they feel that they have some control over events or do things just seem to happen to them? Can they link the causes and consequences of some of the events they have experienced? Listening to the phrases a parent uses to attribute intent towards their children is also helpful. For example, a parent who reports that a child really knows their “triggers” or “how to push their buttons” suggests a belief system that may predispose them to coercive and abusive parenting strategies due to the perception of malicious intent on the child’s part. Although it may not be possible to record the entire interview verbatim, recording key responses in the exact language used by the parent will provide helpful material for the report.

If the clinician has concerns about significant psychopathology, a structured diagnostic interview might be indicated. For example, the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID; First, Spitzer, Gibbon, & Williams, 1996) is a semistructured diagnostic interview designed to assist clinicians in making reliable DSM-IV Axis I (clinical) psychiatric diagnoses. Although the presence of a mental health disorder in and of itself does not determine whether parenting is ineffective or abusive, a diagnosis can alert the assessor to specific areas of functioning

that might be impaired. For example, if a parent has been diagnosed with bipolar disorder and experiences periods of mania accompanied by poor impulse control and judgment, it would be important to assess the parent’s insight into the need for parenting support during these episodes.

Self-Report Measures of Interpersonal Functioning, Adjustment, and Personality

During the interview, a history of the parent’s clinical symptomatology may be addressed by discussing mood and affect changes, anxiety, recent or chronic health problems, and medical treatments. This interview procedure may be assisted by the administration of a standardized psychiatric symptom checklist or inventory to rule out particular forms of psychopathology and/or determine the extent of psychopathology. Several options are presented here that vary in length, extent to which they focus on pathology versus general functioning and personality, and ability to detect social desirability. These measures are further summarized in Table 14.2.

The Symptom Checklist–90—Revised (SCL-90-R; Derogatis, 1983), a relatively brief self-report symptom inventory designed to reflect psychological and health-related symptoms of the respondent over the past 7 days, has been shown to have strong psychometric properties. Two subscales of this 90-item questionnaire are particularly useful indicators of adult interpersonal style: (1) Interpersonal Sensitivity, which measures personal inadequacy and inferiority (e.g., self-deprecation, feelings of uneasiness); and (2) Hostility, which reflects thoughts, feelings, or actions that are characteristic of the negative affect state of anger. The SCL-90-R has demonstrated utility with at-risk parents (Ammerman & Patz, 1996; Budd, Heliman, & Kane, 2000). There is also a shorter version of the SCL-90-R, the 53-item Brief Symptom Inventory (BSI—Derogatis, 1992; Derogatis & Melisaratos, 1983). Although the efficiency of the BSI makes it an attractive alternative, little research has been conducted with the BSI in the context of assessing parenting competence or risk (Budd, 2001). More recently the BSI-18 was developed as a brief, self-report symptom inventory designed to screen for psychological distress and psychiatric disorders (Derogatis, 2000). The 18 items take approximately 4–5 minutes to complete and provide scores on So-

TABLE 14.2. General Measures of Personality, Psychopathology and Interpersonal Functioning for Assessing Parents

Measure	Description of scales	No. of items (time)	Validity scales	Comments
Symptom Checklist-90-R	9 primary symptoms scales plus 3 global indices measuring overall distress, intensity of symptoms, and number of symptoms	90 (12–15 min)	No	The SCL-90-R and shorter versions have not received much research attention with respect to utility in child abuse assessments.
Brief Symptom Inventory	9 primary symptoms scales plus 3 global indices measuring overall distress, intensity of symptoms, and number of symptoms	53 (8–10 min)	No	
Brief Symptom Inventory-18	3 scales—Anxiety, Depression, Somatization, plus an Overall Severity Index	18 (4 min)	No	
Minnesota Multiphasic Personality Inventory-2	10 clinical scales 9 restructured clinical (RC) scales 15 content scales 27 content component scales 20 supplementary scales 31 clinical subscales (Harris–Lingoes and social introversion subscales) Various special or setting-specific indices	567 (60–90 min)	Yes: 8 validity scales	Validity scales make the MMPI very useful in child abuse assessments.
Personality Assessment Inventory	11 clinical scales 5 treatment scales 2 interpersonal scales	344 (40–60 min)	Yes: 5 validity scales	Has validity scales, but there is preliminary evidence that these may not detect defensive responding patterns in child abuse assessments.

matization, Depression, and Anxiety subscales, in addition to a Global Severity Index.

One of the most commonly used but relatively time-consuming self-report options for assessing functioning and pathology is the Minnesota Multiphasic Personality Inventory—Second Edition (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989). The MMPI-2 is considered by many to be the gold standard in personality and psychopathology assessment. It has 567 true–false items and is estimated to take between 60 and 90 minutes to complete. Scores are produced on a wide range of clinical, content, and validity scales, and there are now more than 50 years of research on the original MMPI. Several translations of the MMPI-2 are available, including Spanish, Hmong, and French for Canada. Although the MMPI-2 is significantly longer than the SCL-90-R and other, similar measures, it was found to be much more useful in detecting

defensive responding in a sample of parents undergoing parenting capacity assessments (Carr et al., 2005). Based on the results of all of the measures evaluated in this study, the authors recommended that the MMPI-2 be used routinely in all assessments due to its rigorous validity scales. Furthermore, they note that self-report measures that do not have validity scales are of little use in this context (Carr et al., 2005). Although the pattern of defensive responding investigated in this study was based on clients undergoing parenting capacity assessments, it is consistent with our experience in assessing maltreating parents pre- and postintervention (Scott & Crooks, in press).

The Personality Assessment Inventory (PAI; Morey, 1991, 1996) is a 344-item measure that takes approximately 50–60 minutes to complete. It has 11 clinical scales, 5 treatment scales, and 2 interpersonal scales. In addition, the PAI has a number of validity scales, some of

which correspond in concept to scales on the MMPI-2. However, in the aforementioned study evaluating social desirability in parenting capacity assessments, the PAI was found to be more conservative than the MMPI-2 in detecting positive impression management, and likely missed a number of individuals who were not completely forthcoming in their responses (Carr et al., 2005). Furthermore, the style of defensive responding that was found to be pervasive among participants in this study had a profound impact on clinical scale elevations; thus, rather than being an independent issue, defensiveness has significant implications for identifying areas of challenge for the client.

In summary, there are a number of measures and approaches for assessing general personality functioning and psychopathology, and the three discussed in this section each have their strengths and weaknesses. The SCL-90-R is relatively brief and has shown some discriminant validity for use with abusive parents; however, defensive responding patterns for adults being assessed in the context of child abuse have not been studied. The MMPI-2 has undergone extensive research and has more sophisticated validity scales, which may be more successful in identifying overt and subtle defensiveness. On the negative side, the length of the MMPI-2 is daunting. The PAI is longer than the SCL-90-R but shorter than the MMPI-2. Although the PAI has validity scales, these did not detect positive impression management reliably in a child protection context. Given these various trade-offs, clinician must base their choices on time, resources, and concerns about detecting defensiveness.

Social Support and Life Stress

As noted, social support and life stressors may be assessed during the parent interview. Clinicians may wish to include some short, standardized measures, but if they are attempting to minimize the administration of paper-and-pencil tasks, these are not areas of priority. Standardized measures of social support and life stress are highly face valid and the information is quite easily obtained during an interview. One reason to include standardized measures in these domains is to assess the impact of treatment, if increasing social support is a specifically articulated intervention goal.

If a standardized measure of social support is preferred, two widely used options are the So-

cial Support Questionnaire (SSQ; Sarason, Levine, Basham, & Sarason, 1983) and the Perceived Social Support from Friends and Family scales (PSS; Procidano & Heller, 1983). The SSQ, a 27-item measure, has individuals rate both availability and satisfaction with social support from specific individuals in a particular scenario. There is also a 6-item brief version of the SSQ that correlates well with the original measure (Sarason, Sarason, Shearin, & Pierce, 1987). The PSS, a 20-item scale, differs from the SSQ in that it distinguishes between the sources of perceived social support (i.e., friends vs. family), on the grounds that these sources may serve different social support functions, with different consequences. One advantage of the PSS is that it is available in the widely used third edition of the handbook *Measures for Clinical Practice: A Sourcebook* (Corcoran & Fischer, 2000). As an interesting aside, Swedish and Turkish translations of the PSS scales have been reported in the research literature (see summary on METRIC website, retrieved April 18, 2006, from www.metric.research.med.va.gov/index.asp).

Stress may be measured by one of two general approaches, either by evaluating the perceived experience of stress or by looking more objectively at the number of stressors experienced. One widely used instrument that takes the former approach is the Perceived Stress Scale (Cohen, Kamarck, & Mermelstein, 1983; Cohen & Williamson, 1988). The Perceived Stress Scale is a measure of the degree to which situations in one's life are appraised as stressful. Items were designed to tap how unpredictable, uncontrollable, and overloaded respondents find their lives. There are three versions of the scale, with 4 items, 10 items, or 14 items, although the 10-item scale has the best reliability.

Life stressor indices typically ask participants to indicate which of a number of events have occurred within a particular time frame. The list includes major stressful life events that occur in people's lives, such as death of a loved one, loss of a job, being divorced, moving, and going to court. In general, the idea of life events instruments is that the negative impact of major life events increases with the number of events. No life event instrument is appropriate for all populations or generally accepted in the field. There are also questions about the sensitivity (appropriateness) of any of the standard life events instruments for lower socioeco-

conomic status (SES), or specific ethnic populations, in part because events are only counted if they are part of the scale, and these measures may not represent the breadth of negative experiences faced by a particular group. Strategies to measure parenting-related stress are discussed more specifically later in this chapter.

Intimate Relationships: Satisfaction, Conflict, and Violence

Marital conflict and satisfaction may be assessed through several methods, including interview, standardized instruments, and observation of interactions during conflict resolution tasks. For child abusive families (in which couples have not requested marital counseling and are often hesitant to discuss other issues), it may be useful to follow the previously discussed interview procedure with a brief satisfaction measure, such as the *Dyadic Adjustment Scale* (DAS; Spanier, 1976).

Violence between intimate partners should be assessed for a number of reasons. The presence of adult violence has implications for individuals' capacity to parent, role models to which children are being exposed, and is a general red flag for physical child abuse, given that the overlap between the two forms of violence is estimated to be in the range of 30–60% (Edleson, 1999). In some jurisdictions, exposure to domestic violence has been defined as a form of child maltreatment and/or risk that triggers a child protection response (see Box 14.2). The *Conflict Tactics Scales* measure (CTS—Straus, 1979, 1995; revised version [CTS2]—Straus, Hamby, Boney-McCoy, & Sugarman, 1996) was specifically designed to elicit information concerning conflict resolution tactics between adults and/or between parents and child(ren). The CTS is administered in an interview fashion, whereby each partner is asked to rate the frequency of occurrence (on a 7-point scale, ranging from *Never*, to *More than 20 times*) of tactics that he or she has used toward the partner in disputes over the past 12 months. These tactics include, for example, "Discussed the issue calmly," "Insulted or swore at the other one," "Threatened to hit or throw something at the other one," and "Kicked, bit, or hit with a fist." This instrument has been widely used in clinical and research studies to assess verbal and physical aggression in the family (see Archer [1999] for meta-analytic review on couples agreement of

aggression ratings). A shorter version has been developed; however, the authors note that the brief version may miss cases of violence and is best used as an initial screen (Straus et al., 1996). Regardless of the version of the CTS used, information obtained from this approach should be combined with other sources (e.g., interview, direct observation) to provide the best estimate of marital conflict resolution tactics (Jouriles & O'Leary, 1985; for additional procedures for assessing marital violence, see Jacobson, Gottman, Waltz, & Rushe, 1994).

Although there are many measures of general marital satisfaction, the Parenting Alliance Measure (PAM; Abidin & Konold, 1999) is unique in its evaluation of the parenting aspects of a couple's relationship. Parents' perceptions of their own cooperativeness, communicativeness, and respectfulness with regard to caring for their children are assessed. The PAM is appropriate for a variety of parenting partners and living situations.

Use of Collateral Information

Parent interviews, self-reports, and testing should be augmented with collateral information where possible. For example, child protection services, physician, police, and other service provider information help to provide a more comprehensive picture. If the assessment has a particularly forensic focus (e.g., a parenting capacity assessment), careful documentation of collateral information becomes even more critical.

Collateral information is important in two ways. The first and more obvious benefit is the additional information, which may highlight difficulties that parents did not mention or help to resolve a difference in reported versions of a particular event (e.g., when a police report of a domestic violence call clarifies parents' contradictory accounts of the events). A second way that collateral information may be useful is to review it with the parents and provide them with the opportunity to clarify or help the clinician understand the reports. This review is important, because written records sometimes contain incorrect information. Beyond the factual verification, it is informative to assess parents' understanding and/or responsibility taking for previous events. For example, reviewing police records that relay multiple charges of drinking and driving provides clinicians with an opportunity to assess whether a parent un-

BOX 14.2. Legal Issue: Should Exposure to Domestic Violence be Considered a Form of Legal Child Abuse?

Over the past 20 years, concern about children exposed to domestic violence (DV) has grown rapidly, as a result of an emerging awareness that these children may experience difficulties similar to those of children who are directly abused. In response, legislators and policymakers have attempted to develop laws and protocols to protect these children (Jaffe, Crooks, & Wolfe, 2003). In some jurisdictions, exposing children to DV has been defined as a form of criminal child abuse, whereas in others, it may be considered abuse if there is direct, observable harm to the children. In yet other states, none of these laws has been implemented. These legal changes have been the subject of significant debate.

Proponents of defining exposure to DV as child abuse identify benefits such as sending a clear message to perpetrators about the unacceptability of the behavior, recognizing children exposed as a vulnerable group, and providing a mechanism for accessing and offering service to children who need it. In addition, given the significant overlap between DV and physical child abuse, the presence of DV may warrant further inspection of other risks children may be facing.

At the same time, there are a number of potential problems with identifying exposure to DV as a form of child abuse. First, although children exposed to DV have more problems in general, there is considerable variability in adjustment, and many exposed children do not experience these difficulties (Wolfe, Crooks, Lee, McIntyre-Smith, & Jaffe, 2003). Second, women's advocates have noted that although these legal changes are intended to help hold perpetrators of violence more accountable, the result may be revictimization of an abused mother, who in extreme cases can be charged with failure to protect. Third, in cases where there needs to be a demonstrated link between exposure to DV and the harm experienced by children, assessments methods have lagged behind these policy changes. The concept of a demonstrated link seems to make sense, but the practicality of assessing the *cause* of particular child difficulties is a challenge, especially in multiproblem families in which partner violence may be one of a multitude of risk factors. Finally, promoting legal changes as a way to identify and provide service to more children is flawed logic, in that these services typically are not available. The end result in such cases may be more children being identified (and possibly drawn into the child protection system) but not receiving any further service (Edleson, Gassman-Pines, & Hill, 2006).

The growing consensus among experts in the field is that the best practice in such cases is a *differentiated response*, which means saving the most intensive supports and resources for the families who need it. Broad-based laws identifying all exposure to domestic violence as a form of child abuse are not consistent with a differentiated response.

Implications for Assessment

As the framework for differentiated response emerges, there will be an increasing need for assessors to help guide the process of a system that can respond appropriately to different levels of severity. Research in the area of assessing the specific impact of children's exposure to domestic violence is greatly needed.

understands the severity of the behavior, takes responsibility (vs. explaining it away on external factors), and has developed a plan to avoid future similar difficulties.

At the end of the adult portion of the assessment, the evaluator should have an overall view of the parents' strengths and challenges as individuals and in relation to their parenting roles. This view will have emerged within the context of a historical understanding of parents' families of origin, as well as their relationship with each other. Significant psychological difficulties should be clear, as well as resources

and coping styles that the individuals use to mitigate the impact of these difficulties.

STEP 2: ASSESSING CHILDREN

Children may be assessed as part of a larger strategy to determine a family's overall intervention needs. In these cases they are one component of an assessment addressing the strengths and needs of the larger family system. They may also be assessed with a very narrow focus to answer a specific question about the

children's intervention needs. The following three examples demonstrate this more focused, narrow type of child abuse assessment.

Brenda, an 8-year-old, was removed from her mother's care following substantiated allegations of child abuse. In foster care, she has continued to demonstrate significant trauma symptoms such as nightmares, bedwetting, and hypervigilance. Despite these difficulties, Brenda is adamant about wanting to move back home. Her mother has completed a parenting program and is also requesting reunification. An assessment has been requested to explore the possible impact on Brenda of being reunited with her mother and to identify necessary supports for this family.

Juan, a 17-year-old with a long history of chronic abuse, neglect, and disrupted living arrangements, has been seeing an individual therapist for the past year to help him with anger and stress management, as well as interpersonal functioning. His therapist has become concerned about symptoms that might be consistent with early psychotic processes. She has referred him for an assessment to determine whether his symptoms of alienation, paranoia, and hostility are indicative of emerging psychosis or more likely sequelae of his long-standing abuse and losses.

Gina, a 6-year-old currently in inpatient care at a hospital following breakdown of her foster placement and several group home placements, has a documented history of abuse, and recent computed tomographic (CT) scans show some anomalies in her brain structure. The possibility of a seizure disorder has been raised in the past but is not well documented. She is observed by the hospital staff to have tantrums that seem to appear out of nowhere and are noteworthy for their magnitude and intensity. The referring psychiatrist is wondering whether the tantrums and observed emotional dysregulation could be related to a seizure disorder, or whether they are better understood as a result of psychosocial stressors and abuse.

Some assessment components would be common for all of these referral questions, such as administering standardized measures that compare the child's behavior to others of his or her age, obtaining a history of school and academic functioning, and identifying possible strengths or protective factors through interview and/or questionnaires. Other components would vary depending on the age of the child

and the specific referral question. For Brenda, assessment strategies that measure the range and severity of PTSD symptoms would be important. In the example of Juan, measuring his reality testing would be indicated. In addition, understanding the nature of his paranoid thoughts would be important. Due to the concerns about possible neurological impairment, a more thorough assessment of memory and learning would be indicated for Gina than for Juan or Brenda. There is always a trade-off between a broad assessment strategy that addresses the widest range of functioning and a more efficient, focused strategy that addresses the specific needs of any one child in greater depth.

In formulating an assessment strategy for an individual child, the clinician must be concerned about achieving some balance among child self-report (both interview and questionnaires), report by parents (especially if he or she is suspected of maltreatment), and observation of the child with peers and/or caregivers. The assessment usually begins with reports from significant sources in the child's life (including the referral source), because generally speaking such information from these sources (i.e., teachers, parents, social workers) provides a global understanding of the child that is then useful for narrowing down the choices for additional self-report, interview, or observational procedures. Following a clinical interview, self-report and observational methods yield considerable information concerning the child's strengths and deficits, especially in terms of his or her views of self and others (social cognition), and feeling states (socioemotional development).

Interview

An individual interview with the preschooler or school-age child can assist the practitioner in understanding the child's overall functioning and provide insight as to current fears or anxiety that might be quite debilitating. The possibility that the older child (age 6 or older) has developed a distorted perspective of family life in which violence is commonplace or acceptable should be investigated by discussing his or her attitudes about interpersonal aggression, sex roles, and responsibility for aggressive behavior. For example, when asked, children who have witnessed violence toward their mothers state that men should not hit women, but more

subtle questioning may reveal that these children believe violence is permissible in certain situations (e.g., if a parent has been drinking, if the wife does not do what her husband says). The child may also respond to the examiner in a very guarded manner that is not a valid reflection of his or her typical behavior, out of possible fear of reprisal or confusion over the events that have occurred. For this reason the examiner should prioritize developing a rapport with the child and establishing a sense of trust and comfort prior to discussing his or her family's problems. Seeing the child on more than one occasion might be more important in these cases than in some other assessment situations.

Due to the sensitive (and possibly litigious) nature of the material being discussed, it is imperative that clinicians have a good sense of developmentally appropriate interviewing. A highly readable book to assist both novice and experienced clinicians is *What Children Can Tell Us: Eliciting, Interpreting, and Evaluating Critical Information from Children* (Garbarino & Stott, 1989). If a practitioner seeks to become specialized in forensic interviewing, additional training and ongoing professional development are highly advisable.

A good beginning point is to use a semi-structured interview format in discussing the child's comprehension and reaction to family problems. The interview begins with a general discussion of activities and events that the child enjoys, which leads to a more specific discussion of recent crisis events. The child's "crisis adjustment" is assessed in reference to (1) his or her feelings about changes in the family (e.g., foster care, parental separation) and (2) discussion of major life events (e.g., aided by the Life Events Checklist for Children; Johnson & McCutcheon, 1980). Safety skills (e.g., "What do you do if your mom and dad are arguing?"; "How can you tell when your mom or dad is angry?"; "Who do you call in an emergency?") are also important areas to consider during the child interview. The child's comprehension of personal safety and knowledge of appropriate actions to take provides useful information in planning for the immediate needs of the child (i.e., out-of-home placement, alternative actions to avoid high-conflict situations).

The clinician can then turn the discussion to the child's attitudes and responses to interpersonal conflict and expression of anger, by en-

couraging the child to discuss events, for example that "make you really mad," followed by identification of his or her actions, feelings, and attitudes about such "anger situations." We find it useful to describe attitudes and reactions to anger provocation in reference to favorite television characters, to determine the child's ability to recognize the inappropriateness of aggressive behavior. For example, some abused children reveal the influence of aggressive modeling in the family or on TV through their inability to recognize nonviolent means for resolving interpersonal conflicts. Although this impaired social problem solving is by no means unique to abused children, the presence of such rigid adherence to coercive problem solving signals a need for exposure to alternative strategies.

Standardized Assessment of Behavioral, Cognitive, and Emotional Development

Assessments of children need to be abuse-informed but not abuse-specific (Saunders et al., 2003). The task of assessing all potentially relevant dimensions of child psychopathology can become unmanageable unless a systematic, problem-solving approach is used. As noted in the first part of this chapter, child abuse is a non-specific risk factor and can lead to impaired functioning in virtually every domain of children's adjustment. Rather than attempting to address all possible outcomes, we identify strategies for assessing major domains of functioning that may be impaired by experiencing child maltreatment and more narrow, abusive-specific concerns. When widely used measures have been researched with a child maltreatment population, implications for the measure's use are discussed. Self- and other-report measures and standardized procedures are discussed in the following section under the major headings of social and behavioral functioning, cognitive and social-cognitive development, and emotional and moral development. There may be areas outside of these that have been influenced by inadequate or abusive parenting (e.g., academic performance). If there were concerns of this nature in a particular case, a standard psychoeducational assessment would be performed.

Social and Behavioral Functioning

The child's primary caregiver, usually the parent, is a critical source of information concern-

ing the child's development and behavior. Parental report of child behavior is a useful starting point for assessment and intervention planning, because it permits the clinician to obtain a broad spectrum of information as to the parent's perception of problem areas in the child. The Child Behavior Checklist (CBCL; Achenbach, 1991) is the most widely used measure of child social, emotional, and behavioral functioning. The CBCL requires only a sixth-grade reading level, takes about 20 minutes to complete, and the results can be easily discussed with the respondent to clarify the nature and specific circumstances surrounding his or her report of child behavior problems.

Although the CBCL has excellent general psychometric properties and has been used extensively in research, in a recent study of participants undergoing parenting capacity assessments, parents' general tendency to respond in socially desirable ways extended to their ratings of their children (Carr et al., 2005). In other words, in this particular study, parents undergoing parenting capacity assessments (i.e., parents who had perpetrated abuse or neglect, or were considered high risk for perpetrating) *underreported* their children's problems compared to the reports of teachers and foster parents. This finding is somewhat surprising in that general clinical wisdom is that abusive parents tend to *overreport* child misbehavior, in part because of their attributions of having less power over their children. These concerns notwithstanding, the CBCL is an efficient way to gather information on a range of behaviors. Furthermore, the availability of a Teacher Report Form and a Youth Self Report (YSR; for children age 12 and older) create the ability to look at differences in perception among informants. As of February 2006, versions of the CBCL had been translated into 74 languages (retrieved April 20, 2006, from www.aseba.org/ordering/translations.html).

An alternative system for assessing child and adolescent functioning, the Behavior Assessment System for Children, Second edition (BASC-2; Reynolds & Kamphaus, 2004), comprises a set of rating scales and forms, including Teacher Rating Scales, Parent Rating Scales, Self-Report of Personality, Student Observation System, and Structured Developmental History. Taken together, these forms provide a comprehensive overview of children and adolescents' emotional and behavioral functioning. The Self-Report of Personality form can be

used with both college-age students and younger adolescents. Similar to the CBCL and related forms, the BASC-2 includes a wide range of internalizing and externalizing scales, as well as other learning-related dimensions. Compared to the earlier version of the tool, the BASC-2 has several new scales, new norms, and the addition of content scales, including Anger Control, Bullying, Emotional Self-Control, Executive Functioning, Resiliency, Ego Strength, and Test Anxiety (although not all content scales are applicable for all age ranges). One of the advantages of the BASC-2 over alternative assessment measures is the inclusion of three validity indices, which are not found in the CBCL measures, that help clinicians assess the quality of the information received from each informant (i.e., adolescent, parent, and teacher).

The Eyberg Child Behavior Inventory (ECBI; Eyberg & Pincus, 1999) provides a shorter measure of child behavior (compared to the CBCL) by focusing on more common behavior problems. It comprises 36 items and is appropriate for children ages 2–16 years. Caregiver respondents rate the frequency of a particular behavior along a 7-point scale and indicate whether the behavior is considered a problem with a dichotomous rating. The ECBI generates both an intensity score and a problem score from these ratings. The reliability and validity are well established, and the ECBI has been widely used in research. The trade-off between the ECBI and the CBCL or BASC-2 is that the ECBI takes less time to complete, but the latter two provide more detailed information about the *nature* of the behavior problem and are more likely to detect unusual behaviors.

More recently, the Social Behavior Inventory (SBI; Gully, 2001) was developed specifically as a measure of children's interpersonal behavior in a child abuse population. In comparison to more general measures of children's interpersonal functioning, the SBI was designed to measure five dimensions of social behavior that are especially pertinent for children who have been maltreated—Aversive–Miscommunication, Aversive–Insensitive, Aversive–Argumentative, Prosocial–Genuine, and Prosocial–Direct. Furthermore, it was developed to be quick (30 items) and sensitive enough to monitor progress in therapy. Although there is some preliminary evidence for the reliability and validity of this measure, more research is needed.

The Brief Symptom Inventory (BSI; Derogatis, 1993), mentioned in the assessing parents section of this chapter, is also suitable for use with adolescents. As noted, it has Hostility (e.g., “Feeling easily annoyed or irritated”) and Interpersonal Sensitivity (e.g., “Feeling that people are unfriendly or dislike you”) scales, which may be particularly useful in capturing the perceived experience of maltreated adolescents and identifying interpersonal difficulties. Other scales include Somatization, Obsessive-Compulsive, Depression, Anxiety, Phobic Anxiety, Paranoid Ideation, and Psychoticism, and as such, the measure covers a broad spectrum of psychological difficulties. At 53 items, it is much shorter than the YSR and may create less testing fatigue. Finally, there are specific adolescent norms to which scores may be compared.

In addition to these general measures of internalizing and externalizing symptoms, and interpersonal functioning, there is a need for

abuse-specific measures in an assessment, especially concerning trauma symptoms and sexual behavior problems. Table 14.3 highlights several measures designed specifically to assess abuse-related difficulties in functioning. A well-established tool for measuring trauma symptoms, the Trauma Symptom Checklist for Children (TSCC; Briere, 1996), was designed to measure the impact of child abuse (sexual, physical, and psychological) and neglect, other interpersonal violence, witnessing trauma to others, major accidents, and disasters. In addition to measuring posttraumatic stress, it evaluates other symptom clusters evident in traumatized children. Its 54 items load onto six clinical scales (Anxiety, Depression, Posttraumatic Stress, Sexual Concerns, Dissociation, and Anger). In addition there are two validity scales (Underresponse and Hyperresponse). TSCC items are explicitly written at a level thought to be understood by children age 8 years or older. The TSCC requires approxi-

TABLE 14.3. Measures of Abuse-Related Child Functioning

Measure	Purpose/scales	No. of items	Informants/versions	Comments
Social Behavior Inventory	5 scales: aversive-miscommunication, aversive-insensitive, aversive-argumentative, prosocial-genuine, prosocial-direct	30	Self-report	Developed to measure social functioning in children and adolescents who have been abused. Psychometrics are preliminary at this point.
Trauma Symptom Checklists	6 clinical scales (anxiety, depression, posttraumatic stress, sexual concerns, dissociation, and anger) 2 validity scales	44–90 depending on version	Self-report version for ages 8–16 years Alternate version without sexual content Caregiver report version for children as young as 3 (and up to 12) years	Has good validity scales and strong psychometric properties.
Sexual Behavior Inventories (Child and Adolescent Clinical versions)	Measures normative and non-normative sexual behavior in 9 content areas (boundary issues, sexual interest, exhibitionism, sexual intrusiveness, gender role behavior, sexual knowledge, self-stimulation, voyeuristic behavior, sexual anxiety) Adolescent version also measures sexual risk taking, nonconforming sexual behaviors, sexual interest, and sexual avoidance	38 in Child version 45 in Adolescent version	Caregiver report for children Adolescent version has self-report and caregiver report forms	Only standardized measure of children’s sexual behavior. Has strong psychometric properties and considerable use in research.

mately 10–20 minutes to complete for all but the most traumatized or clinically impaired children, and can be scored and profiled in approximately 10 minutes. A 44-item Alternate version of the TSCC (the TSCC-A) that does not contain Sexual Concerns items is for use in circumstances where sexual item content must be avoided. The TSCC (and TSCC-A) have been demonstrated to have strong reliability and validity. Particular strengths include the validity scales (especially for identifying underreporting), large samples used to generate norms, and norms that are specific to different age ranges.

More recently, a version has been developed that is completed by a caregiver and can be used for children as young as age 3 (and as old as age 12). The Trauma Symptom Checklist for Young Children (TSCYC; Briere et al., 2001) is a 90-item instrument that contains two caregiver validity scales in addition to clinical scales similar to the TSCC. In a multisite sample of 219 traumatized children (Briere et al., 2001), the TSCYC clinical scales had good reliability (alpha values for the clinical scales ranged from .81 to .93) and were predictive of exposure to childhood sexual abuse, physical abuse, and witnessing domestic violence. In addition to tapping posttraumatic difficulties, the TSCC appears to be sensitive to the effects of therapy for abused children (Lanktree & Briere, 1995). The TSCC has been translated into several languages to study the effects of trauma in other cultures.

Another cluster of symptoms that deserves special attention among maltreated children is sexual behavior problems. Although a history of sexual abuse (see Wolfe, Chapter 15, this volume, for a discussion of the assessment of children who have been sexually abused) has been posited as a major predictor of sexualized behavior, empirical evidence suggests a much more complex picture. Indeed, in a study involving more than 2,300 children ages 2–12 years, sexual abuse was not found to be the predominant predictor of sexual acting out. A multidimensional model that incorporated family adversity, modeling of coercive behavior, exposure to sexuality, and child emotional and behavioral factors provided much better prediction of sexual behavior problems than did a history of sexual abuse alone (Friedrich, Davies, Feher, & Wright, 2003). Thus, sexualized behavior problems can be part of a clinical pattern for children from disorganized and vio-

lent families, even in the absence of sexual abuse. It is important to inquire explicitly about sexual behavior problems, because children and parents may not spontaneously disclose them due to embarrassment and the highly private nature of the behavior. The Child Sexual Behavior Inventory (CSBI; Friedrich, 1997), the only standardized measure available, has been used extensively in research. The CSBI is a parent- or caregiver-administered checklist that assesses the presence of a wide range of normative and non-normative sexual behaviors in nine content areas (e.g., Intrusiveness, Gender Role Behavior, Sexual Anxiety). More recently, the Adolescent Clinical Sexual Behavior Inventory (ACSBI; Friedrich, Lysne, Sim, & Shamos, 2004) was developed to measure sexual risk taking, nonconforming sexual behaviors, sexual interest, and sexual avoidance in clinical samples. The ACSBI has both adolescent and parent report forms, and preliminary research has indicated good psychometric properties.

Although most of the measures discussed to this point emphasize deficits in functioning (with some subscales that measure prosocial functioning), it is also important to evaluate the children's or adolescents' strengths and the resources available to them. A number of measures have recently been developed to measure youth assets. These measures vary in length but tend to share certain similarities, such as being very face valid. The Youth Asset Survey (YAS; Oman et al., 2002), for example, is a 54-item measure that provides scores on eight subscales of assets: Family Communication, Peer Role Models, Future Aspirations, Responsible Choices, Community Involvement, Non-Parental Role Models, Constructive Use of Time—Groups/Sports, and Constructive Use of Time—Religious Time. The use of a measure such as the YAS provides a systematic means to assess protective factors and possible resources upon which to build intervention plans. Including a measure such as the YAS balances out the negative focus of some of the other checklists and allows youth to identify and share some of the areas of life about which they may feel more positive.

Cognitive and Social-Cognitive Development

Research with both child and adult victims of violence points to the importance of the victim's assessment of the conflict, because individual attribution may in turn influence the vic-

tim's emotional reaction. For example, the child who attributes physical maltreatment to his or her parent's mean character would be expected to fare worse than the child who sees the same behavior as caused by external circumstances (e.g., job stress). Moreover, as the severity of the maltreatment increases, attributions of blame to the perpetrator increase (Wolfe & McGee, 1991). If attributions of blame (either to self or to the perpetrator) result from the maltreatment, then emotional reactions of sadness or anger are more likely to result. Children's attributions may be measured by self-report with the Children's Attribution Style Questionnaire—Revised (CASQ-R), which is available in a 48-item version or a briefer, 24-item format (Kaslow, & Nolen-Hoeksema, 1991; Thompson, Kaslow, Weiss, Nolen-Hoeksema, 1998). The CASQ-R measures the extent to which children attribute negative events to internal, global, and stable causes (e.g., "I failed the test because I am dumb") versus external, specific, and unstable causes (e.g., "I failed the test because I stayed up late and watched TV instead of studying"). Although the CASQ-R was not specifically designed to measure attribution in abused children, its use has identified attributional style as a mediator between parental child abuse risk and children's internalizing symptoms (Rodríguez, 2006).

A more abuse-specific attributional assessment may be done with the Attribution for Maltreatment Interview (AFMI; McGee, 1990), which comprises four structured interviews, corresponding to hostile maltreatment (i.e., physical and emotional abuse), exposure to family violence, sexual abuse, and neglect (respondents only complete those interviews that pertain to their experiences). After generating a list of all possible causes for their maltreatment, they are asked to make agreement ratings (from 1, *Do not agree* to 4, *Strongly agree*) in relation to 26 statements read aloud by the interviewer. For each of the maltreatment types, the AFMI yields five subscales (derived from theory and factor analysis): Self-Blaming Cognition, Self-Blaming Affect, Self-Excusing, Perpetrator Blame, and Perpetrator Excusing. In a study involving 160 maltreated youth, Wolfe and McGee (1994) found that the majority viewed the offender as the major cause for their maltreatment; however, for physical and emotional abuse, one-third of the sample identified their own behavior as the ma-

major cause for what happened. Further research in this area has indicated that attributions about maltreatment contribute uniquely to adolescent adjustment, even after accounting for maltreatment severity (McGee, Wolfe, & Olson, 2001). In the latter study, adolescents rarely saw themselves as causing the maltreatment, but they did exhibit more nuanced self-blame cognitions (such as self-recrimination for not doing anything to *prevent* the abuse). These findings underscore the importance of assessing the youth's attributions for maltreatment, both for targeting self-blame statements and the underlying beliefs that he or she could have prevented such acts and was therefore somewhat at fault.

An alternative procedure, the Home Interview with Children (Conduct Problems Prevention Research Group, 1991), provides an assessment of the degree to which children attribute hostile intent to hypothetical peer behavior and the extent to which it manifests in their problem-solving ability. The measure comprises eight vignettes accompanied by pictures that depict problematic peer interactions in which the peer's intentions are ambiguous. Four problems relate to exclusion by peers and four relate to a physical conflict. Participants are asked to imagine that they are the protagonist child in each situation, and to tell why the antagonist child in each vignette behaved as he or she did. Responses are coded as either hostile (e.g., "He was being mean") or benign (e.g., "It was an accident"). The child is also asked what he or she would do in response to the other child's behavior, and these responses are coded as either aggressive (e.g., hitting the other child), assertive (e.g., asking the other child to fix the problem), passive (e.g., walking away), solution-focused (e.g., cleaning up the mess), or seeking information (e.g., asking the other child why he or she did that). As with the AFMI, the Home Interview with Children is likely more useful as a research tool at this point, and less practical as a clinical measure. Alternatively, the procedure might be a useful interview aid when a child is reluctant to share personal information, and it can be used to branch into discussing peer conflicts and problem solving in the child's life. Thus, attribution can be measured more generally with an easily available, quick self-report measure (i.e., the CASQ-R) or with a more involved interview procedure that requires additional experience to administer and code.

Emotional and Moral Development

Children's emotional functioning, particularly with respect to self-perception, can be profoundly shaped by experiences of maltreatment and neglect. In particular, negative perceptions of individual competence across a wide range of domains may result. Rather than measuring global self-esteem, a multidimensional measure of self-perception may be more informative and help to identify any relative strengths experienced by the child. Some of the most widely used instruments for assessing perceived self-competence are the Harter scales (Self-Perception Profile for Children [SPPC; Harter, 1982] and Self-Perception Profile for Adolescents [SPPA; Harter, 1988]). There are numerous domains, and the clinician or researcher can pick and choose the domain(s) of interest. For example, the SPPA contains eight domains of perceived competence (i.e., Scholastic Competence, Athletic Competence, Social Acceptance, Close Friendship, Romantic Appeal, Physical Appearance, Behavioral Conduct, and Job Competence), as well as a Global Self-Worth subscale. The format of both versions is similar, in that individuals are presented with two options that define opposite ends of a spectrum and asked to decide which end is more like them, for example, "Some teenagers do very well at their classwork, or other teenagers don't do very well at their classwork." After choosing which "self" is more like them, they are asked to indicate whether this is *Sort of true for me* or *Really true for me*. This structured alternative format was used specifically to decrease socially desirable responding. One of the advantages of a multidomain self-perception scale is that it allows clinicians to identify potential strengths and weaknesses to assist in treatment planning. For example, knowing that an adolescent who had been abused has high perceived competence in the area of athletics, but low perceived competence in peer and romantic relationships, would allow a therapist to build on strengths, and use the adolescent's skill and confidence in a particular area to scaffold new skills in weaker areas.

The Harter scales have several attractive feature related to their development, availability, and applicability, including the fact they have been widely used in research for more than 20 years. These scales are available for a nominal cost from the developer and involve a one-time purchase of a manual that allows for photo-

copying of actual items, making them very accessible both to researchers and clinicians. There have also been some promising cross-cultural studies and language translations with the Harter scales, specifically the SPPC (e.g., with African American and biracial children [Schumann et al., 1999], with Spanish-speaking children [Pereda & Forns, 2004], with Dutch schoolchildren [Muris, Meesters, & Fijen, 2003], with Mexican American schoolchildren [Hess & Petersen, 1996], and with samples from three Chinese cultures [Wang, Meredith, & Tsai, 1996]). Although there have been relatively fewer studies on cultural adaptation with the SPPA (compared to the SPPC), there are some promising studies, including published psychometrics for a sample of early-adolescent African American youth (Thomson & Zand, 2002), with French Canadian adolescents (Bouffard et al., 2002), and with a rural Mexican American sample (Dimmitt, 1996). Other ongoing initiatives include validating the measure with Native American youth, for whom the format has been changed to accommodate cultural taboos about referencing the self compared to others. The combination of cross-cultural studies with both the SPPC and SPPA indicate that perceived self-competence may have both different norms and different domains (i.e., factor structure) for different cultural groups, and highlights the importance of these measures being adapted for and normed with nonwhite populations.

Whereas the Harter scales measure a wide range of perceived self-competence, other measures have a more narrow focus. The *Adolescent Interpersonal Competence Questionnaire* (AICQ; Buhrmester, 1990), a 32-item measure, assesses domains of competence that are important in adolescent close relationships: Self-Disclosure, Providing Emotional Support to Friends, Management of Conflicts, and Negative Assertion. This measure can also be completed by another respondent, such as a dating partner, parent, and so on, who knows the person well. The respondent rates his or her own competence on a 5-point scale (1, *Poor at this; would be so uncomfortable and unable to handle this situation that it would be avoided if possible*, to 5, *Extremely good at this; would feel very comfortable and could handle this situation very well*). Reliability for the factor scores has been high, and the scales correlate with adjustment and friendship intimacy measures (Buhrmester, 1990). The AICQ does not

cover as wide a range of competencies as the SPPA; however, it covers relationship-related competence in more detail, which may be more pertinent to difficulties faced by maltreated adolescents.

Moral reasoning and development subsequent to a history of maltreatment often reflect poor self-regulation and aggressive themes (e.g., Smetana, Kelly, & Twentyman, 1984). Although difficult to measure in a standardized way, innovative procedures that prompt the child's thinking process merit recognition. One prominent example was reported by Buchsbaum, Toth, Clyman, Cicchetti, and Emde (1992) in which a play narrative "stem technique" was used to elicit a child's internal representations of relationships and emotion regulation. The interviewer begins with a story (the "stem") using doll play, and the child is asked to complete it. In addition to recording verbal and behavioral responses, standard probes are used to challenge the child to resolve the dilemma posed by the stem and to pursue the reasons he or she chose to complete the story a particular way. The stories were developed to elicit certain themes of moral reasoning: for example, empathic or prosocial responses; ways to adhere to a rule in the face of temptation; maternal responses to stealing; parental responses to a transgression in which the transgression results in potential harm to the child; and conflict between members of the family/parents. In their study involving a sample of over 100 maltreated preschool-age children and a matched comparison sample, Buchsbaum and colleagues found that the narratives of the maltreated children tended to have more themes involving inappropriate aggression, neglect, and sexualized behavior. Their self-statements also reflected their views of themselves as "bad," and contained more punitive and abusive language. This standard form of administration of story stems serves to avoid the problem of leading questions that often plague interviews with maltreated children, and offers considerable promise for assessing the younger child's belief system and moral reasoning. Clearly, widespread adoption of standardized measures that require this level of training in administration and coding remains a challenge.

What should emerge from an assessment of the children's current adaptive abilities and cognitive and emotional development is an understanding of their resources for coping with

the level of family problems that may exist, as well as their current attitudes, beliefs, and emotional and behavioral expression vis-à-vis their role in their families. Children who have been removed from the home (or who have had their parents separate or leave the home), as well as older children who have experienced prolonged family conflict and abuse, often display the more extreme signs of adjustment difficulties (e.g., aggression, withdrawal, peer problems, anger at family members). This finding presumably reflects the relationship between child behavior and critical situational variables that must be considered throughout the interpretation of the child's needs. Information provided by the parent, child, caseworker, and through interview procedures should be integrated in a fashion that permits a comparison of how the *parent* views the child and how the child views his or her own situation, behavior, and affect that follow from the assessment procedures described herein. Furthermore, objective information on the child's cognitive development and behavioral adjustment, obtained through observational or normative assessment devices, can provide a framework for establishing treatment priorities that are consistent with the child's abilities and needs.

STEP 3: ASSESSING PARENT-CHILD RELATIONSHIP AND ABUSE-NEGLECT DYNAMICS

Assessing the parent-child relationship, particularly with respect to abuse and neglect dynamics, is perhaps the most challenging part of child abuse assessments. Due to the private and shameful nature of abuse and neglect, assessing related dynamics may be more realistic than assessing the actual maltreatment (although parents are clearly questioned specifically about abuse as well). Furthermore, developing an understanding of the underlying dynamics of abuse in a family provides important direction for changing parent behavior. Domains of interest in this area include abuse risk, neglect, parents' view of their children, and empathy. Table 14.4 highlights some of the measures most related to directly assessing child abuse and neglect in the parent-child relationship.

For practitioners seeking a semistructured interview guide, the Child Abuse and Neglect Interview Schedule—Revised (CANIS-R; Ammerman, Van Hasselt, & Hersen, 1993) assesses the presence of maltreatment behaviors

TABLE 14.4. Measuring Risk for, or Presence of, Abuse and Neglect in the Parent–Child Relationship

Measure	Purpose/description	Format	Comments
Child Abuse and Neglect Interview Schedule—Revised	Assesses presence of maltreatment behaviors and factors related to abuse and neglect. Four sections include: <ul style="list-style-type: none"> • Child behavior problems and disciplinary practices • Parental past and current history of family violence • Child’s exposure to violence, psychological abuse, and neglect • Sexual abuse (both the child’s and parent’s experiences) 	Semistructured interview with parent	Unpublished interview (available from author). Requires skilled administration.
Child Abuse Potential Inventory	Designed to measure areas related to increased likelihood of abuse; 160 items result in six subscales: <ul style="list-style-type: none"> • Distress • Rigidity • Unhappiness • Problems with child and self • Problems with family • Problems with others Has validity scales	Parent self-report	Brief version available. Has validity scales, but concerns have been raised about the validity of the measure for certain purposes. Rigidity scale may be most resistant to defensive responding. Used widely in research.
Adult–Adolescent Parenting Index—Second Edition	Designed to measure dimensions pertinent to child abuse risk patterns: <ul style="list-style-type: none"> • Inappropriate expectations of children • Lack of empathy towards the needs of children • Strong belief in the use of corporal punishment, • Reversing parent–child family roles • Oppressing children’s power and independence 	Parent self-report	Good scales in theory, but lack of validity scales makes the use of the measure questionable in abuse assessments.
Children’s Experiences of Victimization Questionnaire	Measures experiences of: <ul style="list-style-type: none"> • Child physical abuse • Child sexual abuse • Witnessing domestic violence • Physical punishment • Peer-on-peer violence 	Youth self-report	Covers a broad range of victimization experiences. Developed for research, not clinical use.

Mother–Child Neglect Scale	Measures mother-reported neglectful behavior toward children	Parent self-report	Developed based on interview format as part of a large research project. Developers caution against clinical use until more research is conducted.
Multidimensional Neglectful Behavioral Scale—Child Report	Measures four broad domains of neglect including: <ul style="list-style-type: none"> • Cognitive • Emotional • Physical • Supervisory Additional scales assess exposure to violence, alcohol-related neglect, abandonment, and children’s appraisals of parenting	Child self-report Computer-assisted technology	First standardized measure of neglect for children to complete. Computer-assisted technology is a strength of the measure but also makes it expensive to obtain.
Parental Empathy Measure	Measures several components of parental empathy: <ul style="list-style-type: none"> • Attention to signals • Attributions • Behavior • Emotion • Overall empathy Also contains a “faking good” validity scale	Semistructured interview with parent	Promising preliminary psychometrics, but needs more research.
Parenting Stress Index	Measures parental stress related to: <ul style="list-style-type: none"> • The child domain (related to children’s adaptability, acceptability, demandingness, mood, distractibility, and responsibility to parent) • The parent domain (i.e., stress related to depression, role restriction, sense of parental competence, social isolation, health, and relationship with spouse) • The parent–child domain An optional 19-item Life Events Stress scale is contained within the PSI. Also provides a total stress score.	Parental self-report Standard version, short-form version, and version for parents of adolescents	Has a validity index. Useful to see how parents explain source of their stress.

(e.g., corporal punishment, physical abuse), as well as factors related to abuse and neglect (e.g., parental history of maltreatment). The CANIS-R comprises over 100 questions and takes approximately 45 minutes to administer. The four sections include child behavior problems and disciplinary practices; parental past and current history of family violence; child exposure to violence, psychological abuse and neglect; and sexual abuse (both child and parental experiences). The CANIS-R is a semi-structured interview rather than a set of questions to be read verbatim; as such, the training and skill of the interviewer is an important component in administration.

Standardized Self-Report Measures and Administered Procedures

Self-report measures are used routinely with parents and children to assess components of parent-child interactions and/or child abuse risk. Although standardized measures have many attractive features, it is critical to be aware of whether a particular measure was developed for the express purpose of assessing child maltreatment. Use of measures that were developed for other purposes and normed on other groups must be undertaken with caution (Budd, 2001). Even instruments developed to measure parent-child problems are not necessarily specific to measurement of attributes of parents at risk for maltreatment (Budd & Holdsworth, 1996). Furthermore, many of the measures have been developed and used predominantly for research. In some cases, these measures may detect between-group differences well (i.e., distinguish between groups of abusive and nonabusive parents). However, between-group differences may mask important within-group differences, and concepts such as sensitivity and specificity, or clinical cutoffs (established with valid criteria) may be more important than deviation from a population mean.

Unfortunately, many of these self-report measures are used routinely, without an appreciation of the complexity of the issues. Furthermore, strong general psychometrics and the ability to differentiate among groups are important starting points for a measure, but there are additional considerations. Issues such as feasibility, sensitivity of the measure to treatment effects, and predictive validity are also important considerations. We include these

considerations in relation to the measures as they are discussed. Most of the measures that consider parent-child relationships vis-à-vis abuse risk are administered to parents, although there are also a few child-report options.

Risk for Abuse—Presence of Abuse

Attempts to develop a direct measure of child abuse dynamics in the parent-child relationship have met with limited success. The Child Abuse Potential Inventory (CAPI; Milner, 1986) is the best known and most widely used measure in this regard. The CAPI was specifically designed to measure problem areas related to parental and family background associated with an increased probability of abuse. Since its development in the late 1970s, this instrument has undergone considerable psychometric investigations by the author and others (see Milner, 1989; Ondersma, Chaffin, Mullins, & LeBreton, 2005) that have produced norms for general and abusive populations, and reliability and validity information. The Major Abuse Scale comprises six factor subscales: Distress, Rigidity, Unhappiness, Problems with Child and Self, Problems with Family, and Problems with Others. In addition, a Lie Scale indicates the degree of deceptive responding (e.g., “I love all children”). The 160 items on the scale are written at the grade 3 reading level and require only an *Agree* or *Disagree* response (e.g., “I am often mixed up”; “A child should never talk back”; “My parents did not understand me”). More recently, a brief version of the CAPI has been published, with psychometric properties similar to the original version (Ondersma et al., 2005).

Despite reasonably strong general psychometric properties, relatively easy and quick administration, and its widespread popularity, recent studies have raised concerns about some aspects of the clinical validity of the CAPI. Indeed, among parents being investigated for child abuse and neglect, a positive self-presentation bias substantially compromises the interpretation of traditional self-report measures such as the CAPI, although the Rigidity Scale did not appear to be as affected as the other scales (Carr et al., 2005). Furthermore, the validity of interpreting *changes* in CAPI scores as being indicative of change in child abuse risk is questionable. In a study utilizing data from 459 parents in 27 community-based

interventions, improvements in CAPI scores following intervention did *not* predict reduced rates of official child maltreatment reports in the ensuing 2 years (Chaffin & Valle, 2003). In this study, algorithms classifying significant change produced counterintuitive and misleading results; that is, participants classified as improved were actually at similar or even high risk to perpetrate future abuse compared to those classified as unchanged or worse. In our work with abusive fathers, clients who have been referred with a documented history of child maltreatment consistently avoid detection with the clinical cutoffs of the CAPI (Scott & Crooks, 2006). Thus, despite being a measure specifically designed to assess child abuse risk, the CAPI does not detect risk reliably in many cases, nor can changes in risk, as measured by the CAPI, be considered an adequate indicator of success in the absence of corroborating information. This latter shortcoming is particularly concerning given that the CAPI is routinely used to indicate success following intervention. Ironically, the test developer (Milner) has raised many of these questions and concerns in his own research (e.g., Milner, 1989, 1994); nonetheless, other researchers and clinicians have adopted the measure wholesale and without regard for these intricacies. Thus, the CAPI is probably best used as one piece of a comprehensive assessment, with the proviso that it is not a litmus test for abuse. Similarly, it should not be the sole outcome in intervention research to judge treatment success; unfortunately, it is often used in this manner.

A second widely used measure, the Adult-Adolescent Parenting Index—Second Edition (AAPI-2; Bavolek & Keene, 1999) has even greater problems than the CAPI, due to the lack of validity scales. At a construct level, the AAPI-2 was designed to measure dimensions that are highly pertinent to measuring child abuse risk patterns: inappropriate expectations of children, parental lack of empathy toward the needs of children, strong parental belief in the use of corporal punishment, reversal of parent-child family roles, and oppression of children's power and independence. The AAPI-2 is problematic in that items are highly face valid, which is concerning given client defensiveness and the sensitivity of the topics being addressed, and because there are no validity scales to evaluate or temper the effects of socially desirable responding (Carr et al., 2005). In our work with abusive fathers, we have vir-

tually no men endorse the Corporal Punishment scale, despite the fact that many of these same clients describe spanking as part of their parenting repertoire during the interview portion of the assessment, and harsh and frequent corporal punishment has been recorded by child protective services in many cases.

In comparison to the CAPI and AAPI-2, which are administered to parents, other measures assess children's experiences of abuse directly. The Childhood Experiences of Violence Questionnaire (CEVQ; Walsh, MacMillan, Trocmé, Boyle, & Jamieson, 2006) is one such measure that directly assesses children's experiences of a broad range of victimization. The CEVQ has 18 items that measure Child Physical Abuse, Child Sexual Abuse, Witnessing Domestic Violence, and Physical Punishment (Wekerle et al., 2006). One strength of the CEVQ is that it includes extrafamilial (peer-on-peer) violence, which may be an important area to assess and to accommodate in treatment planning with abused children. The CEVQ was developed for large, survey-based research studies and has not been used clinically to date; however, it provides a relatively efficient format for assessing a range of victimization experiences with adolescents and may be a useful adjunct to an interview.

Neglect

Although neglect is by definition difficult to measure (because it involves acts of omission rather than commission), a couple of well-designed, standardized neglect measures have emerged during the past 5 years. The Mother-Child Neglect Scale (MCNS; Lounds, Norkowski, & Whitman, 2004) was adapted from the Neglect Scale (Straus, Kinard, & Williams, 1995), a self-report measure of personal experience of neglect as a child, to assess neglectful behaviors perpetrated by a parent. The MCNS was developed as part of a longitudinal study of adolescent mothers and their firstborn children that followed mother-child dyads from the third trimester of pregnancy through the child's 14th year of life (Whitman, Borkowski, Keogh, & Weed, 2001). The questionnaire included a phone interview in which mothers were asked about their behavior toward their children when the children were 8 years of age. The questionnaire was validated with videotaped play episodes between mothers and children, and an adapted, shorter

version of the CAPI (Milner, 1986), which primarily used items from the Rigidity and Unhappiness Scales. The resulting 20-item MCNS (and a briefer 8-item form) show promise in terms of reliability and validity, and may be useful as part of a multimethod approach to assessing neglect in research settings. However, the developers clearly caution against its application in clinical or child protective settings, until much more research can be undertaken (Lounds et al., 2004).

A major, recent advance in the direct measurement of neglect is the development of the Multidimensional Neglectful Behavior Scale—Child Report (MNBS-CR; Kantor et al., 2004), the first standardized measure to canvas children in a systematic way about the level of care they receive and possible neglect. The MNBS-CR taps into four broad domains of neglect, including Cognitive (e.g., parent does not talk to child a lot, does not read to child), Emotional (e.g., parent does not comfort child, does not do fun activities with child), Physical (e.g., child is improperly dressed for weather, has poor dental hygiene), and Supervisory (e.g., parent does not know where child is playing, leaves child alone in the car for lengthy periods). Additional scales assess exposure to violence, alcohol-related neglect, abandonment,

and children's appraisals of parenting. This measure has utilized computer technology in an innovative manner to gain several advantages over traditional paper-and-pencil surveys. Using audio computer-assisted self-interview (ACASI) technology, children see pictorial items, hear a voice read the item, and respond by touching the computer screen.

ACASI technology offers several benefits. The items can be tailored to the child's age (item content differs for older and younger children as threshold for neglectful behavior differs) and gender (pictorial representations are generated to match the child's gender). In addition, the audio-assisted portion means that reading level is less important, and the child experiences a more comfortable and private administration than possible in a face-to-face interview with an adult. Finally, the use of a computer program is perceived to be fun. The format of items involves showing children at two different ends of a parenting care–neglect spectrum with respect to a particular behavior, and the child indicates which is more like his or her own experience. The next computer screen has the child rate the extent to which the item represents his or her experience (see Figure 14.1 for a sample from the MNBS-CR Physical Neglect scale).

FIGURE 14.1. Sample item from the Multidimensional Neglectful Behavior Scale—Child Report. From Kantor et al. (2004). Reprinted by permission from authors.

Developing these pictorial items was a challenging undertaking. In the words of the lead developer, operationalizing neglect can be like trying to hear “one hand clapping”; nonetheless, the early psychometrics are very promising (Kantor et al., 2004). The extent to which the MNBS-CR is adopted into clinical practice remains to be seen, in part because the proprietary nature of the ACASI technology makes it a very expensive measure for the developers to make available to others. Even with the expense associated, its use in research will likely grow due to the lack of alternative child-based measures of neglect. A parent version of the MNBS is under development (G. Kantor, personal communication, April 2006).

Parenting Attitudes and Behaviors

Although identifying parent personality traits and general characteristics that predict abuse has not been very useful to date, there is emerging interest in empathy as a foundational construct that mediates risk of abuse (Donald & Jureidini, 2004; Kilpatrick, 2005; Scott & Crooks, 2004). The focus is on parents’ empathy toward their own children specifically, not the more general concept of empathy as a broad characteristic. Donald and Jureidini (2004, p. 5, original emphasis) argue that it is “the parents’ ability to empathetically understand and give priority to *their* children’s needs” that is the critical determining factor in risk to children, *not* the broader constructs of parenting knowledge and social support, and so on. In developing the first measure of parental empathy, Kilpatrick (2005) notes that a model of parental empathy must include a number of emotional, cognitive, and behavioral elements that combine to create empathy. These factors include attending to the child’s signals or emotional cues, making accurate attributions about why the child is feeling that way, and experiencing child-focused positive emotions. Furthermore, these emotions and cognitions must lead to child-focused behavior. The Parental Empathy Measure is a semi-structured interview that uses a combination of forced-choice items, scenarios, and open-ended questions to assess Parent Beliefs, Behavioral Responses (both typical responses and on a “bad day”), Emotional Responses, and Attributions (Kilpatrick, 2005). There is also a Social Desirability scale included in the measure. Although the *Parental Empathy Measure* is rel-

atively new, the initial developmental work suggests promising psychometrics in terms of good internal reliability, interrater reliability, construct validity, and concurrent validity.

Parents’ Views of Children and Parenting Stress

There are a number of measures designed to assess parents’ views and expectations of their children, as well as stress experienced in the parenting role. A number of these measures are discussed herein. Parental views about their influence on their children’s behavior may be assessed with the Parent Attribution Test (PAT; Bugental et al., 1989). This measure grew out of research indicating that abusive parents tend to experience subjectively less power over their children and attribute more negative intent to child behavior compared to nonabusive parents. The PAT measures respondents’ attributions about potential causes of caregiving success and failure on a 7-point scale. Items are grouped according to four subscales (e.g., attributed control to adults for unsuccessful outcomes, attributed control to children for unsuccessful outcomes). The construct and discriminant validity of the PAT has been established in numerous studies (Bugental & Lewis, 1999; Bugental, Lewis, Lin, Lyon, & Kopeikin, 1999).

The Parental Childrearing Cognitions Questionnaire (PCCQ; Jefferis & Oliver, 2006) was developed to measure dysfunctional cognitions that likely influence parenting behavior and the quality of the parent–child relationship negatively. Respondents are presented with six challenging but developmentally appropriate child-rearing dilemmas (i.e., noncompliance, overactive and impulsive behavior, and demanding behavior that interrupts parental activity) and asked to imagine themselves in that scenario. Next they are presented with a series of statements with which they indicate their agreement. Categories for the statements include Attribution of Child Behavior to Negative Motivations, Negative Cognitions Concerning Limit Setting, Child Perceived as Excessively Demanding or Problematic, and Behavior Perceived as Predictive of Future Problems. The PCCQ has shown promising psychometrics with respect to reliability and validity (comparing clinical and nonclinical parents; Jefferis & Oliver, 2006).

The Parent Opinion Questionnaire (POQ; Azar, Robinson, Hekimian, & Twentyman,

1984), an 80-item questionnaire that measures unrealistic parental expectations of appropriate children's behavior, has six subscales based on content areas of unrealistic expectations (i.e., Self-Care, Family Responsibility and Care of Siblings, Help and Affection to Parents, Leaving Children Alone, Proper Behavior and Feelings, and Punishment). POQ scores have been found to distinguish between maltreating and nonmaltreating parents (Azar et al., 1984), as well as between parents who are perpetrating abuse and those who are not, within the same family (Azar & Rohrbeck, 1986). More recently, POQ scores (particularly with respect to unrealistic expectations about children providing support to parents) were associated with at-risk maternal behavior in videotaped mother-child interactions among mothers with major mental illnesses who were involved with the child welfare system (Leventhal, Jacobsen, Miller, & Quintana, 2004). It has also been recommended for use as part of a clinical assessment for parenting capacity (Budd, 2001).

The Parenting Stress Index (PSI; Abidin, 1995) is a widely used measure that assesses the stress experienced by parents, as well as the perceived source of the stress. The PSI contains 120 items rated on a 5-point scale. It is grouped into the Child domain (i.e., parental report of stress related to their children's adaptability, acceptability, demandingness, mood, distractibility, and responsive to the parent); the Parent domain (i.e., stress related to depression, role restriction, sense of parental competence, social isolation, health, and relationship with spouse); and the Parent-Child domain. An optional 19-item Life Events Stress Scale is contained within the PSI. The PSI also provides a total stress score that sums across all of the domains. It has strong psychometrics and is widely used in both clinical and research settings. In addition to the full 120-item version, a 36-item PSI Short Form (PSI-SF) yields a total stress score from three subscales: Parental Distress, Parent-Child Dysfunctional Interaction, and Difficult Child. Although the PSI-SF does not capture the same richness of data as the original, longer version, it has been shown to have reasonably strong psychometric properties with a range of populations and purposes (Haskett, Ahern, Ward, & Allaire, 2006).

The PSI (both the original and short form) was developed for use with parents of children ages 3 months to 10 years, but an upward extension is also available with the Stress Index

for Parents of Adolescents (SIPA; Sheras, Abidin, & Konold, 1998). The SIPA is for use with parents of children ages 11-19. It is a 90-item self-report questionnaire and, similar to the PSI, measures stress with reference to an Adolescent domain (Moodiness/Lability, Social Isolation/Withdrawal, Delinquent/Antisocial, and Failure to Achieve/Persevere), a Parent domain (Life Restrictions, Relationship with Spouse/Partner, Social Alienation, and Incompetence/Guilt), and an Adolescent-Parent Relationship domain.

The PSI & SIPA are useful in child abuse assessments, because they measure not only stress (which, in and of itself, is linked to maltreatment) but also the source of the stress. The extent to which the parent views the child as the source of all negative experience in his or her life is an important clinical consideration in assessment and treatment planning. Furthermore, PSI scores have been found to differentiate between abusive and nonabusive parents (e.g., Holden & Banez, 1996), although they may not be very effective at detecting defensive responding patterns (Milner & Crouch, 1997).

Observations

Child abuse researchers have long recognized the validity and feasibility of direct parent-child observations with this population (Wolfe, 1985). There are several ways to approach this task, each with advantages and disadvantages. For example, observing families in the home may provide the most naturalistic setting, yet the family's typical pattern of interaction may be so disrupted that little information is gained (particularly with abusive families who have *not* requested service). In terms of setting, structured clinic observations have gained wide acceptability and support as a valid assessment of parent-child interactions, and they have the potential advantage of videotaping the observed interactions. In addition to coding behavior from the tape, the scenes may be played back to have the parent retrospectively indicate his or her emotional reactions, level of arousal, and thoughts during the interaction. Another consideration for using structured clinic observations is that observations of low-frequency behaviors (yelling, grabbing, etc.) yield more relevant data in a more efficient manner when structured tasks are presented (e.g., Herrenkohl, Herrenkohl, Toedter, & Yanushefski, 1984; Oldershaw, Walters, & Hall, 1986).

Observations of child behavior in the home or clinic serve two assessment functions: They provide a measure of the child's typical behavior with his or her parent, and they also allow the examiner to view the child's range of behavior under controlled conditions. By observing the parent and child from behind an observational mirror the examiner may record selected target behaviors during contrived situations and free interaction. For very young children and infants, these situations are limited primarily to basic caregiving, such as feeding, holding, verbal and physical forms of communication, and simple compliance or instructional tasks (e.g., attending to the parent's voice commands). Preschool and older children may be given more specific instructions by the parent to engage in activities that resemble common areas of conflict at home (e.g., to complete one activity, then switch to another).

Quantitative assessment of family interactions is best approached by using an existing or modified structured procedure for coding family interactions. Since no particular behavior categories are unique to abusive families, the investigator can choose from among an expanding variety of family observation systems, and base his or her choice upon considerations such as diversity of definitional codes, ability to conduct sequential interactions, and field experience. These assessment strategies range from highly formal coding of videotaped interactions to ratings of more unstructured home observations, and an example of each is provided here. There are relative advantages and disadvantages associated with either approach.

The Dyadic Parent Interaction Coding System-III (DPICS-III; Eyberg, Nelson, Duke, & Boggs, 2005) is a well-researched behavioral coding system that measures the quality of parent-child social interactions. In the DPICS-III, behaviors are recorded, with 26 behavioral categories to measure child and parent verbalizations (i.e., the content of the verbal behavior) and physical behaviors (i.e., positive and negative touch). In addition, child vocalizations (i.e., the tone of the verbal behavior) and response behaviors (e.g., compliance to command, answer to question, no opportunity to comply) are also coded. The DPICS-III has a number of supplemental scales in addition to the standard ones. The various iterations of the DPICS have been shown to have good psychometrics. A thorough description of psychometric properties and research using the DPICS is

included in the manual, which is available online (Eyberg et al., 2005).

A less rigidly scored procedure than the DPICS-III is the Home Observation for Measurement of the Environment Inventory (HOME; Caldwell & Bradley, 1984). The HOME was designed to measure the quality and quantity of stimulation and support available to a child in the home environment. Since its original development, multiple versions have emerged to correspond to children's stages. In addition to the original Infant/Toddler version, there is an Early Childhood version for children ages 3-6, a Middle Childhood version for ages 6-10, and an Early Adolescent version for youth ages 10-15. Administration of the HOME requires an unstructured home visit, lasting typically between 45 and 90 minutes. In addition to the target child and his or her primary caregiver, other family members and even guests may be present, but their presence is not necessary. The procedure is a low-key, semistructured observation and interview aimed at minimizing intrusiveness and allowing family members to act normally.

The intent is to understand the child's opportunities and experiences; in essence, to understand what life is like for the particular child in the child's most intimate surroundings. This inventory was designed to sample certain aspects of the quantity and quality of social, emotional, and cognitive support available to a young child. The HOME is completed following visits to the family's residence, and items not obtained by direct observation (e.g., "takes the child out of home more than twice per week") are based on parental report. The original version comprised 45 yes-no ratings corresponding to 6 subscales: Emotional and Verbal Responsivity of the Mother, Avoidance of Restriction and Punishment, Organization of the Physical and Temporal Environment, Provision of Appropriate Play Materials, Maternal Involvement with the Child, and Opportunities for Variety in Daily Stimulation. Subsequent versions differ slightly in length and number of subscales. Psychometric information about all of the different versions is found in the administration manual (Caldwell & Bradley, 1984). The alpha coefficients for the total scores are all above .90; and the interobserver agreement for each measure is 90% or higher. The measure has been used throughout North and South America (including the Caribbean), in several European and Asian countries, in

Australia, and in at least two African nations. It has been used in a wide variety of clinical and research settings, and to evaluate the impact of intervention programs. Reviews of research on HOME can be found in Bradley (1994; Bradley, Corwyn, & Whiteside-Mansell, 1996).

If a formal behavioral coding system or checklist is not practical, possibly due to the logistics of the parent-child interaction (i.e., visit undertaken in an office, videotaping is not available) or impractical because of the extensive training necessary for some of the coding systems, a plan for outlining areas to assess during the observation session is still a useful adjunct to general impressions. The clinician needs to be alert to parent behaviors, child behaviors, and the interaction between these. Budd (2001) provides a useful list of questions to guide observation for a parent-child interaction assessment in the context of parenting capacity assessments (see Table 14.5). This list should not be considered exhaustive, but it highlights several key areas to which clinicians must remain vigilant. Furthermore, it underscores the importance of evaluating what is left unsaid or undone, in addition to the more obvious observations about what is being said and done. Although parents are typically on their best behavior while being observed, children's reactions to particular parental overtures will help the clinician assess whether Mom or Dad is behaving in an unusual manner. At the same time, it is important to remember that the situation itself is stressful and may elicit some negative behavior patterns from parents and/or children.

Checklists that are completed following a home visit or by a social worker who is familiar with the family can be useful assessment tools, particularly in identifying cases of neglect. Polansky, Chalmers, Butenweiser, and Williams (1978) developed the *Childhood Level of Living Scale* (CLLS) to assess the extent of positive and negative influences present in the child's home environment. This instrument is particularly well suited for assessing neglectful families, in that it lists the major areas of concern relative to children's minimal health, safety, and stimulation requirements. The CLLS has two main scales: Physical Care, containing items comprising five subscales labeled General Positive Care, State of Repair of House, Negligence, Quality of Household Maintenance, and Quality of Health Care and Grooming; and

TABLE 14.5. Potential Content Areas for Informally Observing Parent-Child Interactions

-
- I. Parent behavior patterns
- A. How does parent structure interactions through instructions, toys, or activities?
 - B. How does parent show understanding or misunderstanding of children's developmental levels?
 - C. How does parent convey acceptance or approval of children's behavior (praise, descriptive feedback, physical affection)?
 - D. How does parent convey disapproval of children's behavior (criticisms, negative comments, threats, physical roughness)?
 - E. Does parent notice and attend to children's physical needs (e.g., hunger, need to use bathroom, safety risks)?
 - F. Is parent responsive to children's initiations via verbalizations, facial expressions, and actions?
 - G. Does parent accept children's right to disagree or express their own opinions?
 - H. Does parent follow through with his or her instructions or rules?
 - I. Does parent spread attention fairly across children, if more than one child is present?
 - J. Does parent appear distracted, withdrawn, or bored during session (e.g., ignoring children or watching television instead of interacting with children)?
 - K. Does parent make "troublesome" comments (e.g., asking children if they love parent, making negative comments about family members or foster parents, swearing)?
- II. Child behavior patterns
- A. Are children at ease around parent (e.g., smiling, playing, and verbalizing vs. remaining distant, quiet, or fearful)?
 - B. Do children initiate interactions with parent?
 - C. Do children display developmental, emotional, or behavioral difficulties that require more skilful parenting strategies than the parent exhibits?
 - D. Do children respond to parent's initiations by showing interest and acceptance of parent's attention?
 - E. Do children disagree with parent or express their own opinions?
 - F. How do children show affection and interest toward parent?
 - G. What topics do children bring up in conversations with parent (e.g., activities in foster family, desire to be with parent)?
-

Note. Data from Budd (2001).

Emotional–Cognitive Care, with subscales labeled Encouraging Competence, Inconsistency of Discipline and Coldness, Encouraging Supererogatory Development, and Material Giving. The 99 items are rated by home visitors as *yes* or *no*. The authors provide preliminary normative data for this instrument, with cutoff scores indicating neglectful care, adequate care, and good child care, although reliability and validity data are limited (with the exception of one report indicating discriminative validity between neglect and control families; Polansky et al., 1978). The CLLS has both rural and urban versions available, because neglect concerns vary somewhat with context; however, it has been argued that widespread adoption of the CLLS has been limited due to its length (Lounds et al., 2004) and concerns about item relevance (Gaudin, Polansky, & Kilpatrick, 1992).

Specifically designed to measure key components of the home environment that are perceived to be representative of child neglect (Trocmé, 1996), the Ontario Child Neglect Index requires social workers to make ratings of neglect in three major areas that are identified in legislation, with the assistance of behavioral anchors. These areas include supervision, physical care (rating food/nutrition, and clothing and hygiene separately), and provision of health care (evaluating physical health care, mental health care, and development and educational care separately). Although the measure was designed to match a specific jurisdiction's neglect laws, it can easily be adapted for other jurisdictions (Trocmé, 1996). Strengths include its brevity and face validity (for the social worker completing the measure).

In summary, assessment of the parent–child relationship requires special attention due to the relational nature of child abuse. This assessment is best conducted through a combination of parent and child report and observation. The domains being measured include specific abuse and neglect categories, as well as related parent–child dynamics (e.g., stress and communication).

INTEGRATING INFORMATION AND MAKING RECOMMENDATIONS

Subsequent to undertaking the assessment procedures described in this chapter, the assessor is faced with the challenge of integrating findings

from parents, children, and parent–child relationships, and noting both challenges and strengths upon which to build intervention. It is important to return to the specific referral question(s) when formulating results and making recommendations; vague recommendations rarely serve either the family or the referral agent. Some additional challenges are involved with child abuse assessments compared to other areas.

First, due to the dynamics of defensiveness and minimization displayed by many abusive families, it is especially important to note the limitations and source of the data for a particular finding. For example, rather than noting that an individual does not have a police record, the assessor might note that the individual *reported* no police record, but that confirmation was not received directly from the police. Because the individuals making decisions on the basis of the report may not be familiar with particular tests or measurement theory, conveying an understanding about the meaning of validity scale scores is crucial, rather than assuming that the referral agent will make the connection between elevated validity scale scores and likely underreporting of difficulties.

A second challenge relates to the difficulty of providing feedback in a way that is respectful to clients, yet accurate and honest. All too often clients seem to be given a watered-down version of assessment findings in the verbal feedback meeting, and are then shocked when they later see the report, or conversely, never realize what has actually been written, because the report is not shared with them. Although it is challenging to convey negative feedback in a forthright yet compassionate manner, these skills are critical to develop if clinicians want to be effective in this area.

Finally, it is important to include findings that do not fit the overall conceptualization, as well as those that do. Although it may be tempting to focus on the findings that support the assessors' global view of the family, the complexity of abusive families is such that it is rarely a uniformly bleak picture. Capturing the strengths of a family, even if the resulting recommendations of the assessment are that the parents continue to pose a risk to their children, or that the children should be placed outside of the family, is a way to ensure respectful service to the most difficult families and may result in their feeling more validated in the process than they would otherwise feel.

Child Sexual Abuse

Vicky Veitch Wolfe

The study of childhood sexual abuse (CSA) began in earnest in the 1970s, a relative late-comer in the field of childhood psychopathology. However, since that time, tremendous gains have been made in our understanding of this serious problem. The growing recognition of the extent of CSA, and concern about its lifelong effects, led to significant changes in law, social work, education, and mental health. Indeed, there is even evidence that our increased knowledge and efforts toward recognition, prevention, and intervention have led to overall reductions in the prevalence of sexual abuse (Finkelhor & Jones, 2004). The professions of psychology and the behavioral sciences have made enormous contributions toward the understanding of the effects of sexual abuse and have led to great improvements in assessment, prevention, and treatment of sexually abused children and adolescents, and their families. These advancements have moved the field forward from the initial need to document and describe sexual abuse, to advancements in understanding the specific ways that sexual abuse affects children and results in psychological processes that often lead to lifelong adjustment difficulties.

This chapter reviews current issues related to child sexual abuse, with the general assumption that from our core bases of knowledge, assessment methodology will grow. The chapter consists of three main parts: (1) an epidemio-

logical overview of the problem of sexual abuse, including prevalence and incidence, characteristics of the abuse and perpetrators, child victims, their families and communities, and the types of stress they encounter subsequent to abuse disclosures; (2) an overview of the impact of sexual abuse on children and adolescents, and factors that attenuate and exacerbate those effects; and (3) an overview of assessment strategies and tools that have been developed especially for CSA victims and their families. Drawing from extant evidence-based methods, practical suggestions are made for clinical assessments.

EPIDEMIOLOGICAL OVERVIEW OF THE PROBLEM

Epidemiological studies of CSA have varied considerably in methodology, yielding large discrepancies in sexual abuse estimates, ranging from 2 to 62% for women and from 3 to 16% for men among U.S. studies, and from 3 to 20% for women and from 7 to 36% for men among international studies (Finkelhor, 1994b). Prevalence rates vary considerably depending on how sexual abuse is defined. For instance, studies that include noncontact forms of abuse and abuse by peers tend to yield high abuse estimates (Goldman & Padayachi, 2000). Due to the complicating factor of adolescent consensual sexual activity, definitions

for adolescents tend to vary regarding the upper age limited considered as abuse, the age difference required between the victim and offender for noncoercive sexual contacts (typically increased to 10 years), and the ways that coercion and abuse of authority are defined. Survey questions about sexual abuse also vary across studies. Some studies use a general question about sexual abuse history as a gate to asking more detailed questions, sometimes using vague terms such as “unwanted sexual touching,” whereas other studies ask about history of a number of specific acts without necessarily defining the acts as sexual abuse. The latter method tends to yield higher estimates of abuse, because some respondents may not consider their experiences as abusive (e.g., young males abused by older females). Research suggests that more inclusive definitions have an advantage when studying the impact of abuse, because more victims who are affected by abuse are included (Long & Jackson, 1990).

Based on a review of 19 studies of adult retrospective reports of childhood experiences, Finkelhor (1994a) concluded that approximately 20% of women and 5–10% of men had at least one episode of sexual abuse during their childhood. More recent studies yield similar estimates. A large-scale study of 17,337 adult members of a managed care program in California revealed that 25% of women and 16% of men reported at least one episode of abuse during childhood (Dong, Anda, Dube, Giles, & Felitti, 2003). In another large-scale population-based study ($N = 3,958$), Fleming, Mullen, and Bammer (1997) found that 20% of women reported CSA. Although some have suggested that epidemiological studies overestimate prevalence, most studies indicate that even in anonymous studies, individuals tend to underreport CSA by at least 16–50% (Fergusson, Horwood, & Woodward, 2000; Goodman et al., 2003; Greenhoot, McCloskey, & Gisky, 2005; Widom & Morris, 1997; Williams, 1994). Overall, these statistics reveal that sexual victimization is higher among youth compared to adults. Indeed, Hashimi and Finkelhor (1999) reported that rates of abuse of adolescents ages 12–17 were 2.0 to 3.3 times higher than rates for young adults ages 18–24.

Incidence data reflect the number of cases made known to public agencies during a specified period of time. Incidence data grossly underestimate true rates of sexual abuse, because

most cases are never reported to official agencies. However, in addition to providing information about agency-reported abuse, incidence data may be used to detect epidemiological trends, including rates of disclosure to official agencies. Recent retrospective surveys estimate that between 8.7 and 12.0% of CSA was reported to police or other authorities (MacMillan et al., 1997; MacMillan, Jamieson, & Walsh, 2003; Saunders, Villepontoux, Lipovsky, Kilpatrick, & Veronon, 1993). However, Finkelhor (1994a), combining prevalence and incidence estimates, calculated that approximately 30% of sexual abuse is currently disclosed to official agencies during childhood. In some cases, abuse is disclosed to parents and peers, but not to official agencies. Data from the National Survey of Adolescents, which included 1,958 girls ages 12–17 years, revealed that 48% of sexual abuse victims had disclosed their abuse to an adult, and an additional 25% had disclosed to a peer (Kogan, 2004). Hanson, Resnick, Saunders, Kilpatrick, and Best (1999), also reporting data from the National Survey of Adolescents, found that only half of those who disclosed their abuse to a relative, friend, or other confidant had also made a disclosure to an official agency.

Based on both incidence and prevalence data, evidence suggests a decrease in sexual abuse during the past two decades. Adult retrospective surveys from Australia and Ireland have demonstrated trends toward less abuse reported by younger, compared to older, cohorts (Dunne, Purdie, Cook, Boyle, & Najman, 2003; McGee, Garavan de Barra, Byrne, & Conroy, 2002). Surveys of adolescents have also demonstrated decreases in rates of sexual abuse and sexual assaults from 1992 to 2001 that range from 22 to 56% (Finkelhor & Jones, 2004). Reports of sexual abuse to official agencies have also decreased since the mid-1990s, with a 39% decrease in the United States (Jones, Finkelhor, & Kopiec, 2001) and a 49% decrease in Ontario, Canada (Trocmé, Fallon, MacLaurin, & Neves, 2003). Indeed, 1990 U.S. statistics indicated that sexual abuse cases comprised 17% of all confirmed or validated reports of maltreatment, whereas in 2004, CSA accounted for only 9.7% of reported maltreatment cases (Sedlak & Broadhurst, 1996; U.S. Department of Health and Human Services, 2004). In Ontario, the decrease in sexual abuse substantiation occurred at the same time that reports of other forms of maltreatment were on

the rise (Trocmé et al., 2003). However, in the United States, these declines coincided with similar declines in physical abuse, crime, teen pregnancies, runaway youth, and teen suicides (Finkelhor & Jones, 2004). Although there is some evidence that declines in incidence rates were in part due to changes in child protective service procedures, verification, and recording methods, other evidence indicates that the trend appears to reflect actual declines in sexual abuse. Positive effects of prevention programs, public awareness campaigns, and increased prosecution likely contribute to the decline (Jones et al., 2001). Finkelhor and Jones (2004) argued that societal deterrents against sexual abuse have been particularly effective. Between 1986 and 1997, the number of persons incarcerated for sex crimes against children doubled (Finkelhor & Ormrod, 2001), and this data did not include the increased number of offenders who received nonincarceration penalties following sexual abuse charges (e.g., probation). Citing data collected in Illinois and Pennsylvania, Finkelhor and Jones highlighted significant declines in sexual abuse cases involving fathers. They argued that biological fathers, who may be the least compulsive of CSA offender types, may be particularly deterred by the possibility of detection and prosecution.

Abuse Characteristics

Perpetrators

Sexual abuse varies on a number of dimensions, including the child's relationship to the perpetrator, the sexual acts involved, the use of coercion or force, and the duration and frequency of abuse. For female sexual abuse victims, 92% report abuse by males, 2% report abuse by females, and 4% report abuse by both males and females; for male sexual abuse victims, 51% report abuse by males, 21% report abuse by females, and 18%, by both males and females (Dube et al., 2005). Researchers have historically distinguished intrafamilial or incestuous abuse from extrafamilial abuse. Roughly 33–50% of female victims and 10–20% of male victims are abused by family members; 10–30% are abused by strangers, and approximately 40% are abused by someone known but not related to them (Fergusson, Lynskey, & Horwood, 1996; Finkelhor, 1994b; Vogeltanz et al., 1999). From 4.5 to 6.0% of girls are

abused by a father figure (Bagley & Mallick, 2000; Hanson et al., 2003; Russell, 1984). Although biological fathers account for more sexual abuse than do stepfathers (more children live with fathers than stepfathers), stepfathers are up to seven times more likely to abuse their stepdaughters and are more likely to commit more serious forms of abuse (Russell, 1983, 1984). Indeed, males in surrogate father roles (e.g., stepfathers, adoptive father, the mother's boyfriends) account for 18% of reported sexual abuse, whereas biological fathers account for 14% of reported sexual abuse (U.S. Department of Health and Human Services, 2004). Sexual abuse by family members tends to be more severe and repeated. Fergusson and colleagues (1996) reported that 61% of CSA episodes involving family members involved attempted or completed intercourse, and more than one incident occurred in 71% of cases.

Despite considerable focus on abuse by father figures, sibling abuse is the most prevalent form of incest, with between 7 and 15% of women and 10% of males reporting abuse by a sibling during childhood (Finkelhor, 1980; Hardy, 2001; Romero, Wyatt, Loeb, Carmona, & Solis, 1999). Sibling abuse occurs at least five times more often than does parent-child abuse (Finkelhor, 1980; Smith & Israel, 1987) and accounts for between 16 and 50% of incest cases (Laurence, 2000; Romero et al., 1999). In most cases, sibling incest is perpetrated by boys between the ages of 10 and 14, and their victims are typically at least 5 years younger (Laurence, 2000). Although some might consider sibling incest to be within the realm of sexual exploration, there is growing awareness that sibling incest can lead to serious emotional sequelae for victims (Adler & Schultz, 1995). Clinic-based studies of sibling incest reveal that 46–89% of cases involve attempted or completed vaginal or anal penetration, with most victims at least 5 years younger than the offenders. Russell (1986) found that 44% of brothers who committed sibling incest used physical force, such as pushing and pinning down the victim.

In their review of the literature, Pithers and Gray (1998) estimated that 40% of CSA was perpetrated by youth under the age of 20, and that 13–18% of offenses were committed by children ages 6–12. Likewise, in their study of sexual abuse among U.S. Latinos, Romero and colleagues (1999) found that 51% of offenders against females were younger than age 20

years. From a United Kingdom study, 32% of offenders were younger than age 18 (Oaksford & Frude, 2001). In the United States, individuals under age 18 account for 17% of all arrests for sexual crimes (Federal Bureau of Investigation, 1999) and roughly 33% of all arrests for sexual offenses against children (Snyder & Sickmund, 1999). Well over half (57%) of identified adolescent offenders had multiple victims prior to being caught (Fehrenbach, Smith, Monastersky, & Deisher, 1986). Furthermore, Sperry and Gilbert (2005) found that 8% of females and 4% of males reported sexual abuse prior to the age 12 by a peer who was 12 years old or younger.

During recent years, Internet-initiated sexual abuse has become a serious concern. A recent national survey documented that 20% of children and adolescents report at least one episode of Internet-initiated sexual solicitation within a 1-year period (Mitchell, Finkelhor, & Wolak, 2003). Case-based evidence suggests that Internet predators operate in ways similar to other perpetrators (Dombrowski, LeMasney, Ahia, & Dickson, 2004; Walsh & Wolak, 2005); that is, they select children and adolescents who show some level of vulnerability—either through the use of sexually suggestive nicknames on the Internet or by presenting themselves as isolated, lonely, passive, or emotionally vulnerable. Internet perpetrators may at first present themselves as peers. Like other perpetrators, they may engage in grooming behaviors in the forms of exchanging pictures, and providing pornography and gifts. Once a relationship is established, online predators may progress to requesting personal information, phone numbers, and face-to-face meetings. Adolescents, more than children, tend to be more common targets of online predators because they have greater autonomy, mobility, and sexual curiosity.

Walsh and Wolak (2005) studied Internet-initiated, nonforcible sex crimes against youth that resulted in felony charges. The majority of victims were adolescents (81%), 61% female and 39% male. In most cases, the abuse was discovered by a parent or guardian and reported directly to police. Investigation by police revealed that 45% of perpetrators were in possession of child pornography, 39% had given pornography to the victim, and 27% had taken pornographic pictures of their victims. Fifty percent of cases involved sexual penetra-

tion, and in 34% of cases, the victims were supplied drugs or alcohol. Of great concern, many offenders (30%) volunteered or had jobs that put them in positions of trust with minors. Nine percent had prior sexual offense arrests. Because Internet predators typically leave computer-based evidence of their crimes, prosecution of these types of offenses tends to be successful. Of the 77 arrests reviewed for the study, the conviction rate was 91%, with 59 individuals incarcerated, 59 placed on a sexual offender registry, and half ordered into mental health treatment.

Abusive Acts

Sexually abusive acts vary along a number of dimensions, ranging from inappropriate sexual overtures to fondling, and to oral, vaginal, and anal intercourse. Most epidemiological studies make a distinction between abuse that involves some form of penetration and other forms of abuse, and estimates have varied considerably. Several studies of adult retrospective reports reveal that approximately 25% of male and female abuse includes sexual intercourse (Coxell, King, Mezey, & Kell, 2000; Dube et al., 2005; Sachs-Ericsson, Blazer, Plant, & Arnow, 2005; Ullman & Filipas, 2005; Vogeltanz et al., 1999). Studies of adolescents and young adults suggest that younger generations experience more severe forms of abuse that include sexual intercourse. Data from the National Survey of Adolescents revealed that roughly 33% of victims reported sexual intercourse (Hanson et al., 2003). Tubman, Gil, and Wagner (2004) found that 42% of 18- to 23-year-old males and females who experienced sexual abuse prior to age 16 reported that their abuse had included sexual intercourse.

A *Los Angeles Times* poll (Timnick, 1985), which defined “coercion” as abuse that involved a weapon or forcible physical restraint, found that 15% of male victims and 19% of female victims experienced coercion. In more recent studies, Vogeltanz and colleagues (1999) reported that 38% of female victims reported some form of physical coercion, 15% thought their lives were in danger, and 3% sustained physical injury. Hanson and colleagues (2003) found that 27% of adolescents felt that their life was in jeopardy as a result of the sexual abuse.

Adult and adolescent retrospective studies indicate that 60–71% of abuse occurs only

once (Finkelhor, 1979; Stevens, Ruggiero, Kilpatrick, Resnick, & Saunders, 2005; Wyatt, Loeb, Solis, Carmona, & Romero, 1999). Boys tend to be abused less frequently and over shorter durations compared to girls (Kendall-Tackett & Simon, 1992), with 11% of girls and 8% of boys abused repeatedly over at least 1 year (Timnick, 1985). Bagley and Mallick (2000) noted differences in onset between those who experienced one-time versus multiple abuse episodes. Among those who experienced one-time abuse, onset during preschool years was rare (3%), whereas one-time episodes were more common among girls age 11 and older (12–19%). In contrast, among those who reported multiple episodes of abuse, onset during preschool years was not uncommon (14%), but it was uncommon after age 11 (5%). Not surprisingly, those who experience multiple episodes of abuse are more likely to report more serious forms of maltreatment. Bagley and Mallick found that only 3% of one-episode abuse cases include vaginal or anal penetration; for those who experienced multiple abuse episodes, 48% experienced vaginal penetration, and 19% experienced anal penetration.

Sexual abuse often occurs amid other forms of maltreatment and adversity. In addition to the cumulative effects of these events and circumstances, multiple forms of abuse and adversity suggest serious familial and social inadequacies that fail to protect and nurture the child (Fleming, Mullen, Sibthorpe, & Bammer, 1999). In a large-scale epidemiological study, Dong and colleagues (2003) found that CSA was associated with a history of physical abuse (45.5% of women, 42.7% of men), emotional maltreatment (26.1% of women, 17.3% of men), emotional neglect (29.6% of women, 19.9% of men), exposure to domestic violence (23.6% of women, 20.5% of men), and parental substance abuse (43.3% of women, 34.4% of men). Only 22% of sexual abuse victims reported no other form of maltreatment, and 29% had four or more forms of maltreatment and adversity. Finkelhor and his colleagues conducted two nationwide surveys of children and adolescents (ages 10 and older) that revealed high prevalences of nonsexual victimizations among sexually abused children (Boney-McCoy & Finkelhor, 1995; Finkelhor, Ormrod, Turner, & Hamby, 2005): 43% experienced another form of maltreatment (physical abuse, emotional

abuse, neglect, family abduction, custodial interference); 70% experienced property victimization (e.g., vandalism, theft), and 84% witnessed violence or indirect victimization (e.g., witnessed domestic violence, saw a violent crime). Children who present for clinical services are even more likely to have multiple victimization experiences. For example, two clinic-based studies of CSA victims reported that more than 50% had witnessed spousal violence (Bowen, 2000; Kellogg & Menard, 2003), with 77% reporting that the spousal violence and sexual abuse occurred within the same time period. Bowen (2000) found that 41% of victims reported delaying disclosure out of fear of violence by the perpetrator.

Children who experience CSA are also particularly likely to experience subsequent, distinct sexual victimizations in later childhood, adolescence, and as adults (Classen, Paresh, & Aggarwal, 2005). Stevens and colleagues (2005), drawing from the National Survey of Adolescents, found that children who are abused at a young age and those who experienced more severe forms of abuse are particularly likely to be revictimized. In their survey of children and adolescents, Boney-McCoy and Finkelhor (1996) found that those with a history of sexual abuse were 11.7 times more likely to report a different sexual victimization within the next year. Indeed, a number of studies have identified that history of sexual abuse was related to revictimization during adolescent years. For example, Small and Kerns (1993) found that roughly 33% of adolescents who experienced a sexual assault reported prior childhood sexual abuse. Fergusson, Horwood, and Lynsky (1996), in their longitudinal sample of adolescents, found that among those who reported contact forms of CSA, 10% experienced rape or attempted rape between the ages of 16 and 18, five times the risk of their nonabused peers. An additional 13% experienced other forms of sexual assault during that period, three times the risk of their nonabused peers. In a long-term follow-up of a sample of sexual abuse victims in Australia, Swanston and colleagues (2002) found that 17% had official reports reflecting subsequent sexual victimizations. In turn, adolescent sexual victimization is a powerful predictor of subsequent sexual victimization of young women (Gidycz, Coble, Latham, & Layman, 1993; Humphrey & White, 2000).

Victim Risk and Resiliency Factors

Three child factors have received attention as risk factors for CSA: age, gender, and disabilities. Approximately 10% of sexually abused children are under age 6, with a slight increase in onset at age 6–7 years, and a dramatic increase around age 10 (33%; Bagley & Mallick, 2000; Finkelhor & Baron, 1986; Vogeltanz et al., 1999). Indeed, data from the National Survey of Adolescents (Hanson et al., 2003) revealed that 60% of sexual abuse occurred between the ages of 11 and 16. Because of the large age span considered under the umbrella of sexual abuse, the nature, impact, and etiology of sexual victimization vary at different developmental points (Black, Heyman, & Slep, 2001).

Not surprisingly, girls are at higher risk for sexual abuse than boys, and are victims 3 to 5 times more often than boys (Boney-McCoy & Finkelhor, 1995; Fergusson, Lynskey, & Horwood, 1996; Sachs-Ericsson et al., 2005; Sedlak & Broadhurst, 1996). Sexual abuse experiences differ for boys and girls (Gordon, 1990; Watkins & Bentovim, 1992), with girls generally describing their experiences more negatively (Fischer, 1991). This may be because girls tend to be younger at the onset of their abuse (Dong et al., 2003) and their perpetrators tend to be older (Romano & DeLuca, 2001). Girls are abused by family members more often, and abuse perpetrated by family members tends to be more serious. Fergusson, Lynskey, and Horwood (1996) reported that 61.3% of abuse perpetrated by family members included some form of intercourse, and that 71% of familial abuse involved more than one episode. Boys are more likely to be abused by adolescent males and by females (Dube et al., 2005; Finkelhor, 1990). They may perceive abuse by adolescent males as a form of sexual experimentation (Romano & De Luca, 2001), and up to 20% of males describe sexual abuse by older females as either nonthreatening or pleasurable (Bagley & Thurston, 1996).

Children with developmental disabilities are at heightened risk for sexual abuse, with prevalence estimates two to three times greater than those of children without disabilities (Crosse, Kaye, & Ratnofsky, 1993; Sullivan & Knutson, 1998). Four factors have been linked to increased risk among children with disabilities (Westcott & Jones, 1999): (1) greater physical and social isolation; (2) increased dependence

and lack of control over their lives and bodies (e.g., need for assistance when bathing, dressing, and toileting, often by individuals other than parents, such as residential and disability care providers); (3) institutional care, with concerns raised about the level of staff training and qualifications, and insufficient efforts to ensure patient safety; and (4) communication impairments that may increase risk of being selected by perpetrators, prevent reporting, and impede validation of abuse allegations. Much of the increased vulnerability in this population is among boys, particularly those between ages 6 and 11 (Randall, Parrila, & Sobsey, 2000; Sobsey, Randall, & Parrila, 1997; Sullivan, Brookhouser, Scanlan, Knutson, & Schulte, 1991). Sobsey and Doe (1991) found that increased contact with disability service providers accounted for 78% of the increased risk to children with disabilities. Indeed, Sobsey and colleagues (1997) queried whether the disproportionate representation of boys among sexually abused children with disabilities is related to a tendency for their nonfamilial caregivers to be male, whereas nonfamilial caregivers of girls tend to be female.

Family Risk and Resiliency Factors

Several interrelated family factors have been linked with risk of sexual abuse: unplanned pregnancy, low maternal education, parental alcohol and drug abuse, parental mental illness, harsh discipline, parent–child relationship problems, maternal death, living with only one or with no natural parent, marital discord, separation, divorce, and maternal remarriage (Bagley & Mallick, 2000; Boney-McCoy & Finkelhor, 1995; Brown, Cohen, Johnson, & Salzinger, 1998; Dong et al., 2003; Fergusson, Lynskey, & Horwood, 1996; Finkelhor, Moore, Hamby, & Straus, 1997; Hanson et al., 2006; Mullen, Martin, Anderson, Romans, & Herbison, 1993; Walsh, MacMillan, & Jamieson, 2003). Increasing levels of family-related adversity correspond to increasing risk of child sexual victimization, and family-based risk factors are relevant to both intrafamilial and extrafamilial sexual abuse of boys and girls (Fergusson, Lynskey, & Horwood, 1996). Indeed, in a longitudinal study of 267 low socioeconomic status (SES) primiparous women and their children, Pianta, Egeland, and Erickson (1989) found that children identified as having experienced sexual abuse ($n = 11$) had mothers

who previously had reported more stressful life events and less social support at every prior assessment point, which occurred at 6- to 12-month intervals when the children were between the ages of 2 and 5 years. Compared to the other mothers in the study, mothers whose children were sexually abused had described themselves as more tense, depressed, angry, confused, restless, skeptical, and calculating.

Factors that negatively affect parental ability to monitor child safety appear to be particularly potent in predicting risk for sexual abuse. Drawing from the National Survey of Adolescents, Hanson and colleagues (2006) found that not living with a biological parent increased the odds of sexual abuse by 1.8. As well, parental alcohol abuse, which affects parental availability and child monitoring, increased the odds of adolescent reports of extrafamilial sexual abuse by 1.7 and doubled the odds of multiple victimization (Hanson et al., 2006; Stevens et al., 2005). Finkelhor and colleagues (1997) found that leaving a child at home alone without adequate supervision increased the odds of child sexual victimization by 3.4. Likewise, Fergusson, Lynskey, and Horwood (1996) found that poor parental supervision, lack of knowledge about sexual abuse risk factors, and child exposure to risky social environments increased odds of sexual abuse.

In line with intergenerational theories of child abuse, maternal history of childhood sexual abuse has been linked with increased risk of problematic parenting, child adjustment problems, and risk of sexual abuse and other forms of child maltreatment. Parenting issues are apparent even during pregnancy. Smith, Poschman, Cavaleri, Howell, and Yonkers (2006) reported greater alcohol use during pregnancy among women with posttraumatic stress disorder (PTSD); although the sample experienced different forms of traumas, CSA was the most commonly identified trauma. A number of studies have found that mothers with sexual abuse histories tend to lack confidence and competence in their parenting skills and abilities (Banyard, 1997; DiLillo & Damashek, 2003; Ruscio, 2001; Zuravin & Fontanella, 1999). Maternal mental health, particularly PTSD and depression, along with low levels of maternal social support and high levels of stress, appear to mediate the links between maternal CSA history and their children's adjustment problems, including both internalizing and externalizing behavior problems and child

social competence (Banyard, Williams, & Siegel, 2003; Koverola et al., 2005; Pianta et al., 1989; Wright, Fopma-Loy, & Fischer, 2005). In their national survey of children and adolescents, Finkelhor and colleagues (1997) found that parents with a history of childhood sexual victimization were 10 times more likely to have a child who experienced sexual abuse compared to parents without such a history. Zuravin and Fontanella (1999) also found that adolescent mothers with a sexual abuse history, compared to other adolescent mothers, were more likely to neglect their children.

Community/Social Risk Factors

Studies that have examined race, culture, and ethnicity as risk factors for sexual abuse have been inconclusive (Kenny & McEachern, 2000). However, there is some evidence that sexual abuse is more common among lower SES families (Costello, Erkanli, Fairbank, & Angold, 2002; Finkelhor et al., 1997; Sedlak, 1997; Manion et al., 1996). Living in high-risk communities also appears to increase CSA risk. Drake and Pandey (1996) found that communities with higher percentages of families in poverty (> 41%) had significantly higher rates of child sexual victimization compared to other communities. As well, Boney-McCoy and Finkelhor (1995) found that children from dangerous communities were at increased risk for child sexual victimization (odds ratio [OR] = 1.5) compared to other communities.

Postdisclosure Stressors

Who Discloses Abuse?

Despite widespread efforts to encourage early disclosure (Finkelhor & Dziuba-Leatherman, 1995; Wurtele, 2002), 50–70% of children and adolescent sexual abuse victims do not disclose their abuse to anyone during childhood (Arata, 1998; Finkelhor, 1990; Usher & Dewberry, 1995). As noted earlier, even fewer cases are reported to official agencies (Arata, 1998; Fergusson, Lynskey, & Horwood, 1996; Hanson et al., 2003; Smith et al., 2000; Usher & Dewberry, 1995). Among those who disclose their abuse during childhood, less than 33% disclose shortly after the incident (Arata, 1998; Smith et al., 2000) and another 33% within 6 months (Smith et al., 2000), with 42% disclosing within 1 year (Finkelhor, 1990). For

those who disclose during childhood, delays average at least 1.5 to 3.0 years (Goodman et al., 1992; Henry, 1997; Oxman-Martinez, Rowe, Straka, & Thibault, 1997; Sas, Cunningham, Hurley, Dick, & Farnsworth, 1995).

Failure to disclose and delays in disclosure pose serious problems for victims and society. The most serious outcome of delayed disclosure is the risk of further abuse. Sas and colleagues (1995) reported that among those who did not immediately report their abuse, 44% were abused again by the same perpetrator. Failure to disclose also places other children at risk, because many offenders have multiple victims, including incestuous offenders (Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988). Delays in disclosure diminish prospects for prosecution when the abuse is eventually disclosed (Goodman-Brown, Edelstein, Goodman, Jones, & Gordon, 2003; Myers, 1992). As well, disclosures delayed by 1 month or more are associated with increased risk of developing PTSD and major depressive disorder (MDD) (Ruggiero et al., 2003), and delay access to mental health services that can address early-onset symptoms.

Children's decisions to disclose sexual abuse should be viewed within a developmental framework, influenced by issues relevant to the abuse itself, the perpetrator, the family, and personal characteristics of the child. Older children are more likely to disclose their abuse in a planned and purposeful way (Mian, Wehrspann, Klajner-Diamond, LeBaron, & Winder, 1986), whereas younger children are often prompted to disclose after an adult suspects abuse, often due to inappropriate sexualized behaviors, changes in personality, detection of a sexually transmitted disease, or learns that a child spent time with someone suspected of abusing others (Kelley, Brant, & Waterman, 1993; Sorenson & Snow, 1991). Even after an initial disclosure, young children are less likely than older children to disclose in the context of formal investigations (DiPietro, Runyan, & Frederick, 1997), though additional interviews may aid the disclosure process (Gries, Goh, & Cavanaugh, 1996). School-age children tend to confide their abuse experiences to a parent or primary caregiver (Arata, 1998; Lamb & Edgar-Smith, 1994), but adolescents are more likely to confide in a peer (Everill & Waller, 1995; Henry, 1997; Kellogg & Huston, 1995; Lamb & Edgar-Smith, 1994).

There are many reasons why children avoid disclosure; they may fear retaliation from the perpetrator or others, may wish to avoid the stigma and family turmoil that might ensue, or may worry that they will be blamed or punished. Unfortunately, these fears are often justified, in that disclosures are often met with disbelief, do not lead to protection, and result in significant family upheaval and victim blaming (Sauzier, 1989; Sorenson & Snow, 1991). Although children sometimes deny abuse even when faced with compelling evidence (DiPietro et al., 1997; Lawson & Chaffin, 1994), in cases with strong corroborating evidence, 84% of children disclose abuse when interviewed or shortly thereafter (London, Bruck, Ceci, & Shuman, 2005). Stressors associated with disclosure increase the possibility of recantation, including disbelief by mothers (Elliott & Briere, 1994) and court proceedings (Gonzalez, Waterman, Kelly, McCord, & Oliveri, 1993). As well, abuse-related PTSD avoidance symptoms may serve as a catalyst to recant abuse allegations, particularly when children are faced with situations that require them to remember and talk about what happened (Gonzalez et al., 1993; Koverola & Foy, 1993).

Several additional predictors of disclosure in childhood have been identified. Boys are less likely to disclose their sexual abuse than girls (Hanson et al., 2002; Lynch, Stern, Oates, & O'Toole, 1993; Stroud, Martens, & Barker, 2000; Violatao & Genius, 1993), in part due to the stigmatization of male-perpetrated abuse, and also because some boys may not define sexual acts by older girls or women as abuse (Hecht & Hansen, 1999). Disclosures are more common when the perpetrator is a stranger rather than a family member (Hanson et al., 2003; Smith et al., 2000), and delays in disclosure tend to be longer for intrafamilial than for extrafamilial abuse (Sas et al., 1995; Usher & Dewberry, 1995). Despite higher prevalence of sexual abuse among children with disabilities, disclosure rates are disproportionately small, and disclosures are often not reported to child protective service agencies (Kvam, 2000).

Some victims report that school-based personal safety programs or conversations with their parents influenced their decisions to disclose. Children's motivations also influence disclosure, including need for protection and emotional support, and feelings of anger and desire for revenge (Lamb & Edgar-Smith, 1994; Sas et

al., 1995; Sorenson & Snow, 1991). Children who experience severe forms of maltreatment (e.g., sexual penetration), physical coercion, and threats tend to have one of two reactions (Gomes-Schwartz, Horowitz, & Cardarelli, 1990). For some, the severity of the abuse facilitates disclosure, because the children may fear for their lives. However, other children may delay their disclosure until they feel safe from retribution. Paine and Hansen (2002) reported that delays in disclosure were twice as lengthy when perpetrators were violent with either the children themselves or with members of their families. Kogan (2004) found that children were most likely to delay disclosures when family members had been threatened.

The Justice System for Juvenile Victims

INVESTIGATIONS

Finkelhor, Cross, and Cantor (2005) coined the term “justice system for juvenile victims” in reference to the complex set of agencies and institutions that serve child victims and their families, which includes police, prosecutors, child protection agencies, mental health services, and criminal, civil, and family courts. Collaboration among professionals and agencies facilitates thorough investigations, protects children from unnecessarily redundant interviews, and helps to ensure child safety. Among the system-induced stressors associated with children’s disclosures, having to endure multiple investigative interviews by various interviewers with different agencies has repeatedly been demonstrated to have negative effects on children (Berliner & Conte, 1995; Goodman et al., 1992; Henry, 1997). To avoid the problems associated with multiple interviews and to encourage interagency cooperation, many communities conduct joint police–child protective service investigations, whereas other communities pool resources to create child abuse multidisciplinary teams. Some multidisciplinary teams have a designated workspace such as a child advocacy center (CAC) or a child abuse assessment center (CAAC), whereas others meet informally to plan investigation strategies and review evidence. The National Child Advocacy Center in Huntsville, Alabama, serves as a prototype for multiagency cooperation. It provides office space for professionals involved in investigations and treatment, comfortable

interviewing rooms for children, and a Court Prep Group (Pence & Wilson, 1994; Whitcomb, 2003). There are now at least 724 such centers in all 50 states and the District of Columbia (National Children’s Alliance, 2006). Programs typically have multidisciplinary teams and case review procedures that include law enforcement, child protective services, prosecutors, health care, mental health care, and victim advocates. Most have trained interviewers on site and provide ongoing staff training. Emerging evidence indicates that these programs are rated more positively by children, and require fewer child interviews by fewer interviewers in fewer locations (Saywitz, Goodman, & Lyon, 2002). Multidisciplinary teams also tend to facilitate access to investigative and treatment services, enhance the efficacy of court-related decision making and substantiation of allegations, promote more confessions and guilty pleas by perpetrators, and increase criminal charges and conviction rates (Joa & Edelson, 2004; Smith, Witte, & Fricker-Elhai, 2006).

In the United States, approximately 30% of reported maltreatment cases are substantiated, with 12% of those involving sexual abuse (Golden, 2000). From the Canadian Incidence Study, which surveyed child protective service agencies across Canada, 38% of sexual abuse allegations were substantiated, 20% were suspected (evidence that allegations are true, but insufficient to substantiate), 36% were unsubstantiated, and 6% were considered intentionally false (Trocmé & Bala, 2005). These findings are similar to earlier studies that found that half of allegations tend to be substantiated or suspected (Everson & Boat, 1989; Jones & McGraw, 1987). Studies indicate that only about 2.5% of allegations are deliberately false (Oates et al., 2000; Trocmé, McPhee, & Tam, 1995). The Canadian Incidence Study found that false reports of sexual abuse by children were very rare (none were identified); otherwise, false reports tended to come from custodial parents (19%), noncustodial parents (16%), relatives, neighbors, and acquaintances (14%), and anonymous reporters (16%). When maltreatment allegations were made in the context of custody and access allegations, 12% of allegations were deemed false, mostly by anonymous reports and noncustodial fathers. However, evidence suggests that only a small percentage (0.3%) of custody and access

disputes involve allegations of sexual abuse (Thoennes & Tjaden, 1990; Trocmé & Bala, 2005).

CRIMINAL PROSECUTION AND COURTROOM TESTIMONY

Compared to other forms of maltreatment, sexual abuse is more likely to result in criminal charges (Sedlak et al., 2005), and sexual abuse cases are the most common type of trial that involves child witnesses (Goodman, Quas, Bulkley, & Shapiro, 1999). However, only about half of substantiated cases of sexual abuse result in criminal charges, and up to half of those are dropped or dismissed following preliminary hearings (Cross, Whitcomb, & De Vos, 1995; Martone, Jaudes, & Cavins, 1996; Stroud et al., 2000). Cases that involve latency-age female victims, older male perpetrators, and multiple victims are more likely to be prosecuted. On the other hand, prosecution is less likely when a child is preschool age or male, when the mother does not support prosecution, and when the accused individual is a family member (Cross, De Vos, & Whitcomb, 1994; Cross et al., 1995; Stroud et al., 2000).

Of those cases that remain viable following preliminary hearings, most take at least 1 year to resolve. To address the problem of excessive delays, 12 states and the District of Columbia have statutes mandating speedy trials that involve children as victims and/or witnesses (American Prosecutors Research Institute, National District Attorneys Association, 2007). On the whole, cases slated for trial are successful for the prosecution. Fifty to 85% of defendants plead guilty prior to trial, and of the small number of cases proceeding to trial, roughly 67% result in guilty verdicts (Cross et al., 1995; DeJong & Rose, 1991; Faller & Henry, 2000; Martone et al., 1996; Stroud et al., 2000). Sentencing varies considerably across jurisdictions. For example, Stroud and colleagues (2000) reported that convicted perpetrators (guilty pleas and guilty verdicts) averaged 11-year jail terms, but most sentences were suspended. Parole sentences averaged just less than 4 years. On the other hand, Martone and colleagues (1996) found that most perpetrators served time, with average sentences of 6.8 years. Cross and colleagues (1995) reported that 38% were incarcerated more than 1 year, 40% were incarcerated less than 1 year, and 22% were placed on probation.

Approximately 50% of cases referred for prosecution require that children testify at some legal proceeding, such as a preliminary hearing (Goodman et al., 1992); if cases proceed to trial, at least 80% of child victims testify (Cross et al., 1995). However, because of the small number of cases that proceed to trial, this accounts for only 1–4% of sexually abused children known to official agencies (Saunders, Kilpatrick, Resnick, Hanson, & Lipovsky, 1992; Stroud et al., 2000). Most children find testifying in court to be very stressful (Lipovsky, Tidwell, Kilpatrick, Saunders, & Dawson, 1991; Sas et al., 1995). Prior to testifying, children identify a number of fears, including fears of the testimony itself, of the defense attorney, and of seeing the defendant; after testifying, children report that the most distressing aspects were seeing the defendant and not having their parents in the courtroom (Goodman et al., 1992). Children also fear that the defendant will retaliate and that they will not be believed.

INVOLVEMENT WITH CHILD PROTECTIVE SERVICES

Child protective services (CPS) tend to limit their continued involvement to cases in which parents or caregivers are implicated in the abuse, or when concerns are raised that parents cannot protect the children from further harm by the perpetrators or other potential offenders. In most cases, CPS monitor “at-risk” children in their home through voluntary agreements or through court-imposed supervision orders. However, approximately 17% of sexually abused children go into foster care (Finkelhor, 1983), often because of concerns about the mother’s ability to protect the child from further abuse (Ryan, Warren, & Weincek, 1991). Indeed, sexually abused children who go into foster care are more likely to come from low-SES families, to have experienced multiple abuse episodes, and to have mothers who did not support their allegations (Hunter, Coulter, Runyan, & Everson, 1990; Leifer, Shapiro, & Kassem, 1993). Placement outside the home following sexual abuse allegations is associated with greater mental health concerns, particularly when children experience multiple placements (Gomes-Schwartz et al., 1990; Melton et al., 1995); however, because of the close connection between foster placement, poor maternal support, and preexisting behavioral and

emotional problems, it is difficult to determine whether foster placement has an additive effect on adjustment problems. Compared to other reasons for foster placement (e.g., neglect, physical abuse), sexually abused children tend to remain in foster care for shorter durations (approximately 8 months shorter; Lie & McMurtry, 1991). Thus, because reintegration with families is highly likely for CSA victims in foster care, efforts to resolve family problems and facilitate successful reunification are very important.

Family Reactions

FAMILY SUPPORT REGARDING ABUSE ALLEGATIONS

Drawing from the Adolescent Health Survey, Chandy, Blum, and Resnick (1997) found that one of the strongest predictors of resilience subsequent to sexual abuse was children's perception that their parents cared about them. Although maternal support has received considerable attention, supportive reactions from other family members have also been identified as a resilience factor (Garbarino, Dubrowi, Kostelney, & Pardo, 1992). Several studies have investigated mothers' reactions to their children's abuse allegations. Gomes-Schwartz and colleagues (1990) described four types of maternal responses: (1) a decisive, nonambiguous, protective response, with responsibility attributed to the accused; (2) ambivalent loyalties between child and perpetrator, requiring support from CPS to ensure adequate protection; (3) an immobilization response, resulting in a failure to protect the child, but moderate support and no overt blame of the child; and (4) rejection of the child, alignment with the perpetrator, and no child protective action. However, Elliott and Carnes (2001) note that maternal reactions of belief and support tend to be fluid and change over time with different circumstances. Nonetheless, evidence suggests that parental support and protection subsequent to abuse allegations are a function of the quality of the preexisting parent-child bond (Bolen & Lamb, 2002). Although most mothers are decisive, supportive, and protective in response to their children's allegations, 16–50% of mothers do not support their children's allegations (Pierce & Pierce, 1985; Sas et al., 1995; Tufts New England Medical Center, 1984). Belief in a child's allegations does not

necessarily result in protective action, however. Pintello and Zuravin (2001) found that, on the one hand, 20% of mothers who believed their children's allegations failed to take protective actions. On the other hand, they also found that 52% of mothers who were ambivalent about their children's allegations nonetheless took protective action. Although one might anticipate that previous involvement with CPS might sensitize parents to concerns about abuse and neglect, this does not appear to be the case. Previous involvement with CPS has been found to have either no relationship to parental belief and protection (Pintello & Zuravin, 2001) or a negative relationship (Bolen & Lamb, 2002).

The more seriously the abuse allegations affect a mother's lifestyle and sense of self, the less likely the mother is to believe the allegations (Elliott & Briere, 1994; Gomes-Schwartz et al., 1990; Lawson & Chaffin, 1992; Sirles & Franke, 1989). Mothers tend to have more difficulty believing allegations against their current partners, particularly when allegations are against stepfathers and common-law partners with whom the mother has either a new, intense, or financially reliant relationship (Elliott & Briere, 1994; Everson, Hunter, Runyan, Edelsohn, & Coutler, 1989; Faller, 1984; Gomes-Schwartz et al., 1990; Leifer, Kilbane, & Grossman, 2001). Alaggia and Turon (2005) examined the impact of spousal abuse on responses to child sexual abuse allegations. Interestingly, mothers who were abused in nonphysical, psychological, or emotional ways were less supportive of their child's sexual abuse allegations compared to those who experienced physical spousal violence. When mothers are faced with the difficult choice between their spouses and their children, approximately one-fourth of them opt to stay with their spouses (Everson et al., 1989; Gomes-Schwartz et al., 1990). In contrast, mothers are often quite supportive when allegations occur in the midst of preexisting spousal problems or when the spouses have already separated (Faller, 1984; Sirles & Franke, 1989).

Mothers are also less likely to believe their children's allegations when alternative explanations are available (Sirles & Franke, 1989). Young children are perceived as having little sexual knowledge and little motive for making false allegations, and are therefore most often believed. As children grow older, allegations are less likely to be believed, particularly when

the allegations include very serious forms of abuse or when a child's story indicates that the mother was home when the abuse occurred. Sadly, children with unsupportive mothers tend to suffer more episodes of abuse and are ultimately more likely to recant their allegations (Elliott & Briere, 1994; Leifer et al., 1993). Mothers also tend to have more difficulty believing their children when their partners have substance use problems or when their partners also physically abuse the children. Apparently, in these circumstances, mothers are more likely to find a reason for the children to lie about the abuse (e.g., retaliation for the physical abuse), or are more accustomed to making excuses for the partners' inappropriate behavior (Elliott & Briere, 1994).

ONGOING CONTACT WITH THE OFFENDER AFTER ABUSE ALLEGATIONS

In paternal and sibling abuse cases, many children continue to have contact with their incestuous relative following disclosure, although this contact is usually supervised by a CPS agency, a supervised access program, or a family member (Hamilton, 1997). Supervised access with an incestuous relative can serve several positive functions (Straus, 1995): It can (1) help the child gain a realistic assessment of the person and their relationship; (2) serve as a stepping-stone to less restricted access; and (3) allow the child to maintain a relationship with the family member in a safe situation. On the negative side, a child may fear this relative, and visits may stimulate PTSD symptoms. When legal proceedings are in progress, a child's access may introduce divided loyalties between wanting to please the perpetrator and following through with prosecution. Tebbutt, Swanston, Oates, and O'Toole (1997), in their longitudinal study of abuse-related sequelae, found that contact between intrafamilial perpetrators and victims between the 18-month and the 5-year follow-up period was predictive of long-term depressive symptoms. In an exploratory study, Hamilton (1997) reviewed 40 CPS files to examine factors associated with father-child access and with positive adjustment to access. Access supervisors were more likely to note positive adjustment to access when the father (1) had admitted to the abuse, (2) emotionally supported the child, (3) abided by supervision rules, (4) was highly involved in treatment ser-

vices, and (5) demonstrated positive parenting behaviors during access visits.

IMPACT OF ABUSE ALLEGATIONS ON MATERNAL MENTAL HEALTH

Mothers of sexual abuse victims tend to have relatively high rates of psychopathology. As noted earlier, in some cases the mothers may have had mental health problems prior to their child's sexual abuse; however, for many, their child's disclosure of sexual abuse can lead to great psychological distress, increasing the odds of mothers' developing their own post-traumatic stress symptoms and/or depression (Davies, 1995; Deblinger, Hathaway, Lippman, & Steer, 1993; Elliott & Carnes, 2001; Hooper, 1992; Manion et al., 1996). In many cases, mothers of sexual abuse victims are victims of domestic violence by the same offender (Bowen, 2000; Kellogg & Menard, 2003). In addition to concerns about their child's well-being, many mothers often feel guilt and self-blame after learning about their child's sexual abuse. As well, the aftermath of the disclosure can lead to serious financial, occupational, and residential setbacks (Hooper, 1992; Massat & Lundy, 1998). Parental psychopathology tends to interfere with parenting in general, and may interfere with caregivers' ability to provide the nurturance needed to support children following sexual abuse (Kelly, Faust, Runyon, & Kenny, 2002). Indeed, the level of distress shown by sexually abused children often mirrors their parents' level of distress (Avery, Massat, & Marta, 1998; Lipton, 1997; Newberger, Gremy, Waternaux, & Newberger, 1993). Research indicates that depressed mothers tend to be less responsive and more helpless, hostile, critical, disorganized, and inconsistent in their parenting compared to nondepressed mothers (Gelfand & Teti, 1990; Goodman, 1992). Parental depression increases the odds of a number of child mental health problems, including depression, anxiety, somatic complaints, and behavior problems (Downey & Coyne, 1990; Gelfand & Teti, 1990). Depressed mothers of sexual abuse victims, compared to nondepressed mothers of sexual abuse victims, are more likely to describe their children as having externalizing behavior problems, attentional problems, and as being immature and showing extreme forms of pathology, such as delusions and hallucinations (Kelly et al., 2002).

MATERNAL HISTORY OF MALTREATMENT

To complicate matters, mothers of sexually abused children often have their own history of childhood sexual abuse and/or other forms of maltreatment (Collin-Vézina & Cyr, 2003). Preliminary evidence indicates mothers who experienced childhood maltreatment find parenting more stressful, report less effective parenting styles, find parenting less rewarding, and report less spousal support than mothers without abuse histories (Cole, Woolger, Power, & Smith, 1992; DeOliveira, Bailey, Wolfe, & Evans, 2006; DiLillo & Damashek, 2003; Douglas, 2000; Fitzgerald, Shipman, Jackson, McMahon, & Hanley, 2005; Ruscio, 2001). Although the literature is quite underdeveloped at this point, different types of childhood maltreatment appear to have different effects on subsequent parenting. Lyons-Ruth and Block (1996), in one of the few studies to examine the impact of childhood maltreatment on parenting behaviors, found that a history of physical abuse was associated with mothers' increased hostile-intrusive behavior toward their infants, whereas a history of sexual abuse was associated with decreased involvement and restricted maternal affect. Mental health issues such as depression, dissociative tendencies, and avoidant coping likely mediate the relationship between maternal history of childhood maltreatment and parenting outcomes (Banyard et al., 2003; Koverola et al., 2005; Schuetz & Eiden, 2005; Wright et al., 2005). DeOliveira et al. (2006) found that maternal history of maltreatment affected parenting in different ways based on the child's gender. Mothers with trauma-related intrusive symptoms were less likely to engage in emotion-focused dialogues with their sons, whereas mothers who experienced either emotional neglect or physical abuse showed more hostility in their interactions with girls.

Implications of Epidemiological Findings on Clinical Assessment

Epidemiological findings provide an important framework for identifying the types of background and contextual information relevant to clinical assessment. Most importantly, however, extant epidemiological data highlight the broad extent of CSA and other life adversities, and relatively low rates of disclosures. Although considerable attention has been given

to false CSA reports, underreporting of CSA is more common and its detection is essential for proper diagnosis and treatment. Thus, all clinicians working with children and youth, not just those who specialize in CSA and childhood trauma, should be mindful that many children who are identified for mental health service have undisclosed histories of CSA and life adversities. Underreporting of CSA is most common among males, children with disabilities, and children who perceive either negative or ineffectual consequences to their disclosures. Adolescents tend to disclose to their peers rather than to adults. In many cases, CSA is reported to caregivers, but caregivers do not inform official agencies. At the very least, it is important to screen for known histories of CSA, other forms of maltreatment, and other negative life events and adversities, through CPS records and/or caregiver reports. Consideration should also be given to routinely asking children about maltreatment experiences. Recent large-scale surveys with children and youth have demonstrated the feasibility of collecting such information from children. Research demonstrates that most children do not disclose CSA unless prompted, so well planned, nonsuggestive interviews can provide a catalyst for disclosures that might not otherwise occur.

When screening for CSA, clinicians need to discard some common myths. Although most consider sexual abuse to be perpetrated by adults, particularly parents and caregivers, abuse by siblings, older youth, and peers is quite common. For disabled youth, attention should be paid to institutional caregivers and to whether institutional policies are in place to protect and monitor children. The way questions are asked about history of CSA is also important. Simply asking about CSA may not be sufficient, because some children and parents may have a limited understanding of what CSA includes. Thus, more detailed questions without reference to "abuse" likely prompt more accurate information.

Epidemiological studies have also revealed the sad fact that for many CSA victims, *when it rains, it pours*. CSA often occurs in the midst of dysfunctional and inadequate caregiving that falls short in monitoring and protecting children, lacks the emotional sensitivity needed to detect child problems, and fails to nurture adequate communication needed to promote early disclosures. CSA victims often experience other

forms of childhood maltreatment, witness domestic violence, live in violent and impoverished communities, and experience other life adversities. They are also at increased risk of subsequent sexual victimization during their childhood, adolescence, and adult years. Thus, in addition to documenting CSA and other adversities, it is important to obtain historical and current information about parenting, with the goal of identifying past and current risk factors. Given the high risk of revictimization, assessment strategies must identify current child, family, and community risks risk factors.

Disclosure of CSA exposes children and youth to a host of family and system stressors. Family reactions to the disclosure are among the most potent predictors of child adjustment subsequent to CSA. Caretakers' inability to provide protection from further maltreatment leads to children's placement outside of the home with relatives or in foster or group homes. Alternative care can be stressful for youth, who may perceive these protective actions as punishment for their disclosure. Even when in alternate care, most youth continue to have contact with their families, and in some cases have ongoing contact with the accused. Furthermore, most CSA victims in CPS care eventually return home. In many cases, CSA leads to a number of criminal and child protection legal proceedings. Although most children do not testify in criminal or child welfare proceedings, those who do often find the experience very stressful. Even when the child is not directly involve in the process, criminal and child protection legal proceedings create stress for those involved in the child's care, which is often communicated to the child. Thus, the assessment process should include an examination of how family, alternative care, and system stressors have affected the child, and how the family, child, and system adapt to these stressors.

IMPACT OF SEXUAL ABUSE ON CHILD VICTIMS

Sexual abuse is not a disorder with a clearly delineated list of symptoms. Rather, sexual abuse is best considered a negative life event that poses significant risk for the development of a broad spectrum of behavioral and emotional problems. Because of the magnitude of problems that often result from sexual abuse, and because of the associated familial and social

contexts, sexual abuse has the potential to affect a number of developmental processes negatively, setting the stage for a lifetime of sequelae. In some cases, the sexual abuse was a defining event that led to abuse-related mental health concerns. However, many sexual abuse victims had behavioral, emotional, and developmental problems before the abuse occurred, or live within familial and/or community contexts that likely would have led to mental health problems even if the sexual abuse had not occurred. Thus, evaluating the impact of sexual abuse per se can be quite complex, particularly given developmental issues that affect manifestation of symptoms for preschoolers, latency-age children, and adolescents.

For the purposes of this chapter, sexual abuse effects are conceptualized at three levels. *Abuse-specific* symptoms are specifically linked with sexual abuse experiences, characterize a significant proportion of sexual abuse victims, and differentiate between sexual abuse victims and their nonabused peers, and other clinic-referred children. *Abuse-related* symptoms are linked with the sexual abuse experience, characterize a significant proportion of sexual abuse victims, and differentiate between sexual abuse victims and their nonabused peers, but either do not differentiate between sexual abuse victims and other, clinic-referred children or are likely not caused by the sexual abuse, but rather by individual, family, and community risk factors associated with sexual abuse (e.g., family dysfunction, increased negative affect). *Pathological changes in psychological processes* refer to changes resulting from exposure to sexual abuse that have implications for adjustment problems in general, such as changes in affect regulation ability, cognitive style, or coping reactions.

In the past, it was difficult to assess the impact of sexual abuse during childhood and adolescence due to ethical and methodological difficulties associated with surveying large populations of children and adolescents on the topic. As a result, up until the past decade, most studies that investigated the impact of CSA on children and adolescents relied upon assessment of sexual abuse victims identified through CPS agencies or clinical services, and were thus based on small, nonrepresentative samples. Several large-scale representative surveys of children and adolescents that are now available provide evidence of the impact of sexual abuse in the general population of children,

particularly for those 10 years of age and older. These include the National Youth Victimization Prevention Study ($n = 2,000$; Boney-McCoy & Finkelhor, 1996), the Developmental Victimization Survey ($n = 2,030$; Turner, Finkelhor, & Ormrod, 2006); the National Survey of Adolescents ($n = 4,023$; Danielson, de Arellano, Kilpatrick, Saunders, & Resnick, 2005; Kilpatrick et al., 2003), the Youth Risk Behavior Survey ($n = 13,601$; Howard & Wang, 2005), and a large survey of U.S. high school students in the Midwest ($n = 17,465$; Luster, Small, & Lower, 2002). As well, several large-scale longitudinal studies have surveyed children and adolescents over time and linked mental health adjustment with history of sexual abuse and other forms of maltreatment. These include a New Zealand high school sample ($n = 1,019$; Fergusson, Horwood, & Lynskey, 1996), a South Carolina high school sample ($n = 3,283$; Cuffe et al., 1998), and a New York sample followed from age 5 through adulthood ($n = 776$; Brown, Cohen, Johnson, & Smailes, 1999). One additional study surveyed a large, multisite sample of clinic-referred children and adolescents ($n = 3,479$; Walrath et al., 2003).

Abuse-Specific Symptoms

Posttraumatic Stress Disorder

The literature on posttraumatic stress disorder (PTSD) (see Fletcher, Chapter 9, this volume) provides an important research and clinical framework for conceptualizing sexual abuse sequelae. The fourth, text revision edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; American Psychiatric Association [APA], 2000) supports consideration of PTSD as a possible diagnosis for CSA victims; in fact, in defining trauma, it includes “developmentally inappropriate sexual experiences with or without threatened or actual violence or injury” (p. 464). A diagnosis of PTSD requires four conditions: (1) experience of an event posing serious threat, to which the individual responds with great helplessness, fear, or horror (criteria A1 and A2, respectively); (2) three sets of symptoms—reexperiencing aspects of the trauma (criterion B), avoidance strategies that serve as a means to escape from trauma-related stimuli (criterion C), and increased autonomic arousal (criterion D); (3) duration of symptoms for at least a 1-month period beyond the initial 3-month

posttrauma period (criterion E); and (4) significant interference with the ability to function effectively at home, with friends, and/or at work or school (criterion F). DSM-IV-TR notes that young children may differ from older children and adults in the manifestation of PTSD symptoms. Young children may express intrusive thoughts through thematic, repetitive play. They may complain of frightening dreams but be unable to describe or recognize the content as trauma-related. Finally, rather than describing flashbacks, young children may reenact their trauma through play or art (APA, 2000).

In a prevalence study with a community sample of older adolescents, experiencing rape or CSA increased the odds of developing PTSD by 49% (Cuffe et al., 1998). Several additional studies with large, representative samples of older children and adolescents have also demonstrated relatively high levels of PTSD symptoms among sexually abused boys and girls compared to their nonabused peers (Bal, Van Oost, de Bourdeaudhuij, & Crombez, 2003; Boney-McCoy & Finkelhor, 1995, 1996; Danielson et al., 2005; Kilpatrick et al., 2003). Other studies of identified sexual abuse victims indicate that between 36 and 60% meet diagnostic criteria for PTSD (Bal, de Bourdeaudhuij, Crombez, & van Oost, 2004; Dubner & Motta, 1999; Kendall-Tackett, Williams, & Finkelhor, 1993; McLeer et al., 1998; Wolfe & Birt, 2005a; Wolfe, Sas, & Wekerle, 1994). Research with clinical and CPS samples have demonstrated relatively high rates of PTSD compared to nonabused controls via a number of assessment strategies, including parent reports (e.g., Wells, McCann, Adams, Voris, & Ensign, 1995); child reports (e.g., Dubner & Motta, 1999; Friedrich, Jaworski, Hexschl, & Bengston, 1997; Wolfe & Birt, 2005a), social worker checklists (e.g., Mennen & Meadow, 1993), chart reviews (e.g., Kiser, Heston, Millsap, & Pruitt, 1991), and diagnostic interviews (e.g., McLeer, Deblinger, Henry, & Orvaschel, 1992; McLeer et al., 1998). Compared with other negative life events in childhood and adolescence, such as serious accidents, natural and man-made disasters, and even physical abuse, sexual abuse is particularly potent in provoking PTSD symptomatology (Bal, Crombez, Van Oost, & Debourdeaudhuij, 2003; Bal et al., 2003; Boney-McCoy & Finkelhor, 1996; Cuffe et al., 1998; Dubner & Motta, 1999). Despite relatively high rates of negative life events among

clinic-referred children, PTSD is more prevalent among CSA victims than among other clinic-referred children and adolescents (McLeer et al., 1998; Wolfe & Birt, 2005a) and as compared to those who experience other types of maltreatment (Runyon & Kenny, 2002). Even when prior mental health and quality of parent-child relationships were controlled, Boney-McCoy and Finkelhor (1996) found that sexually abused youth reported more PTSD symptoms than their nonabused peers, revealing a medium effect size.

A number of factors have been related to the development of PTSD among sexually abused children and adolescents. Younger children and girls appear to be at increased risk of developing PTSD subsequent to sexual abuse (Dubner & Motta, 1999; Feiring, Taska, & Lewis, 1999, 2002; Kaplow, Dodge, Amaya-Jackson, & Saxe, 2005; Wolfe & Birt, 2005a; Wolfe, Gentile, & Wolfe, 1989). Young children may have limited ability to cope effectively with stressors and may be more negatively affected than older youth by sexually abusive acts, the aftermath of disclosure, and involvement in the legal system (Quas et al., 2005). Because of developmental issues, young children may experience more system-induced stressors associated with abuse verification, pretestimony interviews, and court-related adverse experiences, such as continuances, lack of corroborative evidence, defendant acquittal, case being dropped, and having to testify repeatedly (Quas et al., 2005).

Surprisingly, despite considerable variability in individual experiences considered under the umbrella of sexual abuse, most studies have found that these variations add little to the prediction of PTSD symptoms (e.g., Bal et al., 2004, 2005; Feiring, Taska, & Lewis, 2002; Kaplow et al., 2005; Naar-King, Silvern, Ryan, & Sebring, 2002; Spaccarelli, 1995; Wolfe & Birt, 2005a). Indeed, although some studies have identified some aspects of sexual abuse as predictors of PTSD (e.g., age at onset, sexual abuse frequency and duration, and relationship to perpetrator; Ruggiero, McLeer, & Dixon, 2000), no single abuse characteristic, or set of characteristics, has shown a consistent pattern of predicting PTSD across studies. Instead, experiencing other negative life events appears to increase the risk of developing PTSD subsequent to sexual abuse (Cuffe et al., 1998). This is particularly true for youth who experience both sexual and physical abuse (Kiser et al.,

1991; Wolfe & Birt, 2005a). As noted earlier, multiple forms of maltreatment are indicative of serious family dysfunction (Fleming et al., 1999). Indeed, experiencing both sexual and physical abuse has been linked with family alcohol and other problems, and more severe forms of abuse (Stevens et al., 2005).

Goodman and colleagues (1992) and Quas and colleagues (2005), studying a large sample of sexually abused children slated for courtroom testimony, found that the strongest predictor of PTSD-related symptoms in both the short run (subsequent to disclosure and legal proceedings) and the long run (on average 10 years later) was testifying in multiple court proceedings, particularly when victims had to testify repeatedly about very serious forms of sexual abuse. In addition, testifying only once and waiting in court to testify (but not actually testifying) were also associated with long-term PTSD symptoms. Quas and colleagues speculated that such events are not only traumatic but also promote self-perceptions of being a victim. Not testifying in court can be detrimental as well, particularly when offenders do not plead guilty or when they receive a lenient sentence, leading to perceptions that the legal system is unfair.

One reason that abuse-specific factors do not add to the prediction of PTSD may be that even within specific researcher-defined categorizations there may be considerable untapped variation in abuse severity. For example, intra-familial abuse typically includes abuse by resident father figures, but also often includes family members who have limited contact with the victims (e.g., estranged father figures), and individuals who are not emotionally close with the victim (e.g., nonresident uncle). In some studies the severity of the abuse is captured by penetration, which sometimes includes penile-vaginal penetration, as well as fellatio and digital penetration. However, even fine gradations of trauma dimensions do not necessarily enhance the predictive power of abuse variables (Spaccarelli, 1995; Wolfe & Birt, 2005a), a finding that is mirrored in research with other types of violence exposure (Jaycox, Marshall, & Orlando, 2003).

It is possible that subjectively reported peritraumatic reactions and retrospective cognitive appraisals more accurately reflect the stress associated with negative life events such as sexual abuse, and are thus more closely linked with the development of PTSD. However, appraisals

of events may reflect not only the stressfulness of the trauma but also individual differences in cognitive and coping styles, and trauma-related sequelae. Peritraumatic reactions are the thoughts, emotions, and behaviors experienced at the time of the trauma. DSM-IV-TR PTSD criterion A2 refers to the peritraumatic reactions of feeling great horror, fear, and helplessness at the time of the traumatic event, and dissociative peritraumatic reactions are part of the diagnostic criteria for acute stress disorder. Nonetheless, peritraumatic reactions have generally not been formally assessed until recently, and even when assessed, only a limited range of peritraumatic response options, such as peritraumatic dissociation, has been tapped. For sexual abuse, studies have thus far only assessed peritraumatic reactions retrospectively; as such, recollections of past peritraumatic reactions may be affected by current cognitive style and abuse-related symptomatology. Even so, with nonabusive traumatic events such as vehicle accidents and disasters, evidence suggests that peritraumatic reactions are more potent predictors of PTSD than specific trauma factors (Ehler, Mayou, & Bryant, 2003; Shannon, Lonigan, Finch, & Taylor, 1994; Stallard, Velleman, & Baldwin, 1998). Likewise, Wolfe and Birt (2005b) found that children's retrospective recollections of their peritraumatic reactions to their sexual abuse experiences were more powerful predictors of PTSD than specific abuse characteristics, such as abuse severity, force, frequency, duration, and relationship to the perpetrator. Interestingly, peritraumatic reactions were not predicted by abuse characteristics. Negative cognitive appraisals of stressors can have implications for long-term adjustments. In the Quas and colleagues (2005) 10-year follow-up of child victims-witnesses, emotional reactions to the courtroom experience predicted later PTSD, greater internalizing symptoms, and more negative attitudes toward the legal system.

In addition to event appraisals and peritraumatic reactions, PTSD has been linked with both general and abuse-specific attributions and coping. Two studies have linked general attributional style for negative events with PTSD (Feiring, Taska, & Lewis, 2002; Runyon & Kenny, 2002). Specifically, the risk of developing PTSD has been linked with general tendencies to attribute negative life events to factors that are internal, global, and stable. Abuse-specific attributions of self-blame, guilt,

and shame have also been linked with PTSD (Feiring, Taska, & Chen, 2002; Feiring, Taska, & Lewis, 2002; Negrao, Bonanno, Noll, Putnam, & Trickett, 2005; Spaccarelli & Fuchs, 1997; Wolfe et al., 1994; Wolfe, Gentile, Michienzi, Sas, & Wolfe, 1991). Furthermore, positive changes in abuse-related attributions have been linked with improvements in PTSD symptoms (Feiring, Taska, & Lewis, 2002).

Attributional style may affect adjustment in part by affecting the ways that individuals cope with stressors (Muris, Schmidt, Lambrichs, & Meesters, 2001). Several studies have demonstrated links among sexual abuse trauma, emotional distress, and ineffective coping strategies, such as wishful thinking, inappropriate tension reduction strategies (eating, drinking, drug use, sex), emotion-focused coping, and avoidant coping (Bal, Crombez, et al., 2003; Bal, Van Oost, et al., 2003; Chaffin, Wherry, & Dykman, 1997; Tremblay, Hebert, & Piche, 1999). Furthermore, Bal, Crombez, and colleagues (2003) found that avoidant coping mediated the relationship between sexual abuse and psychological distress. Similar mediating effects have been demonstrated with adult CSA survivors (Merrill, Thomsen, Sinclair, Gold, & Milner, 2001; Runtz & Schallow, 1997). Browne, Cloitre, and Linehan (2002) found that perhaps as a reflection of interpersonal trust issues adolescents in foster care with sexual and/or physical abuse histories were more likely to cope with stressful situations independently (without seeking social support or assistance from others), whereas their nonabused peers in foster care were more likely to seek support from peers.

As noted earlier, family support is one of the strongest predictors of resilience subsequent to sexual abuse (Chandy et al., 1997; Garbarino et al., 1992). For both intrafamilial and extrafamilial abuse, both preabuse and concurrent family functioning, particularly family cohesiveness, have been linked with PTSD symptoms (Bal et al., 2004; Boney-McCoy & Finkelhor, 1995, 1996).

COMPLEX TRAUMA AND COMPLEX OR TYPE II PTSD

Early efforts to conceptualize sexual abuse sequelae as PTSD were criticized for failing to account for the full range of symptoms described for sexually abused children (Finkelhor, 1990) and for adult survivors of abuse (Herman, 1992). Terr (1987) recognized that

CSA differs from many forms of trauma, in that it is often repeated over long periods in secret, thereby requiring victims to adapt to their abusive situation via strategies that are either developmentally or psychologically inappropriate or damaging, particularly when these strategies are generalized beyond the abusive situation. Terr described these adaptations as psychogenic numbing, dissociation, distrust, relationship problems, suicidal ideation, rage, and "unremitting sadness." Terr (1987, 1991) proposed a dual classification for trauma-related disorders: Type I disorders follow exposure to a single traumatic event, whereas Type II disorders result from multiple or longstanding experiences with extreme stress (e.g., sexual abuse). Although patients with both types of PTSD are thought to experience core PTSD symptoms (reexperiencing, avoidance, and hyperarousal), those with Type II PTSD also develop atypical coping patterns and psychological symptoms that eventually become integrated into their personalities. Similar dual conceptualizations of PTSD emerged simultaneously within the adult literature (e.g., Herman, 1992).

Over the years, the term "complex trauma" has been used to describe the experience of multiple, chronic, and prolonged traumatic circumstances, typically within the realm of childhood maltreatment. As such, these events are often interpersonal in nature, begin in early life, and have the potential to disrupt normal developmental pathways (van der Kolk, 2005). The complex and intertwined combination of early life traumas, and emotional maltreatment and neglect, has been linked with multiple adverse outcomes. Indeed, Cook and colleagues (2005) identified seven areas of impairment linked with childhood complex trauma: attachment problems, psychophysiological concerns (e.g., medication problems, somatization), affect regulation, dissociation, and poor behavioral control, cognition, and self-concept. Given the unique characteristics and outcomes of complex trauma, van der Kolk (2005) suggested a new diagnostic classification, developmental trauma disorder.

Nonetheless, the idea of an alternative diagnostic classification requires considerable study. Currently, symptom variations are often treated diagnostically and therapeutically as comorbid conditions; some patients with PTSD have concurrent diagnoses such as MDD, dissociative identity disorder, and/or borderline

personality disorder (Shalev, Friedman, Foa, & Keane, 2000). This approach has considerable validity, because several of the common comorbid diagnoses have well developed conceptual underpinnings and empirically supported treatment strategies that inform the study and treatment of trauma effects. Some symptoms identified for developmental trauma disorder may be conceptualized as extreme manifestations of PTSD, and may simply require the addition of refinements to the description of symptom criteria. For example, affect dysregulation and somatization symptoms might be considered part of the PTSD hyperarousal domain, and some dissociative symptoms might be considered extreme manifestations of the avoidance domain. Some symptoms of complex PTSD may be associated with conditions other than trauma, such as dysfunctional family backgrounds and premorbid propensities to cope with life stressors in ineffective ways.

Dissociation

Dissociation is an ephemeral phenomenon that has been difficult to study. Because it is an intrapsychic event that affects one's ability to self-monitor internal states, dissociation is difficult to document by self-report, particularly by children, and only the behavioral manifestations of dissociation are observable by others. In the face of trauma, dissociation can be considered a defensive process that enables a child to avoid mentally the ongoing trauma that he or she cannot avoid physically (Terr, 1991; van der Kolk, van der Hart, & Marmar, 1996). If traumatic events and dissociative reactions occur repeatedly or continuously, dissociation can become a habit-like, unconscious and automatic response triggered by less severe day-to-day stressors, thereby affecting everyday information processing and functioning (Liotti, 1999; Post et al., 1998).

Dissociation is thought to have its roots in early childhood trauma, particularly sexual abuse, physical abuse, and neglect (Briere & Runtz, 1989; Chu & Dill, 1990; Hornstein & Putnam, 1992; Ogawa, Sroufe, Weinfield, Carlson, & Egeland, 1997; Sanders & Golas, 1991; Yeager & Lewis, 1996). In fact, one meta-analytic study demonstrated a strong relationship between sexual trauma and dissociative symptoms, with an effect size of 0.42 (van IJzendoorn & Schuengel, 1996). Family factors such as parental dissociation and lack of family

cohesion appear to contribute to the development of childhood dissociation (Bal et al., 2004; Coons, 1985), perhaps due to psychological unavailability of the parent or because the parent and child experienced simultaneous traumas (e.g., child and spouse abuse). Alternatively, parental dissociation has been linked with increased probability of child maltreatment (Egeland & Sussman-Stillman, 1996). Research into possible genetic contributions are limited, though it is possible that genetic predispositions (e.g., autohypnotic tendencies) define the boundaries of dissociative states available to a particular individual (Putnam, 1997).

Early childhood trauma may set the stage for dissociative disorders because of the extreme vulnerability of young children, who are more likely to experience extreme distress under frightening circumstances, or because young children appear to have innate dissociative abilities that dissipate as more effective coping strategies develop. For instance, Perry, Pollard, Blakley, Baker, and Vigilante (1995) described infantile dissociation as occurring when a caregiver is not available to rescue an infant from a fear-producing situation. If crying fails to summon support, the infant moves from a hyper-aroused condition to dissociation, reflecting either a “freeze” or “surrender” response.

The perpetuation and exacerbation of early dissociative processes disrupt normal processes that integrate different aspects of experience, resulting in the three main components of dissociation: memory disturbance, distortion of perceptions, and failure to develop a consistent and integrated sense of “self” and “identity” (Macfie, Cicchetti, & Toth, 2001; Waller, Putnam, & Carlson, 1996; Zayed, Wolfe, & Birt, 2006). Dissociative individuals often experience lapses in memory for personally experienced events, become so engrossed in an intrapsychic activity that awareness of ongoing events and surroundings is lost, and show variations in personality and behavior patterns across time and situation, as well as failure to integrate thoughts, sensations, and feelings associated with experiences. Dissociation is generally considered to fall along a continuum from typical everyday occurrences (e.g., intense thought absorption, lapses in memory when driving) to the most extreme form of dissociation, dissociative identity disorder (Ross & Joshi, 1992). In contrast, Waller and colleagues (1996) proposed that some dissociative symp-

oms are inherently pathological. Based on taxometric analyses of the Dissociative Experiences Scale with adults (Bernstein & Putnam, 1986), eight items were identified as pathological dissociation: finding oneself in a place and not knowing how one got there; finding new things among one’s belongings that cannot be accounted for; feeling as if one is standing next to oneself; not recognizing friends or family members; other people and objects not feeling real; feeling that one’s body does not belong to oneself; acting differently in different situations; and hearing voices.

Although the onset is believed to occur in early childhood, dissociative disorders are rarely diagnosed in children, perhaps because our current nosologies are based more on the adult than on the child literature. Indeed, Putnam, Hornstein, and Peterson (1996) noted that young children with dissociative symptoms typically do not meet diagnostic criteria for disorders such as dissociative identity disorder; they are more often given the diagnosis of dissociative disorder not otherwise specified. Children’s dissociative symptoms are often attributed to other causes. For instance, trance-like behaviors may be misdiagnosed as truancy, conduct problems, or moodiness (McElroy, 1992). Some dissociative symptoms, such as imaginary friends, may be interpreted as typical (McElroy, 1992). Often dissociation goes undiagnosed, because either symptoms are not evident at the time of assessment (Kluft, 1985) or other diagnoses are given, such as PTSD, MDD, schizophrenia, or borderline personality disorder (Coons, Bowman, & Milstein, 1988). Because children’s sense of self evolves and becomes more cohesive with age, the self aspect of dissociation may not be evident until adolescence or young adulthood. Perhaps with the development of more reliable and valid tools for defining and assessing dissociation in children, diagnostic practices will improve as well.

Depression, Learned Helplessness, and Cognitive Style

The most commonly investigated mental health problem subsequent to sexual abuse is depression. Because history of negative life events has long been linked with increased risk of depression (e.g., Ge, Lorenz, Conger, Edler, & Simmons, 1994; Nolen-Hoeksema, Girgus, & Seligman, 1992), it is not surprising that research has demonstrated increased risk of depression for sexual abuse victims. Numerous

studies have found higher prevalences of depressive symptoms and mood disorders among sexually abused youth compared to nonabused community controls (Boney-McCoy & Finkelhor, 1996; Brant, King, Olson, Ghaziuddin, & Naylor, 1996; Bryant & Range, 1996; Fergusson, Horwood, & Lynskey, 1996; Garnefski & Diekstra, 1997; Howard & Wang, 2005; Kilpatrick et al., 2003; Kiser et al., 1991; Koverola, Pound, Heger, & Lytle, 1993; Ligiezsinska et al., 1996; Luster et al., 2002; Mannarino & Cohen, 1996b; Runyon, Faust, & Orvaschel, 2002). Even after controlling for prior adjustment and parent-child relationship, sexual abuse victims show a four-fold increase in risk for depression subsequent to sexual abuse (Boney-McCoy & Finkelhor, 1996). As well, even when controlling for other types of adversities, including physical abuse, history of sexual abuse is linked with increased risk for depression (Fergusson, Horwood, & Lynskey, 1996; Luster et al., 2002). Indeed, like PTSD, history of child sexual abuse puts individuals at risk for depression more so than other negative life events, including history of neglect and physical abuse (Brown et al., 1999). In their longitudinal study of child sexual abuse victims, Brown and colleagues (1999) reported that one-third of sexual abuse victims met criteria for a depressive disorder in either adolescence or adulthood or both. One-third also had a suicide attempt. ORs for dysthymia and MDD for CSA victims were 9.74 and 3.17, respectively, whereas ORs were 5.71 for suicide attempt and 15.78 for repeated suicide attempts. Furthermore, compared to other clinic-referred youth, CSA victims are more likely to have a diagnosis of depression (Deblinger, McLeer, Atkins, Ralphe, & Foa, 1989; Kolko, Moser, & Weldy, 1988; Walrath et al., 2003).

PTSD subsequent to sexual abuse tends to be comorbid with other disorders, particularly major depressive episodes (Kilpatrick et al., 2003). Having experienced multiple forms of maltreatment increases the odds of having comorbid depression and PTSD. Using data from the National Survey of Adolescents, Danielson and colleagues (2005) found that 11% of depressed youth who had experienced sexual abuse had a comorbid diagnosis of PTSD, whereas among youth who experienced both sexual and physical abuse, comorbidity with PTSD was 34%. Comorbidity of PTSD and depression appears to be particularly common for girls and is charac-

terized by the depressive symptoms of anhedonia, worrying, loneliness, sleep and appetite disturbance, and difficulty making decisions, and by the PTSD symptoms of flashbacks and sleep disturbance (Runyon et al., 2002).

A number of factors have been linked to increased risk of depression among sexually abused youth. Unlike children, adolescents tend to have more depressive symptoms than PTSD symptoms (Feiring, Taska, & Lewis, 2002; Tebbutt et al., 1997). However, as in PTSD, girls show more symptoms of depression than do boys (Danielson et al., 2005; Feiring et al., 1999; Feiring, Taska, & Lewis, 2002; Runyon et al., 2002). A number of abuse-related factors have been linked to increased risk of depression, including abuse severity, physical coercion and assault during the sexual abuse, repeated episodes, and abuse by a family member (Danielson et al., 2005; Feiring, Taska, & Lewis, 2002; Garnefski & Diekstra, 1997). Having experienced other negative life events and/or additional forms of maltreatment, particularly physical abuse, has also been linked with increased depressive symptoms and suicidal ideation (Boney-McCoy & Finkelhor, 1995; Danielson et al., 2005; Garnefski & Diekstra, 1997; Naar-King et al., 2002). Furthermore, continued contact with the offender, which is more common with intrafamilial cases, is associated with long-term problems with depression and self-esteem (Tebbutt et al., 1997).

As with other populations, research with sexual abuse victims has demonstrated a link between depression and attributional style (Feiring, Taska, & Chen, 2002). Abuse-specific appraisals, including shame, have also been linked with depression (Danielson et al., 2005; Feiring, Taska, & Lewis, 2002; Spaccarelli & Fuchs, 1997). Family dysfunction, particularly maternal depression, has been linked with risk of depression and low self-esteem, in both the short and long run (Bal et al., 2004; Kelly et al., 2002; Meyerson, Long, Miranda, & Marx, 2002; Swanston et al., 2003; Tebbutt et al., 1997).

Sexual abuse victims show elevated risks for suicidal ideation and gestures, as well as completed suicides (Fergusson et al., 2000). Sexually abused boys are twice as likely as sexually abused girls to report suicidal ideation (Garnefski & Diekstra, 1997). Risk factors for suicidal ideation and behaviors among sexual abuse victims include family dysfunction and socioeconomic adversity (Fergusson et al.,

2000). Danielson and colleagues (2005) found that 70% of depressed youth with a history of both sexual and physical abuse experienced suicidal ideation.

Sexual Problems

Unlike most of the other problems associated with CSA, childhood sexuality problems have not been identified by DSM-IV-TR as constituting a specific disorder, possibly because there was relatively little research on the topic prior to the 1990s. However, considerable research has since documented the frequencies of various sexual behaviors across childhood and adolescence that now serve to help delineate between typical and atypical and problematic childhood sexual interests and behaviors. For children age 12 years and younger, sexual problems can be sorted into several categories (Friedrich et al., 1992): personal boundary deviations, exhibitionism, general role diversions, self-stimulation, sexual anxiety, excessive or precocious sexual interest, sexual intrusiveness, sexual knowledge, and voyeuristic behavior. For adolescents age 13 and older, other issues emerge (Friedrich, Lysne, Sim, & Shamos, 2004): excessive sexual interest and preoccupation, early onset of sexual activity, multiple sexual partners, sexual anxiety, excessive concern about appearance, divergent sexual interests, prostitution, sexual aggression, and behaviors that place them at risk for pregnancy, sexually transmitted diseases, including HIV infection, and victimization.

SEXUAL PROBLEMS DURING CHILDHOOD

Childhood is typically considered a period of relatively little sexual interest or sexual activities. However, surveys in the United States, Sweden, and Finland reveal that some sexual behaviors are fairly common in children, though the frequencies of various sexual behaviors vary with age (Friedrich, Fisher, Broughton, Houston, & Shafran, 1998). For example, among preschoolers, 44% of girls and 60% of boys engage in genital self-touching, up to 44% of boys and girls touch women's breasts, and 27% of boys and girls try to look at people when they are nude. Among children ages 6–9, it is still fairly common for boys and girls to engage in genital self-touching (40% and 21%, respectively) and to try to look at people when they are nude (20% for both

genders). From ages 10–12, common sexual behaviors include interest in looking at nudity in pictures or on TV (8.5% to 15% for boys and girls, respectively), and both genders show increased interest in the opposite sex (24–29%). Most sexual behaviors decrease across the span of childhood, including genital self-touching, attempts to look at people when they are nude, and touching women's breasts; however, interest in looking at nudity in media (TV, pictures) and interest in the opposite sex tend to increase with age. Several behaviors are unusual regardless of age, particularly overt sexual acts that involve others, such as invitations to engage in sexual acts, French kissing, oral-genital contact, touching animal genitalia, undressing playmates, making sexual sounds, pretend sexual play, and trying to have sexual intercourse. Other unusual sexual behaviors across all childhood ages are drawings that include sex parts, pretending that toys are having sex, and inserting objects in the vagina or rectum.

Chaffin, Letourneau, and Silovsky (2002) defined child sexual problem behaviors by the following conditions: (1) occur at greater frequency than developmentally expected; (2) interfere with child's development; (3) occur with coercion, intimidation, or force; (4) occur in association with emotional distress; (5) occur between children of divergent ages or developmental abilities; and (6) repeatedly recur in secrecy after intervention by caregivers. Research has clearly linked child sexual behavior problems to a history of child sexual abuse. Kendall-Tackett and colleagues (1993) estimated that approximately one-fourth of sexually abused children display such problems. However, the link between sexual behavior problems and CSA appears to be strongest among preschool-age children. Johnson (1988) reported that 72% of 4- to 6-year-olds with sexual behavior problems had a history of being sexually abused, compared with 42% of 7- to 10-year-olds and 35% of 11- to 12-year-olds. Numerous studies have documented sexual behavior differences between sexually abused children and their nonabused peers (see Friedrich [1993] for a review). More recently, Friedrich and colleagues (2001) demonstrated differences on the Child Sexual Behavior Inventory between sexually abused children and both normative and psychiatric controls.

In the Friedrich and colleagues (2001) study, sexual behavior problems were related to sev-

eral sexual abuse characteristics: penetration abuse by a family member, multiple perpetrators, and frequent and longer-term abuse. Family sexuality and child life stress (e.g., events such as parental separations, illnesses, and foster care) also contributed to predictions of sexual behavior problems. Others have linked child sexual problems to child characteristics such as impulsivity, aggression, poor interpersonal skills, and lack of empathy for others (Johnson & Felmeth, 1993; Rasmussen, Burton, & Christopherson, 1992). Several parental characteristics have also been identified: poor monitoring, family violence, life stress, and poor parent-child attachment (Pithers, Gray, Busconi, & Houchens, 1998; Rasmussen et al., 1992). Friedrich and colleagues (2005) found significant continuity of problematic sexualized behaviors over a 1-year period, which was most pronounced for children living in residential treatment centers (perhaps because these were the most disturbed children in the study).

Pithers and colleagues (1998), using cluster analyses with a sample of 6- to 12-year-old children with sexual behavior problems, identified five types of childhood sexual problems. *Sexually aggressive* children were characterized by being male, having conduct disorders, using aggression to gain victim submission, and perpetrating serious sexual offenses that included sexual penetration. Compared to other types of children with sexual behavior problems, sexually aggressive children were less likely to have been sexually or physically abused and, if they had been abused, had fewer abuse episodes. *Abuse reactive* children were also characterized by being male and as not only having high levels of externalizing problems but also parent-reported internalizing problems. They often had a high level of sexual and physical maltreatment, often displaying sexual problems soon after their own abuse. Abuse reactive children were distinguished by the frequency of their sexually abusive acts against others, which often included penetration and aggression to gain compliance. The *highly traumatized* group included both boys and girls who experienced extensive sexual and physical maltreatment. In many cases their first victimization occurred at a young age, and several children were abused by multiple perpetrators. Compared to the other groups, this group had the highest number of psychiatric diagnoses, including PTSD. Children in the highly traumatized group did not penetrate their victims. The

two remaining groups were overrepresented by girls, *rule breakers* and *nonsymptomatic*. Rule breakers tended to have high levels of externalizing behavior problems, but parents also reported high levels of internalizing symptoms. Although their histories reflected moderate levels of sexual and physical victimization, this group had a high proportion of extended families members identified as being a sexual offender. Although they often used aggression to gain victim submission, penetration was not common. For the nonsymptomatic group, most did not have psychiatric diagnoses, though one-fourth of children had attention-deficit/hyperactivity disorder (ADHD). Most did not have a history of physical abuse, though the group was mixed in terms of sexual abuse history. Half were reported to have additional sexual offenders within their extended families. Their sexual behavior problems typically did not include aggressive behavior or penetration, and they tended to have relatively few victims. Nonsymptomatic, highly traumatized, and abuse reactive children were the most responsive to a modified relapse prevention program, and rule breakers were responsive to a combination of modified relapse prevention and expressive therapy. However, the sexually aggressive children did not show benefits from either type of treatment approach.

SEXUAL PROBLEMS DURING ADOLESCENCE

Sexual Offending. Unfortunately, adolescent sexual offending is not uncommon. Adolescent offenders under age 18 are responsible for up to 41% of sexual assaults against children under age 12 (Finkelhor & Dziuba-Letherman, 1995; Snyder & Sickmund, 1999;), with the peak rate of offending between the ages 13 and 14 years (Canadian Centre for Justice Statistics, 1999; Snyder, 2000). Juvenile arrest records indicate that in a 1-year period, 0.19% of males between the ages 11 and 18 are arrested for a sexual offense (Federal Bureau of Investigation, 2000). Even in community samples, up to 2.6% of adolescent males report having used some form of physical force or threat in a sexual act (Ageton, 1983). The most frequently identified risk factors for adolescent and adult sexual offenses are being male and having been a victim of sexual abuse in childhood (Salter et al., 2003). Very little is known about adolescent female sexual offenders, primarily because they comprise only 5% of

adolescent offenders (Fehrenbach et al., 1986). Although sexual abuse is common among adolescent offenders, many have experienced other forms of maltreatment as well. Way, Satwah, and Drake (1999) found that 35% of adolescents who were reported to child welfare agencies for sexually abusing a child had documented histories of themselves being the victim of CSA, physical abuse, or neglect. Among those involved in a specialized treatment for adolescent offenders, 67.7% reported a history of sexual abuse, 72.3% reported physical abuse, and 39.6% neglect (Way et al., 1999).

It should be noted, however, that only a small percentage of sexually abused children go on to engage in sexually abusive behavior. Salter and colleagues (2003) identified the following risk factors, evident at a postdisclosure sexual abuse assessment, that predicted subsequent sexual offenses: female perpetrator (OR = 3.03), witnessed to severe forms of domestic violence (OR = 3.1), physical and supervisory neglect (ORs = 3.4 and 2.0, respectively), history of cruelty to animals (OR = 7.9), and history of encopresis (OR = 2.8). These results replicate those of other researchers, who also identified witnessing domestic violence, neglect, and abuse by a female relative as risk factors for sexual offending among sexually abused boys (Butler & Seto, 2002; Glasser et al., 2001; Widom & Ames, 1994). The pathway between CSA and later offenses as adolescents and adults may in part be a history of childhood sexual behavior problems. Burton (2000) found that among adolescents with an admitted history of sexual offending, 47% reported a history of childhood sexual problems. Those with offenses spanning childhood and adolescence had more extensive sexual abuse histories. Once adolescents are identified as sexual offenders, between 9 and 26% of them will have another sexual offense charge before age 18 (Caldwell, 2002; Hagan & Gust-Brey, 1999; Nisbet, Wilson, & Smallbone, 2004). Studies that have examined risk factors for reoffending have produced mixed results, but the evidence in general suggests that sexual recidivism is linked with evidence of sexual deviancy (e.g., phallometrically measured preference for prepubescent stimuli) and is more common among those who committed high-frequency and/or violent offenses (Caldwell, 2002).

Risky Sexual Behaviors. Both longitudinal and cross-sectional studies of sexual abuse vic-

tims indicate that sexual abuse prematurely sets in motion a series of sexual experiences that have serious lifelong consequences. Sexual abuse victims tend to be younger both when they begin consensual sexual activities and when they have their first consensual sexual intercourse experience (Fergusson, Horwood, & Lynskey, 1997; Miller, Monson, & Norton, 1995; Noll, Trickett, & Putnam, 2000; Wyatt, 1985), which places them at risk for early pregnancy (Woodward, Fergusson, & Horwood, 2001). Indeed, up to 66% of pregnant teens report a history of childhood sexual abuse (Boyer & Fine, 1991; Gershenson et al., 1989). Early teenage pregnancy has important implications of intergenerational transmission of child maltreatment. Teenage mothers tend to leave school early, to have fewer social and economic opportunities in life, to suffer greater social disadvantage, to be less competent and more punitive as parents, to suffer more depression, and to be more often the victims of spousal violence (Bardone, Moffitt, Caspi, & Dickson, 1996; Brooks-Gunn & Chase-Landsale, 1995; Woodward et al., 2001).

CSA victims are at increased risk for a number of sexually transmitted infections including chlamydia, gonorrhea, human papillomavirus (HPV), and HIV infection, as a result of both the abuse (Beck-Sague & Solomon, 1999; Gutman, St. Claire, Herman-Giddens, Johnston, & Phelps, 1992; Lindegren et al., 1998), and risky sexual behaviors (Saewyc et al., 2006; Steel & Herlitz, 2005). Adolescents who report a history of CSA and/or family violence are four times more likely than their peers to engage in sex without condoms, to have sex after drug use, and to have sex with multiple partners (Voisin, 2005). Furthermore, these risky behaviors are twice as prevalent among those who perceive that their peers engage in similar, risky sexual practices. Girls with a history of sexual abuse may find it particularly difficult to assert themselves in sexual situations, either to resist sexual advances or to ensure safe sexual practices (Brown, Kessel, Lourie, Ford, & Lipsitt, 1997; Johnsen & Harlow, 1996).

Sexual risk taking tends to occur within a broader constellation of risky adolescent behaviors that includes smoking, substance use, and involvement with a deviant peer culture (Breitenbecher, 2001; Donovan & Jessor, 1985; Willoughby, Chalmers, & Busseri, 2004). Drug dependence increases the risk of engaging in

risky sexual practices, due to both impaired decision-making and issues such as running away, homelessness, and prostitution associated with both substance use and sexual victimization. In a study of women engaged in prostitution, approximately 60% reported a history of CSA prior to entering prostitution, and 73% indicated that they began prostituting while they were still minors (Fraser, 1985). In a longitudinal investigation of sexual abuse victims, both childhood sexual abuse and neglect were linked with subsequent prostitution (Widom & Kuhns, 1996).

Noll and colleagues (2000) identified three trajectories for sexual development among adolescents/young women with prior histories of sexual abuse. Those who had been abused by their biological fathers, compared to other sexual abuse survivors, tended to be more preoccupied with sex, felt more pressure to have sex, were less effective in their birth control practices, and were more likely to have given birth at least once. These young women reported more male friends and fewer female friends, fewer nonpeer male relationships (father, grandfathers, etc.), and low satisfaction with male nonpeers. Concerns were raised that girls who were abused by their fathers were predisposed to be overly sexual in their relationships with boys, perhaps due to socialization within the father–daughter relationship. In contrast, those who were abused by multiple, nonparental family members and who experienced physical coercion showed less sexual preoccupation, had more negative attitudes toward sex, felt little pressure to engage in sex, and reported more responsible birth control use. Young women who had experienced abuse by one nonparental family member were no different than the comparison group in sexual attitudes and behaviors.

Sexual Revictimization. As noted previously, several literature reviews have highlighted the link between childhood and adolescent sexual abuse, and sexual assaults and subsequent assaults during adult years (Classen et al., 2005; Muehlenhard, Highby, Lee, Bryan, & Dodrill, 1998; Roodman & Clum, 2001). In addition to the invasiveness of the sexual acts, a number of other abuse and trauma variables have been linked with increased risk of subsequent victimization, including closer relationship to the perpetrator, abuse that was more frequent and of longer duration, use of force,

and experiencing other childhood traumas, particularly childhood physical abuse (Classen et al., 2005). Several family variables have also been linked with revictimization, including parent–child conflict, spousal violence, changes in caregivers, and drug and alcohol problems (Classen et al., 2005). Fergusson et al. (1997) found that family-related factors such as disadvantaged home environments, family dysfunction, and parental drug and alcohol problems partially mediated the link between child sexual abuse and subsequent victimization during late adolescence. Lifestyle factors appear to place sexual abuse victims at risk for revictimization (Breitenbecher, 2001). Consensual sexual intercourse at an early age, drug and alcohol problems, and depression also increase risk for revictimization during later adolescence (Breitenbecher, 2001; Fergusson et al., 1997). Wilson, Calhoun, and Bernat (1999) provided experimental evidence that risk of revictimization may be due in part to diminished perception of threat in high-risk situations.

Abuse-Related Symptoms

Externalizing Problems

Across childhood and adolescence, sexual abuse has been linked with increased risk of anger, aggression, and conduct problems. During the preschool and early primary school years, sexually abused children show increased anger and aggression, particularly among children who were very young when the abuse first occurred, and among those who experienced multiple types of maltreatment (English, Graham, Litrownik, Everson, & Bangdiwala, 2005; Lau et al., 2005). Externalizing behavior problems exhibited by sexually abused children can be quite serious. For example, Martin, Bergen, Richardson, Roeger, and Allison (2004) reported that history of sexual abuse is a significant risk factor for firesetting. It is unclear, however, whether these externalizing problems arise specifically from the abuse experiences or from the types of family stressors typical of children who show externalizing problems in general. In their nationally representative survey of children ages 2–11, Turner, Finkelhor, and Ormrod (2006) documented relatively high rates of externalizing problems for sexual abuse victims. However, the increase in externalizing problems was accounted for by

family dysfunction and other types of negative life events and adversities. Furthermore, Tebbutt and colleagues (1997), in their 5-year follow-up of sexual abuse victims, found that increased externalizing problems were primarily linked with family dysfunction.

During adolescence, the externalizing problems displayed by sexual abuse victims graduate to more serious conduct problems in the form of increased aggression, criminal behavior, and addiction-risk behaviors (Bagley & Mallick, 2000; Dube et al., 2006; Fergusson, Horwood, & Lynskey, 1996; Garnefski & Diekstra, 1997; Howard & Wang, 2005; Kilpatrick et al., 2003; Luster & Small, 1997; Luster et al., 2002; Turner et al., 2006). Garnefski and Diekstra (1997) found that history of sexual abuse increased the odds of these externalizing problems for girls 2.5 and 2.3 times, respectively, and for boys, 1.7 and 1.6. Sexually abused boys were particularly likely to report a combination of aggressive/criminal behavior and addiction-risk behavior compared to nonabused boys (OR = 20). Unlike children under age 11, increased problems with anger and aggression among adolescents appear to have direct links with the sexual abuse itself, even when family dysfunction and other life adversities are controlled (Quas et al., 2005; Spaccarelli & Fuchs, 1997; Turner et al., 2006).

Adolescent Substance Use

The link between substance use problems and history of sexual abuse is most pronounced for girls. As a whole, studies do not show elevated substance use problems for sexually abused boys compared to boys in the general population. In their review of this issue, Simpson and Miller (2002) found that adolescent girls who were victims of sexual abuse were overrepresented among females with alcohol and drug problems, regardless of whether the research was conducted with treatment seekers, medical clinic attenders, elementary or high school students, or general community dwellers. Even when other childhood adversities and family dysfunction were considered, history of sexual abuse continued to be a significant predictor of substance use problems for girls.

Eating Disorders

Despite some inconsistent findings across studies, both a literature review (Jacobi, Hayward, de Zwaan, Kraemer, & Agras, 2004) and a

meta-analysis of 53 studies (Smolak & Murnen, 2002) confirmed that CSA is a significant risk factor for both subclinical and clinical eating disorder symptomatology. However, it appears that eating disorder symptoms are not an abuse-specific outcome, but the relationship is mediated through abuse-related negative affect (depression, PTSD) and ineffective coping mechanisms (Hund & Espelage, 2005; Thompson & Wonderlich, 2004). Hund and Espelage (2005) found that both emotional distress and alexithymia mediated the relationship between history of sexual abuse and eating disorder symptoms in a sample of university women. Alexithymia reflects deficits in identifying, verbalizing, and understanding emotions, and inabilities in identifying emotional and physical sensations.

Self-Harm Behaviors

Self-harm behaviors refer to intentional self-injury without the direct intention to commit suicide (Briere & Gil, 1998) and often include repetitive behaviors that inflict superficial wounds, such as making cuts on the arms and other body parts. Superficial self-harm appears to have increased over the past decade (Boyce, Oakley, Brown, & Hatcher, 2001), with up to 15% of adolescents (Laye-Gindhu & Schonert-Reichl, 2005; Ross & Heath, 2002), 12% of university students (Favazza, DeRosear, & Conterio, 1989), and 4% of the general adult populations reporting a history of self-mutilating behavior (Briere & Gil, 1998). Research with adults has demonstrated a link between history of sexual and physical abuse and intentional self-harm behaviors (Low, Jones, MacLeod, Power, & Duggan, 2000; van der Kolk, Perry, & Herman, 1991; Yates & Carleson, 2003), relationships that continue to be apparent even after other negative childhood life events are controlled. However, at this point, the connection between intentional self-harm and history of child sexual or physical abuse has not been demonstrated with child or adolescent populations. With adults, intentional self-harm is often comorbid with a number of mental health problems, including borderline personality disorder, PTSD, depression, and dissociation, which in turn are all linked with histories of child sexual abuse. Surveys of self-mutilators reveal that the most common reason for intentional self-harm behavior is to gain emotional relief and to regulate emo-

tions (Browne et al., 2002), which may be maintained through the negative reinforcement associated with the subsequent reduction or termination of unwanted emotional states (Chapman, Gratz, & Brown, 2006; Nock & Prinstein, 2004).

Pathological Changes in Psychological Processes

Affect Dysregulation and Emotional Competence

Ford (2005) described childhood maltreatment as a “developmentally adverse interpersonal trauma,” noting that maltreatment may not only be traumatic but also may have the potential to alter biological, psychological, and interpersonal regulatory capacities that contribute to a host of child and adolescent problems. Psychophysiological research indicates that childhood maltreatment may negatively affect central nervous system development and functioning, impacting the ability to regulate emotional states (Glasser, 2000; Teicher, Yutaka, Glod, & Anderson, 1997). Affect regulation requires competence in coordinating responses across three systems—physiological, cognitive, and behavioral. Three components of emotional competence have been identified: (1) the ability to recognize emotions and communicate emotional states effectively; (2) the ability to understand the causes and consequences of emotional expressions, and the ability to respond effectively to one’s own emotions, as well as the emotional displays of others; and (3) the ability to regulate emotional expression and emotional experience within differing social and cultural contexts. Within the realm of typical social development, these skills have been linked to children’s social competence and psychological adjustment (Garber, Braafladt, & Weiss, 1995; Rubin, Coplan, Fox, & Calkins, 1995).

Concerns have been raised that child sexual maltreatment, particularly abuse that occurs within the context of family relationships, may disrupt children’s emotional development, as a function of not only the trauma associated with the abuse but also the family context in which abuse occurs (Cole & Putnam, 1992). From a functionalist perspective, atypical social contexts such as sexually abusive relationships and family environments associated with risk for sexual abuse result in atypical emotion management skills (Campos, Mumme, Kermoian,

& Campos, 1994); that is, emotion management strategies that effectively modulate affect in the abusive environment (e.g., decreased emotional awareness, suppression of emotional expression), may subsequently interfere with successful adaptations in other, nonabusive contexts. Research indicates that physically abused children are less able than their nonabused peers to encode and decode facial expressions, understand the dynamics behind emotionally arousing situations, or regulate emotions within the context of peer relationships (Camras et al., 1988; Rogosch, Cicchei, & Aber, 1995). Shields, Ryan, and Cicchetti (2001) studied a group of children who had experienced mixed forms of maltreatment (sexual abuse, physical abuse, and/or neglect) and a comparison sample during a summer camp experience. Camp counselors rated the maltreated children as more emotionally dysregulated, and peers rated them as less cooperative, and more disruptive and aggressive. The relationship between maltreatment and social adjustment was partially mediated by the children’s negative representations of caregivers and by their emotion regulation abilities.

One study specifically examined emotion management skills among intrafamilially abused girls in comparison to a nonabused control group (Shipman, Zeman, Penza, & Champion, 2000). Sexually maltreated girls had poorer understanding of emotions, more difficulty accurately appraising the causes and consequences of emotionally arousing situations, and more negative expectations about reactions to their own emotional expressions. They were less aware of their own emotions, showed more emotion dysregulation, and failed to respond to others’ emotional displays in a culturally appropriate manner. The results suggested that sexually maltreated girls may fail to attend to, process, and interpret emotional information, and that this failure then interferes with their ability to establish and maintain positive interpersonal relationships. For example, in response to questions about how to respond to negative emotional displays in others, maltreated girls were more likely to say that they would ignore the emotional displays or leave the situation. In contrast, their nonmaltreated peers were more likely to indicate that they would provide assistance or support. Thus, although avoidance strategies may protect an intrafamilially maltreated girl in the

course of conflict with her parents (i.e., it might be unsafe for her to confront either the perpetrator or the nonabusing parent), similar avoidance patterns with peers may interfere with her ability to establish relationships outside the maltreatment context.

Cognitive Style

As noted earlier, cognitive style has important implications for the development of a number of mental health problems, including PTSD and depression (Joiner & Wagner, 1995). Cognitive style appears to develop during the latency years and is influenced by the experience of both high- and low-magnitude negative life events (Compas, Ey, & Grant, 1993; Garber & Flynn, 2001; Gibb et al., 2001; Gibb, Alloy, Abramson, & Marx, 2003; Hankin, Abramson, & Siler, 2001; McGinn, Cukor, & Sanderson, 2005), and parenting style (Garber & Flynn, 2001; Stuewig & McCloskey, 2005). Even over the course of adolescence, negative life events continue to mold cognitive style (Garber & Flynn, 2001; Spence, Sheffield, & Donovan, 2002). Research with adults indicates that a history of childhood abuse, including sexual abuse, is particularly linked to negative cognitive style and risk for depression (Rose, Abramson, Hodulik, Halberstadt, & Leff, 1994).

Coping

Coping has been defined as “any and all responses made by an individual who encounters a potentially harmful outcome” (Silver & Wortman, 1980, p. 281). Causey and DeBow (1992) identified six coping factors. Two factors are considered effective (problem solving and seeking social support), and three are considered ineffective (distancing, internalizing, and externalizing). The sixth factor assesses perception of the event as controllable or uncontrollable. Causey and DeBow also highlight that coping is situation-specific, and that no single coping strategy is appropriate for every situation. For example, when a stressor is moderate and controllable, strategies intended to alter the situation are associated with lower levels of distress and fewer negative emotions (Hubert, Jay, Saltoun, & Hayes, 1988; Hyson, 1983). However, when a person is faced with high-stress, uncontrollable stressors, coping

strategies that reduce emotional distress or enable the person to avoid the stressors appear to be most effective (Altshuler & Ruble, 1989; Band & Weisz, 1988; Spirito, Stark, & Williams, 1988). For instance, distraction is a commonly used coping strategy when stressors are perceived as uncontrollable (David & Suls, 1999). Coping may also differ depending on the magnitude of the stressor. High-magnitude stressors, compared to low-magnitude stressors, tend to evoke more negative coping reactions (internalizing and externalizing) and fewer problem-solving reactions (Fair et al., 2006; Wolfe & Birt, 2003). Evidence also suggests that changes in coping over time, particularly utilization of social supports, are related to interim levels of adversity (Fair et al., 2006). Leitenberg, Gibson, and Novy (2004) examined differences in coping among undergraduate women as a function of childhood maltreatment. Women who reported more extensive childhood adversity (sexual abuse, physical abuse, witnessing domestic violence, having an alcoholic parent, and/or parental rejection) reported an increased reliance on disengagement methods of coping (wishful thinking, problem avoidance, social withdrawal, and self-criticism).

Implications for Clinical Assessment

As is evident from this review, CSA has numerous affects throughout the lifespan. Thus the assessment of CSA must be developmentally informed, multidimensional, and integrate historical and current contextual information with an array of emotional and behavioral symptoms and psychological processes. CSA sets in motion a number of negative mental health processes that have the capacity cumulatively to affect a broad range of adjustment concerns. Compared to other serious negative life events, CSA is strongly linked to the development of depression and PTSD, and early childhood abuse appears to sow the seeds of dissociative processes and disorders. CSA is linked with a number of sexuality problems, ranging from increased risk of sexual victimization to age-inappropriate interest in sexual activities, to sexual offending. These problems are exacerbated by disturbances in a number of psychological processes, including affect regulation skills, cognitive style, and coping strategies. In the following section, assessment strat-

egies are reviewed for each of these issues, with the goal of identifying important assessment strategies, methods, and tools.

ASSESSING SEXUAL ABUSE AND OTHER FORMS OF MALTREATMENT AND ADVERSITY

Inherent in conducting an assessment of a child who has been sexually abused is obtaining accurate background information relevant not only to the sexual abuse but also to other forms of maltreatment, trauma, and adverse childhood events, along with other types of family-based adversities. Given that many sexual abuse victims experience multiple types of maltreatment and adversity, broad-based assessment of negative life events is important to gain an understanding of factors that might contribute to child adjustment problems and have bearing on service delivery. Although there is growing awareness of the need to assess multiple forms of adversity, little attention has been paid to the development of psychometrically sound assessment tools for these purposes, particularly tools that are appropriate and feasible for clinical settings (Hanson, Smith, Saunders, Swenson, & Conrad, 1995). Indeed, given the complexity of child maltreatment and adversity, and the difficulty in obtaining such sensitive information on a large sample of children and youth, the task of developing these tools has been quite daunting, particularly because large sample sizes are required to address the many relevant issues adequately.

Due to unique risk factors and psychological outcomes, types of maltreatment need to be considered separately for both research and clinical purposes (Egeland & Sroufe, 1981; Higgins & McCabe, 2000); however, the reality is that many maltreated children experience multiple forms of abuse and adversity, and various combinations of different forms of abuse and adversity appear to have unique outcomes that are not accounted for by simply summing forms of maltreatment. Thus, when assessing the effects of a specific form of maltreatment, it is necessary to assess and consider the impact other forms of maltreatment and adversity. As well, it is important to assess the specific aspects of that particular form of maltreatment, and to consider how that form of maltreatment interacts with other forms of adversity to predict unique outcomes. Broad-based assessment strategies typically assess five types of maltreat-

ment: sexual abuse, physical abuse, emotional abuse, exposure to family violence, and neglect (see Crooks & Wolfe, Chapter 14, this volume). For each type of maltreatment, important details include the acts involved, the offender, the age when the events occurred and ended, the frequency and duration of the events, and whether there were any injuries and health, or developmental consequences directly linked with the maltreatment (Barnett, Manly, & Cicchetti, 1993; Hanson et al., 1995; Wolfe & Birt, 1997).

Developmental issues should also be considered, such as age of first abusive episode and continuity of abuse across the preschool, latency, and adolescent years. For sexual abuse, details about the disclosure process are important, including how the abuse was discovered, to whom the child disclosed (if at all), and whether any CPS, family, and/or criminal legal matters have occurred, are planned, or are in progress. To assess and control comprehensively for other forms of adversity, exposure to nonmaltreatment negative life events should be assessed, as well as family-based risk factors. Many sexually abused children have complex and chaotic backgrounds that necessitate careful history taking; details about biological parents and stepparents, parental separations, past and current living arrangements, and school placements should all be assessed. As noted earlier, caregiver mental health, substance abuse problems, and history of maltreatment have important implications for the adjustment of sexual abuse victims and should also be assessed.

Whenever possible, it is wise to solicit historical data, and maltreatment and adversity information, from multiple sources. In most cases, abuse-related information reported by parents, medical personnel, CPS, and children themselves is consistent and reliable (Kaufman, Jones, Stielglitz, Vitulano, & Mannarino, 1994; McGee, Wolfe, Yuen, Wilson, & Carnochan, 1995). However, Kaufman and colleagues (1994) found that medical records and parent reports often yielded information about abuse severity and other forms of abuse that was not available in CPS files. For example, CPS files revealed that 77% of their sample of sexually abused children and adolescents had experienced emotional maltreatment; when medical, parent, and CPS records were all surveyed for each case, 98% of cases revealed evidence of emotional maltreatment.

Broad-Based Assessment of Child Maltreatment

Chart Reviews

The History of Victimization Form (HVF; Wolfe, Gentile, & Bourdeau, 1986) was designed for completion through CPS chart reviews, supplemented with information from other sources, such as parents, mental health agencies, and children and adolescents, as appropriate. The format was designed to provide the greatest level of detail possible about history of maltreatment, with the idea that users can identify dimensions of abuse relevant for particular purposes. The HVF assesses six sexual abuse dimensions: Severity of Sexual Acts, Use of Coercion or Force, Relationship to the Perpetrator, Number of Perpetrators, and Estimates of Frequency and Duration. Severity of Sexual Abuse, Use of Coercion or Force, and Relationship to the Perpetrator are rated on a Gutman-type scale, with the most serious level of abuse recorded. The number of perpetrators is recorded, along with estimates of the duration and frequency. Frequency of abuse is particularly difficult to ascertain from chart reviews, so estimates are gathered by determining the duration of abuse multiplied by an estimate of frequency within a time period. For example, a child may have said it occurred for a 3-month period when her mother went to play bingo once a week, so the estimate for frequency would be 12. Physical abuse, neglect, emotional maltreatment, and exposure to family violence are also assessed in a similar fashion, with some slight variations relevant to the type of maltreatment considered. In addition to detailed information about each form of maltreatment, the HVF also solicits background information about the child's disclosure and legal status, and the family's involvement with CPS.

Complex measurement systems such as the HVF yield a lot of information, but reduction of variables into meaningful constructs has been a challenge. The majority of research using the HVF has focused on sexual abuse victims, as have psychometric analyses. Based on two separate samples, principal component analyses have yielded two theoretically meaningful factors (Birt, 1996; Gentile, 1988): Severity (a combination of severity, coercion, and number of perpetrators) and Course (a combination of duration, frequency, and relationship to perpetrator). Relationship to perpetrator appears to link with duration and frequency, be-

cause familial abuse tends to occur more frequently over longer durations. These two dimensions have important theoretical relevance, since PTSD and other abuse-related sequelae appear to be related to both the intensity of the trauma and the duration and course of the abuse. Although detailed background information is important for clinical purposes, concerns have been raised about the efficiency of detailed chart reviews to gather abuse information systems for research purposes. Relative to the extensive time required to review files, the incremental predictive power of fine-grain details appears to be limited. Indeed, research with the Record of Maltreatment Experiences (ROME; McGee, Wolfe, & Wilson, 1990), an abbreviated version of the HVF, found that simple ratings of maltreatment severity were as predictive of outcomes as the detailed ROME recordings (McGee et al., 1995).

The most researched maltreatment assessment tool for children under 12 is the Maltreatment Classification Scheme (MCS; Barnett et al., 1993), which has been adapted for use by LONGSCAN, a consortium of five longitudinal studies of child abuse and neglect conducted at several sites across the United States (Runyan et al., 1998). At all sites, assessments are planned for ages 4, 6, 8, 12, 14, 16, and 20 years; for the most recent publications, the sample totaled 1,435 children and their families (English et al., 2005). The MCS was originally developed to collect information from CPS records; LONGSCAN's adapted version is referred to as the Modified Maltreatment Classification Scheme (MMCS). The MCS assesses severity of incidents within each subtype of maltreatment, frequency and chronicity, length of CPS involvement, developmental period during which the events occurred, type and number of placements outside the home, and the perpetrators of the incident. Within the major forms of maltreatment, different subtypes are recorded. For example, the Neglect scale is subdivided into Lack of Supervision, Moral/Legal/Educational Maltreatment, and Failure to Provide subscales; within Failure to Provide, details are provided as to whether the concern is related to food, clothing, or shelter. At each level of maltreatment, severity is rated on a 5-point, Gutman-like scale based on a combination of caretaker actions (or lack thereof) and impact on child (e.g., weight loss for neglect). The Sexual Abuse subscale has the following hierarchical designations: (1) Child is exposed

to explicit sexual stimuli or activities but not directly involved (e.g., child is exposed to pornography, sexual activity, sexual talk in his or her presence); (2) child is invited to engage in sexual activity and/or exposed to caretaker's genitals; (3) offender fondles the child or has the child sexually touch him or her; (4) attempts and actual penetration of child, including coitus, oral sex, anal sex, or any other form of sodomy; and (5) intercourse involving restraint, weapons, brutality, or physical force; prostitution of child. The MCS is available in Barnett and colleagues (1993), and the MMCS LONGSCAN version is available at www.iprc.unc.edu/longscan.

As noted earlier, these complex systems are difficult to reduce to parsimonious, meaningful constructs. In a special issue of *Child Abuse and Neglect* (English, Bangdiwala, & Runyon, 2005), several articles addressed questions related to calculation of abuse type, severity, and chronicity using LONGSCAN data for assessment of children at ages 4 and 8. Overall, despite concerns to the contrary (e.g., McGee et al., 1995), findings supported the importance of preserving fine gradations in abuse information when examining the links between maltreatment and outcome. Lau and colleagues (2005) found that differentiation among multiple maltreatment type combinations was particularly effective in predicting multiple child outcomes (e.g., Child Behavior Checklist [CBCL] total, Internalizing, and Externalizing scores [Achenbach & Rescorla, 2001]; Trauma Symptom Checklist for Children [TSCC; Briere, 1996, 2006a] Posttraumatic Stress and Anger scores). Specifically, the co-occurrence of multiple types of maltreatment was robustly related to multiple outcomes, particularly when sexual abuse was involved. Furthermore, Litrownik and colleagues (2005) found that preserving severity ratings within different types of maltreatment was the most effective strategy for predicting a broad range of outcomes (e.g., CBCL broad-band scores, Vineland Adaptive Behavior Scales [Sparrow, Balla, & Cicchetti, 1985] Socialization scores; TSCC Anger scale) compared to both an amalgamated score that combined severity rating across maltreatment types or the highest rating received across different maltreatment types. The maximum severity by type strategy yielded five maltreatment severity scores, based on the highest severity rating of reports within the five maltreatment domains during a specified pe-

riod of time. This strategy has a conceptual advantage, because different forms of maltreatment are likely to have different types of outcomes (e.g., the ultimate effect of physical abuse is death, whereas the ultimate effect of emotional maltreatment is psychological trauma; Manly, 2005).

In contrast, it appears that chronicity of maltreatment is best considered by combining different abuse subtypes to form one chronicity variable. English and colleagues (2005) identified five progressively detrimental levels of chronicity: situational, limited episodic, limited continuous, extended episodic, and extended continuous). They found that the more developmental periods with any form of maltreatment reported, the more child externalizing behavior problems. Likewise, anxiety and anger were less pronounced for children with developmental periods that were free from maltreatment. These findings mirror those of Bolger, Patterson, and Kupersmidt (1998; Bolger & Patterson, 2001), who found that chronically maltreated children are less popular with peers, regardless of subtype or severity. Evidence also links chronic maltreatment to aggression, and aggression mediated the link between chronic maltreatment and peer rejection (Bolger & Patterson, 2001; Manly, Cicchetti, & Barnett, 1994).

Parent Reports

The Abuse Dimensions Inventory (ADI; Chaffin, Wherry, Newlin, Crutchfield, & Dykman, 1997) was designed to be completed by caregivers in a semistructured interview format, though it has subsequently been used to gather information from CPS workers (Silovsky & Niec, 2002). The ADI has six sections: physical abuse (12 items), sexual abuse (13 items), force or coercion used to gain submission to sexual abuse (9 items), force or coercion used to gain secrecy about either physical or sexual abuse (6 items), role relationships between child and abuser (9 relationships identified), and postdisclosure reactions abusers might express regarding admission and blame (5 items). Rank ordering of items for severity was based on a survey of mental health professionals with specialization in child abuse, with the following rank order from least to most serious for sexual abuse: (1) sexually suggestive talk, hugs, or kisses; (2) exposure to pornography, exposure of genitals, or voyeurism; (3)

fondling of child over clothes; (4) fondling of child under clothes; (5) simulated intercourse over clothes; (6) simulated intercourse under clothes with no penetration, having child masturbate abuser; (7) abuser oral contact with child genitals; (8) child required to have oral contact with abuser's genitals; (9) digital or object penetration; (10) vaginal or anal intercourse, including unsuccessful attempts; (11) paraphilic sex (e.g., urine, feces, bondage) or prostitution; and (12) ritual or satanic abuse or sexualized torture. Interrater agreement was calculated based on 25 interviews that were audiotaped for coding by four independent raters. The overall mean kappa was .80, ranging across scales from .65 to 1.00. Factor analyses of 136 ADIs yielded four factors: Sexual Abuse Severity and Coercion, Sexual Abuse Duration and Number of Events, Physical Abuse Severity and Coercion, and Physical Abuse Duration and Number of Events. Role relationship and abuser's reaction did not load heavily on any factor. In a subsequent study, ADI sexual abuse severity ratings correlated with child-reported PTSD symptoms (Chaffin & Shultz, 2001).

Child and Adolescent Self-Reports

Large-scale epidemiological studies have necessitated the development of assessment tools for children and adolescents to determine prevalence of maltreatment, victimization, and adversity. The Juvenile Victimization Questionnaire (JVQ; Finkelhor et al., 2005; Hamby & Finkelhor, 2001, 2004) has been used as a self-report measure for children and youth age 8 years and older. A caregiver version uses similar wording, so that it is directly comparable to the youth report version, and can be used for children under the age of 8. The JVQ assesses 34 offenses against youth in five areas: Conventional Crime (assaults, property crimes), Child Maltreatment (physical, sexual, and emotional abuse, neglect, family abduction/custodial interference), Peer and Sibling Victimization (assaults and property offenses), Sexual Assault (rape and sexual assaults attempted or completed, flashing, sexual harassment, and statutory sexual offenses), and Witnessing and Indirect Victimization (domestic violence, abuse of a sibling, community violence, civil disturbances and riots, and war-zone violence). Thus far, the JVQ has only been used to assess 1-year incidence data, so it is un-

clear how it would work assessing lifetime maltreatment experiences. The JVQ takes 20–30 minutes to complete, depending on the number of victimizations reported. Following screener questions, more in-depth information is obtained, including perpetrator characteristics, use of a weapon, injuries, and co-occurrence of the event with another reported event (in case one event falls into more than one category).

The Child Trauma Questionnaire (CTQ), perhaps the most commonly used self-report measure of childhood victimization, is a 70-item, Likert-like self-report inventory (Bernstein & Fink, 1998; Bernstein et al., 1994) that yields five subscales: Emotional Abuse, Physical Abuse, Emotional Neglect, Sexual Abuse, and Physical Neglect. Although originally developed for adults, it has been used with youth as young as 12 years. The five subscales are based on two factor analyses, one with adults and a second with adolescents. For the adolescent study, the CTQ demonstrated good sensitivity and specificity with known maltreatment information (Bernstein, Ahluvalia, Pogge, & Handelsman, 1997). Bernstein and colleagues (2003) created a shortened, 28-item version of the CTQ. Using confirmatory factor analyses, results revealed that the five scales were a good fit for the data, which was true with several samples, including adolescent inpatients, adult substance users, and a community sample that provided normative data. As well, the shortened version demonstrated good convergent and discriminant validity, with clinician ratings based on known information about patients.

The Traumatic Events Questionnaire—Adolescents (TEQ-A; Lipschitz, Bernstein, Winegar, & Southwick, 1999), a 46-item self-report questionnaire, uses a multiple-choice format to elicit details about six forms of traumatic experiences: Witnessing Home Violence, Witnessing or Being the Victim of Community Violence, Accidental Physical Injuries, Physical Abuse, and Sexual Abuse. The TEQ-A defines “sexual abuse” as sexual contact between a minor and an adult 5 years older or a peer 2 years older. A two-level gating system is used, with two initial sexual abuse questions: “When you were growing up, did anyone try to have some kind of sexual contact with you in a way that made you feel uncomfortable?” and “If so, how old was the person who did this?” Details of each sexual incident are then obtained, including the age of onset, duration, identity of

perpetrators, use of force, and exact nature of each traumatic experience. When adolescents' responses on the TEQ-A were compared to a best-estimate source (based on information from therapist interviews, chart reviews, and child welfare agencies), the agreement for sexual abuse was 88% ($\kappa = .75$) and physical abuse was 84% ($\kappa = .66$). Comparisons between the TEQ-A and the CTQ revealed that 71% of respondents who reported sexual abuse on the CTQ also reported sexual abuse on the TEQ-A; however, 35% of those above the clinical cutoff on the CTQ did not report sexual abuse on the TEQ-A ($\kappa = -.41$). Discrepancies between the two measures in reports of sexual abuse were more common among males, who reported less severe abuse experiences and fewer mental health problems. Thus, the CTQ is more sensitive than the TEQ-A in detecting sexual abuse of lesser severity. Lipschitz and colleagues (1999) suggested that the differences in format might account for the differences in reporting, in that the Likert-like format might facilitate reporting of less frequent and less distressing events, possibly including events that technically meet criteria for sexual abuse but are not considered by the respondent to have been abusive (e.g., sexual "initiation" of adolescent boys by an older female).

Several available life events checklists include items reflecting childhood maltreatment, as well as other types of negative life events and adversities. The Child and Adolescent Psychiatric Assessment (CAPA) Life Events Module (Costello, Angold, March, & Fairbank, 1998) was developed for use with the Great Smoky Mountain Epidemiological Study. Both high- and low-magnitude negative life events are assessed. The 15 high-magnitude events are death of close relative or friend; witnessing a traumatic event; natural disaster; diagnoses of a life-threatening or disabling physical illness; serious accident, fire, or exposure to a toxic agent; learning of a traumatic event affecting a close family member or friend; war, terrorism, or death or serious harm to someone else; physical violence by someone other than a family member; physical abuse by a family member; being kidnapped or held hostage; and sexual abuse, rape, and sexual abuse with coercion. Low-magnitude events include new child in home (if unwelcome); pregnancy (own or partner's—learned of, premature termination, childbirth, placement of child); parental separation;

parental divorce; new parental figure; moving recently or repeatedly; change of school other than normal promotion; loss of best friend through move; breakup with best friend; breakup with boyfriend or girlfriend; parental arrest; serious reduction in standard of living; forced separation from home; other event. Comparisons of parent and child completed versions yielded good intraclass correlations (.72 [child] and .83 [parent] for high-magnitude events, and .62 [child] and .58 [parent] for low-magnitude events). Kappa coefficients ranged from high for violence and sexual abuse to low for child reports of serious accidents and natural disasters. This format has been adapted as a preface for the Children's Impact of Traumatic Events Scale-II (CITES-II; Wolfe, 2002), which is used to identify negative life events, past (greater than 2 years) and current (within the past 2 years), and has been used in gathering normative data as a tool for participants to identify a negative life event, for which they then complete the event-related questions of the various CITES-II sections.

Unidimensional Detailed Assessment of Specific Traumatic Events

In some cases, a researcher or clinician may prefer to assess the details of a specific identified event rather than survey the full range of negative life events that occurred for a particular individual. The Dimensions of Stressful Events (DOSE; Fletcher, 1996) rating scale is applicable to a broad-range of specified negative life events. The DOSE includes 25 general trauma items and 24 items specific to sexual abuse. A scoring template available for the initial 25 items yields a total DOSE score, and a recommended procedure is provided for obtaining a total score for sexual abuse victims. Fletcher (Chapter 9, this volume) reports a number of studies with diverse populations linking DOSE scores to PTSD symptoms.

Measures That Tap Abuse-Related Stressors

Quas and colleagues (2005) described a long-term follow-up (10 years) of child and adolescent victims of CSA involved in the legal system. They developed a system for quantifying four types of adversity: sexual abuse, family, legal, and other traumas. For the CSA Index, three abuse characteristics were identified from a literature search for those that were robustly

associated with mental health outcomes: severity of the sexual acts (penetration vs. no penetration), closeness in relationship to the perpetrator (parent vs. not a parent), and duration of the abuse (1 day vs. more than 1 day). The CSA Index was the average of the three items. A Trauma Risk Index included additional adverse experiences at long-term follow-up: victim of a crime (with each type of crime coded separately—physical assault, burglary, physical abuse, other crime), death of loved one, foster or group home care, changes in foster/group homes, serious accident, school failure, unwanted pregnancy, rape as a adult, and sexual assault. Again, each was dichotomized and the index was the average of the items. The Legal Risk Index included the following: trial being canceled and rescheduled at least once, case lasting at least 1 year, lack of maternal support following disclosure or during legal trial, case lacking corroborating evidence, child testified in trial, and defendant not serving prison/jail term.

Spaccarelli developed two questionnaires that specifically assess aspects of the sexual abuse experience. The Abusive Sexual Exposure Scale (ASES; Spaccarelli, 1993), developed for use with girls ages 11–18, includes 28 questions about the occurrence of 14 types of sexual abuse and identity by relationship of all perpetrators for each type of abuse. In addition to two noncontact forms of abuse (peeped at, photographed when nude), six other contact forms of abuse are assessed: breast or genital fondling of victim, or victim required to fondle perpetrator; oral copulation of victim, or victim doing same to perpetrator; digital penetration of victim's anus or vagina, and genital penetration of victim's anus or vagina. The Checklist of Sexual Abuse and Related Stressors (C-SARS; Spaccarelli, 1995) includes 70 items designed to assess stressors commonly associated with sexual abuse experiences, falling into three theoretically devised scales: abuse-specific stressors, abuse-related events, and public disclosure events, such as repeated interviews. Abuse-specific stressors included several subscales: Negative Coercion, Inducements in the Form of Bribes or Rewards, Misrepresentation of Issues Related to the Sexual Abuse, Seduction, Violation of Trust, Stigmatizing Messages, and Victim Denigration. Abuse-related events included three subscales: Increased Family Conflict/Dysfunction, Loss of Social Contacts, and Nonsupportive Reactions.

As evidence of convergent validity, C-SARS scales correlated significantly with therapists' ratings of abuse-specific and abuse-related stressors. Internal consistency for the entire scale was .93, and the three scales ranged from .66 to .91.

Subjective Appraisals of Sexual Abuse

The *Children's Impact of Traumatic Events Scale-II: Peritraumatic Reactions Scales* (CITES-II) is a self-report measure that assesses negative life events, peritraumatic reactions, PTSD symptoms, attributions, perceptions of social reactions following abuse discovery/disclosure, and sexuality. It is appropriate for children and adolescents ages 8–16, and depending on reading level, can be administered as a structured interview or as an independently completed questionnaire. A number of psychometric evaluations have been completed with the CITES. A factor analysis of the initial 54-item version of the CITES (Wolfe et al., 1991) supported a two-tiered scale structure of four broad-band categories (PTSD, Attributions, Social Reactions, and Sexuality) and 11 narrow-band scales associated with the broader domains. A multitrait-multimethod analysis supported the convergent and divergent validity of the CITES scales. The original CITES was designed to assess PTSD symptoms and related constructs for sexual abuse victims (Wolfe et al., 1991; Wolfe & Birt, 2004a). The CITES-II has been reworded so that it can now be used to assess PTSD-related constructs with any negative life event. As well, previous versions of the CITES randomly interspersed PTSD, Attributional, and Social Support items throughout the questionnaire. The CITES-II now comprises five sections: Negative Life Event Checklist, Peritraumatic Reactions, PTSD, Attributions/Social Reactions, and two experimental sections, Posttraumatic Growth and Sexuality Issues (divided into child and adolescent sections). Thus, clinicians can administer the entire questionnaire or select particular sections as appropriate for an individual clinical case or research need. The diverse constructs assessed by the CITES-II are discussed within the various sections of the chapter that address different assessment issues relevant to sexual abuse victims (i.e., peritraumatic reactions [PR], PTSD symptoms, abuse-specific attributions, abuse-specific social support, and sexuality issues).

The CITES-II PR scales were developed in the absence of other measures to assess peritraumatic experiences with children. The items were originally a separate questionnaire called the Children's Peritraumatic Reactions Questionnaire (Wolfe & Birt, 2005b). The CITES-II PR includes 38 items and forms five scales based on a principal component analysis: Extreme Reactions (8 items; e.g., *Like I might die; Like I might faint; Like I wanted to kill the person who did this*); Fear and Anxiety (5 items; e.g., *Scared; Shaky; Worried*); Dissociation (9 items, e.g., *Like I left my body; Like I wasn't there; Like I lost sense of time*); Anger and Negative Affect (10 items; e.g., *Mad; Disgusted; Upset*); and Guilt/Self-Blame (5 items; e.g., *Like I caused it; Guilt; Like it was my fault*). Respondents are asked to consider their thoughts and feelings at the time of sexual abuse (or another identified negative life event) and identify their reactions on a 3-point scale of *None, Some, or A lot*. All of the scales have good internal consistency alphas ($> .80$), with the exception of the three-item Guilt scale (alpha = .54), which has since been expanded to include five items. With the exception of the Guilt scale, youth who completed the CITES-II PR scales with regard to sexual abuse experiences reported more intense peritraumatic reactions on all scales compared to youth who responded with regard to other negative life events. For the five scales, Extreme Reactions showed the strongest relationships with PTSD symptoms, whether reported by the child or the parent (Wolfe & Birt, 2005b).

Abuse-Related Attributions

The *CITES-II Attributional Scales* were originally developed to reflect the three attributional dimensions associated with the revised learned helplessness model of depression (internal, global, and specific attributions for negative events), as well as the traumagenic factors (guilt, betrayal, sexualization, and stigmatization) identified by Finkelhor and Browne (1985). Two principal component analyses of two datasets have shaped the content and focus of the Attributional Scales, yielding the following four subscales: Guilt/Self-Blame (7 items; alpha = .81; e.g., "I feel guilty about what happened"), Empowerment (3 items; alpha = .78; e.g., "I know enough about sexual abuse now that I can protect myself in the future"), Dan-

gerous World (7 items; alpha = .67; e.g., "People often take advantage of children"), and Distrust (4 items; alpha = .65; e.g., "Something like this might happen to me again"). A recent psychometric analysis of the revised CITES (CITES-R; Wolfe & Birt, 2005a) resulted in some minor changes to a previous subscale, Personal Vulnerability, with a name change to Distrust. The three more negatively valenced scales correlated moderately (Guilt/Self-Blame, Dangerous World, Distrust; r 's = .26-.29), but Empowerment did not correlate with the other Attributional Scales. Guilt/Self-Blame, Distrust, and Dangerous World correlated with PTSD Reexperiencing and Hyperarousal scales (r 's = .28-.52), and Distrust also correlated with PTSD Avoidance ($r = .32$). As well, Guilt/Self-Blame and Distrust correlated with PTSD Sexual Anxiety (r 's = .62 and .25, respectively). Empowerment did not correlate with any of the PTSD scales. However, Empowerment correlated significantly with both of the Social Reaction scales (r 's = .37 for Social Support and -.22 for Negative Reactions). Of the four attributional scales, only Distrust distinguished between sexual abuse victims and both community controls and other clinic-referred youth. As well, both Distrust and Dangerous World had higher scores among sexual abuse victims with PTSD compared to those without PTSD.

Research from other studies has also supported the psychometric properties of the CITES Attributional Scales. Crouch, Smith, Ezzell, and Saunders (1999) found that Guilt/Self-Blame, Personal Vulnerability, and Empowerment all correlated with the TSCC (Briere, 1996) PTSD scale (r 's = .47, .65, and -.53, respectively). Chaffin and Shultz (2001) found that Guilt/Self-Blame was sensitive to treatment-related changes. Taska and Feiring (1995) found that all four attributional scales correlated with both abuse-related and general measures of shame.

The Children's Attributions and Perceptions Scale (CAPS; Mannarino, Cohen, & Berman, 1994), an 18-item, self-report questionnaire for children ages 7 to 12, was designed for administration in an interview format that uses a 5-point Likert-like scale ranging from *Never* (1) to *Always* (5). The CAPS yields four conceptually derived scales: Feeling Different from Peers (4 items; alpha = .68; e.g., "Do you feel different than other girls your age?"); Personal Attri-

butions for Negative Events (4 items; $\alpha = .65$; e.g., “Do you blame yourself when things go wrong?”); Perceived Credibility (5 items; $\alpha = .73$; e.g., “Do you think people believe you when you tell them something?”); and Interpersonal Trust (5 items; $\alpha = .64$; e.g., “Do you ever feel that people whom you trust do things to hurt you?”). Test–retest reliabilities after 2 weeks were .82, .70, .62, .60 for the individual scales, respectively, and .75 for the total scale. The items do not refer specifically to sexual abuse, so the CAPS can be used with normal comparison samples. Mannarino and colleagues (1994) found that sexually abused children endorsed more items for the total CAPS score and three of the four scales compared to nonabused controls (Feeling Different from Peers, Personal Attributions for Negative Events, and Interpersonal Trust). CAPS scales correlated with measures of depression, anxiety, and PTSD (Cohen & Mannarino, 2000; Mannarino et al., 1994). As well, scores from the CAPS predicted treatment outcome for sexually abused children (Cohen & Mannarino, 2000).

The Negative Appraisals of Sexual Abuse Scale (NASAS; Spaccarelli, 1995; Spaccarelli & Fuchs, 1997) is a 56-item self-report of perceptions of threat or harm related to sexual victimization. The scale yields a total score, as well as eight theoretically based subscales: Physical Pain/Damage, Negative Self-Evaluation–Global, Negative Self-Evaluation–Sexuality, Negative Evaluation by Others, Loss of Desired Resources, Harm to Relationships/Security, Harm to Others, and Criticism of Others. Each item begins with the stem “Because of what happened with (offender’s name), did it make you think or feel. . . .” Responses are rated on a 4-point scale, from *Not at all* to *A lot*. Spaccarelli (1995) recommended using the full scale rather than individual scales because of high intercorrelations among the individual scales. The total score also had a strong internal consistency α value of .93. Scores from the NASAS correlated significantly with higher numbers of sexual acts, as assessed by the ASES, and with scores from the C-SARS. Whereas abuse resulting from stress accounted for only 2% of the variance in PTSD scores, negative appraisals significantly predicted PTSD and accounted for 25% of the variance. Negative appraisals also significantly predicted depression scores, accounting for 29% of the variance.

Measures of Shame

The concepts *guilt/self-blame* and *shame* differ primarily in the focus of the emotional attribution, with *guilt/self-blame* focusing on the event and actions taken or not taken, and *shame* focusing on the negative emotions oriented toward oneself in relation to an event (Berliner, 2005). Shame is considered an important emotional reaction to abuse because of its implication for PTSD; that is, shame is thought to motivate avoidance of self-exposure (Barrett, Zahn-Waxler, & Cole, 1993; Feiring & Taska, 2005; Tangney, 1995; Zupanic & Kreidler, 1998), thus inhibiting the healing processes needed to adjust following negative life events. As an example, Bonanno and colleagues (2002) asked CSA victims to talk about their most negative life event as part of an assessment procedure. Victims who selected an event other than their sexual abuse (presumably indicating avoidance of talking about their sexual abuse), showed more nonverbal indicators of shame while discussing their event. Shame also has implications for depression. Concerns have been raised that shame engenders a wide array of negative self-representations that are consistent with the negative thinking characteristics of depression, and that shame interferes with the development of positive self-traits such as self-agency and self-affectivity (Alessandri & Lewis, 1996).

Feiring, Taska, and Lewis (2002) followed sexual abuse victims from disclosure across several years. At each assessment point, abuse-related shame was linked with PTSD symptoms, demonstrating that shame has significant predictive power for PTSD even years after disclosure. In fact, changes in shame over time were linked with concomitant changes in PTSD. Feiring and colleagues have used several different strategies to assess shame. For two studies, they used four items: I feel ashamed because I think that people can tell from looking at me what happened; When I think about what happened I want to go away by myself and hide; I am ashamed because I feel I am the only one in my school who this has happened to; and What happened to me makes me feel dirty. Each item was rated on a 3-point scale (*Not true* to *Very true*). Despite the small number of items, internal consistency of the scale was good ($\alpha = .85$). As well, test–retest reliability with a small sample of 10 over a 2-week

period was good ($r = .78$). At the third assessment, four more items were added to the scale: *When I think about what happened, I feel like covering my body*; *When I think about what happened, I wish I were invisible*; *When I think about what happened, I feel disgusted with myself*; and *When I think about what happened, I feel exposed*. For the eight items, internal consistency continued to be good ($\alpha = .86$).

Feiring, Taska, and Lewis (2002) also developed a nonverbal assessment tool with line drawings that depicted various postures associated with shame. Participants were asked to rate each drawing for the extent to which it described how they felt when thinking about their sexual abuse, using the same 3-point scale used for the verbal shame scale described previously. The internal consistency for the drawing measure was also high ($\alpha = .92$), and the measure correlated with the concurrently administered verbal items described earlier. As well, the drawing measure results were predicted by prior administrations of the verbal items.

Negrao and colleagues (2005) used facial expressions to examine shame, which were coded from videotapes of CSA victims as they described their most negative life event. The Emotional Facial Action Coding System (EMFACS), which is based on the Facial Action Coding System (FACS; Ekman & Friesen, 1976, 1978), assessed only emotionally relevant facial muscle movements identified in previous research with the FACS. Using the EMFACS, anger, shame, and embarrassment were coded with a 5-point scale, ranging from *Minimum intensity* to *Extreme intensity*. Interrater agreement averaged .80. Interestingly, whereas facial expressions tended to be congruent with verbal content for a nonabused sample, for CSA victims, facial expressions were not necessarily congruent with verbal content. Victims who chose to discuss their sexual abuse tended to express shame and humiliation through words but not facial expressions. However, those who chose not to disclose their abuse history did not display verbal evidence of shame, but instead displayed nonverbal evidence of shame (Bonanno et al., 2002; Negrao et al., 2005).

Other studies have focused more on a general attribute of shame proneness rather than shame that is specific to sexual abuse or maltreatment. The Adolescent Shame Measure (ASM; Reimer, 1995) assesses shame proneness

by presenting 13 brief scenarios (e.g., *You say something mean about a friend. Your friend overhears you*), to which respondents rate the likeliness of four reactions that reflect Shame, Guilt, Anger/Blame, and Detachment (e.g., the shame statement is "I would feel totally awful about myself"; the guilt statement is "I would be sorry that I hurt their feelings"). Internal consistency for Shame ranged from .77 to .81, and for Guilt, .72 to .78 (Reimer, 1995; Stuewig & McCloskey, 2005). Reimer (1996) linked these concepts with self-esteem, self-consciousness, and depressed mood in adolescents. With a mixed sample of adolescents who experienced various forms of maltreatment, shame proneness was linked with parental criticism and depression. Interestingly, guilt was negatively associated with delinquent behavior. Some evidence has linked the experience of guilt with empathetic abilities (Tangney, 1991), perhaps enhancing one's ability to see the harmful consequence of behavioral offenses (Stuewig & McCloskey, 2005).

Bennett, Sullivan, and Lewis (2005) assessed shame proneness with a sample of physically abused and neglected preschool children using success–failure tasks. Conditions were manipulated so that the child experienced either success or failure on timed color-matching and puzzle completion tasks. Facial, body, and vocal behaviors were used to code shame, anger, and sadness from videotapes. "Shame" was defined as collapsed body, turned down corners of mouth, tucked up lower lip, eyes lowered or askance, withdrawal from the task, and negative self-evaluations, such as "I'm too slow." Average interrater reliability across the three emotions' codes was 93%, ranging from 85–97%, with kappas averaging .73, ranging from .62 to .82. Physical abuse, but not neglect, was related to increased shame responses, and shame was linked with anger.

Social and Family Supports and Stressors

The *CITES-II Social Reactions Scales* are two factor-derived scales that tap reactions to the disclosure and postdisclosure support: Social Support (Cronbach's $\alpha = .72$) and Negative Reactions (Cronbach's $\alpha = .81$). The modest negative correlation between the two scales ($-.31$) suggests that these scales are not opposite ends of one construct, but rather tap different aspects of postdisclosure social reactions. Negative Reactions items include concerns that

people disbelieve the allegations, blame the victim, or no longer care about the child. Social Support items reflect a perception that people believed the allegations, protected the victim from further maltreatment, and were helpful and supportive. The Negative Reactions scale appears to tap an important construct related to postabuse adjustment problems. Negative Reactions correlates positively with CITES-II PTSD Reexperiencing ($r = .36$) and Hyperarousal scales ($r = .53$), and differentiates between those who meet PTSD symptom criteria from those who do not (Wolfe & Birt, 2005a). As well, Crouch and colleagues (1999) found significant correlations between the Negative Reactions scale and several TSCC scales, including Posttraumatic Stress ($r = .50$), Anxiety ($r = .38$), Depression ($r = .62$), Anger ($r = .42$), Dissociation ($r = .38$), and Sexual Concerns ($r = .49$). As evidence of convergent validity, Chaffin and Shultz (2001) found that the Negative Reactions scale correlated significantly with a therapists' ratings of parental support using the Parental Response to Abuse Disclosure Scale (PRADS; Runyan, Hunter, Everson, & De Vos, 1992).

Mannarino and Cohen (1996a) developed two parent report measures to assess parental reactions to their child's sexual abuse. The Parent Emotional Reaction Questionnaire (PERQ) is a 15-item, Likert-like 5-point scale (*Never to Always*) that assesses parental emotional reactions to their child's sexual abuse, including fear, sadness, guilt, anger, embarrassment, shame, and emotional preoccupation (Mannarino & Cohen, 1996a, 1996b). Psychometric properties include good internal consistency for the scale ($\alpha = .87$) and test-retest reliability at a 2-week interval ($r = .90$). Two studies have demonstrated a positive relationship between the intensity of the parent's emotional reaction and child adjustment problems, both before and after treatment, with preschool- and latency-age children (Cohen & Mannarino, 1998; Mannarino & Cohen, 1996b).

The Parental Support Questionnaire (PSQ) includes 19 items and yields two scales, Support (Cronbach's $\alpha = .73$) and Blame (Cronbach's $\alpha = .70$). The PSQ was designed to assess parental perceptions of their own behaviors in response to their child's sexual abuse experience. The Support scale includes items such as parents encouraging the child to express feelings associated with the abuse, efforts to enhance the child's sense of se-

curity, and communication of support to the child. The Blame scale includes items such as parental belief that the child could have stopped the abuse if he or she had wanted to and criticism and/or punishment of the child over issues related to the abuse. Like the PERQ, the PSQ had good test-retest reliability over a 2-week period (.79 and .83, respectively). Although it did not predict baseline adjustment with preschoolers (perhaps because most of the sample reported strong support for the children; Mannarino & Cohen, 1996b), Cohen and Mannarino (1998) found that the PSQ was a significant predictor of adjustment at 6- and 12-month posttreatment follow-up points.

The Parental Reaction to Incest Disclosure Scale (PRIDS; Everson et al., 1989) is a three-item scale designed to document parental reactions and support following disclosure of intrafamilial sexual abuse. Professionals rate three issues along a continuum from +5 (*Most supportive*) to -5 (*Least supportive*), based on interviews with the family members and reports from agency staff members involved with the family. The three items are Emotional Support (e.g., from *Committed to child and provides meaningful support*, to *Is threatening or hostile; has abandoned the child psychologically*); Belief of the Child (e.g., from *Makes clear, public statement of belief* to *Totally denies that abuse occurred*); and Action toward Perpetrator (e.g., from *Actively demonstrates disapproval of perpetrator's abusive behavior* to *Chooses perpetrator over child at child's expense*). In Everson and colleagues' (1989) sample of 88 families, interrater agreement was quite high (.95), with 44% of mothers classified as "supportive" (+3 or greater), 32% as "ambivalent" (+2 to -2), and 24% as "unsupportive" (at or below -3). Maternal support on the PRIDS was significantly related to child distress and psychological adjustment, accounting for more variance than any abuse-related variable. Interestingly, supportive mothers and their children had similar reports of child behavioral and emotional adjustment. However, CBCL scores from ambivalent and unsupportive mothers did not correspond to information obtained in clinical interviews with their children.

Measures of General Family Functioning

In addition to assessing abuse-specific aspects of family support, many studies have examined

overall family functioning in terms of how families of sexual abuse victims differ from other families, and how family adjustment affects child psychopathology. Two questionnaires have been used by several researchers, the *Family Environment Scale* (FES; Moos & Moos, 1986) and the *Family Adaptability and Cohesion Scales* (FACES; versions II and III; Olson, Portner, & Bell, 1982; Olson, Portner, & Lavee, 1985). The FES yields seven scales, but research with sexual abuse victims has focused on two scales, Conflict and Cohesion. Families of sexual abuse victims tend to have low levels of Cohesion (Bal et al., 2004; Cecil & Matson, 2005; Dadds, Smith, Webber, & Robinson, 1991; Hanson, Saunders, & Lipovsky, 1992), and two studies have revealed high levels of Conflict, but only for families of girls (Cecil & Matson, 2005; Meyerson et al., 2002). The FACES-II and III both yielded two scores, Adaptability and Cohesion. Mannarino and Cohen (1996b) found relatively low Cohesion for families of sexual abuse victims and linked low levels of Adaptability to higher rates of child behavior problems (Mannarino & Cohen, 1996b). The FACES-IV (Olson & Gorall, 2006), an expansion of the original form, now comprises 62 items. The original Cohesion and Adaptability scales were preserved, but the Adaptability scale was renamed Flexibility. The Cohesion and Flexibility scales are considered balanced, in that higher scores reflect better family functioning. Four new scales were added, labeled unbalanced scales, which assess the low and high extremes of Cohesion (i.e., Disengaged and Enmeshed), and the lows and highs of Flexibility (i.e., Rigid and Chaotic). The circumplex model is used to interpret the scales, which are plotted to yield profile types (Olson & Gorall, 2006). The circumplex model examines different combinations of high and low extremes for Cohesion and Adaptability, and how the variations reflect different forms of familial dysfunction.

Assessing PTSD

Over the past decade, there have been tremendous strides in the assessment of PTSD with children and adolescents (Ohan, Myers, & Collett, 2002; Strand, Sarmiento, & Pasquale, 2005). Fletcher (Chapter 9, this volume) provides a review of these measures as a whole. In this chapter, the discussion is limited to mea-

asures that have been used extensively to assess PTSD with sexually abused children.

The Trauma Symptom Checklist for Children (TSCC; Briere, 1996, 2006a) is a 54-item self-report measure designed to assess children's reactions to trauma across several symptom areas: Anxiety, Depression, Anger, Posttraumatic Stress, Dissociation, and Sexual Concerns (Sexual Preoccupation and Sexual Distress). A 44-item alternative version does not include the Sexual Concerns items. The TSCC also yields two validity scales, Under-response and Hyperresponse, that have demonstrated usefulness in detecting response biases (Davies & Flannery, 1998). Norms are available for males and females ages 6–17, representing over 3,000 youth from various locations across the United States. Each scale has good internal consistency, with alphas in the mid to high .80's; however, the Sexual Concerns scale is somewhat less reliable, with alphas in the .60's to .70's. Several studies have demonstrated the reliability and convergent, divergent, discriminant, and construct validity of the TSCC (Briere, 1996; Elliott & Briere, 1994; Friedrich et al., 1997; Lanktree & Briere, 1995; Sadowski & Friedrich, 2000; Singer, Anglin, Song, & Lunghofer, 1995). As well, the TSCC appears to be sensitive to change following mental health interventions (Henry, 1997; Lanktree & Briere, 1995). The TSCC has been translated into several languages, and the French Canadian version has demonstrated positive psychometric properties (Wright et al., 1998).

The Trauma Symptom Checklist for Young Children (TSCYC; Briere, 2006b; Briere et al., 2001) is a caregiver report measure designed to assess trauma-related symptoms in children ages 3–12. The 90-item measure, written at a grade 6 reading level, yields eight clinical scales: Posttraumatic Stress–Intrusion, Posttraumatic Stress–Avoidance, Posttraumatic Stress–Arousal, Sexual Concerns, Dissociation, Anxiety, Depression, and Anger or Aggression. The three Posttraumatic Stress scales can be amalgamated to form a summary PTSD score. As well, item responses can be used to determine DSM-IV PTSD diagnostic status for children age 5 and older, with a sensitivity of .72 and specificity of .75 (Briere, 2006b). Norms are based on a stratified sample of 750 children. Alpha values for the norm sample averaged .86 per scale, ranging from .78 to .92;

similar alphas have been reported for clinical and child abuse samples. Test–retest reliability ranges between .68 and .96, averaging .88 across scales. Overall, the scales have demonstrated good discriminant, predictive, and construct validity.

Like the other CITES-II scales, the *CITES-II PTSD scale* (Wolfe, 2002) has been shaped by two previous psychometric evaluations. The original PTSD items were influenced by the Impact of Event Scale (IES; Horowitz, Wilner, & Alvarez, 1979), and additional items have been added to tap issues relevant to children and adolescents, and to cover all the symptoms identified in DSM-IV-TR. The CITES-II PTSD scales contain 46 items, reflecting four scales: Reexperiencing, Avoidance, Hyperarousal, and Sexual Anxiety. Past studies have indicated that the CITES-R PTSD scales have good internal consistency (Chaffin & Shultz, 2001; Crouch et al., 1999). As well, the CITES-R PTSD scales have good convergent validity with the TSCC PTSD scales (Crouch et al., 1999; $r = .72$) and with Diagnostic Interview for Children and Adolescents—Revised (DICA-R) PTSD Child Report scale (Reexperiencing, $r = .50$; Avoidance, $r = .38$; Hyperarousal, $r = .45$; and Sexual Anxiety, $r = .25$ —Chaffin & Shultz, 2001). As well, the CITES-R was sensitive in detecting pre- to posttreatment changes (Berliner & Saunders, 1996; Chaffin & Shultz, 2001). Collin-Vézina and Hébert (2005), using a French translation of the CITES-R PTSD scales, reported good internal consistency for the total PTSD score (alpha = .81), and found that history of sexual abuse increased the odds of CITES-R-based PTSD diagnoses fourfold. They also found that sexual penetration was associated with higher PTSD scores.

Wolfe and Birt (2005a) conducted a psychometric analysis of the CITES-R with a sample of sexual abuse victims, clinic-referred youth without a sexual abuse history, and community controls without a history of maltreatment or mental health problems. A principal component analysis of the CITES-R supported the existing factor structure. Alpha values for the PTSD scales follow: Reexperiencing (12 items; .88); Sexual Anxiety (.84); Avoidance (18 items, .78); and Hyperarousal (13 items; .63). Sexual abuse victims reported more total PTSD symptoms than did the comparison samples, with the Reexperiencing, Sexual Anxiety, and Avoidance scales also discriminating among the

groups. The CITES-R covers all the DSM-IV-TR diagnostic criteria; thus, diagnostic status can be calculated for the symptom criteria. Wolfe and Birt found higher rates of PTSD for sexual abuse victims using the CITES-R compared to both clinic-referred and community youth. Depending on the level of symptoms required for a diagnosis, 55% of CSA victims met the low PTSD criterion (sufficient symptoms endorsed, each at least rated as *Somewhat or sometimes true*), and 24% met the high PTSD criterion (sufficient symptoms endorsed, all rates as *Very or often true*).

Thus far, my colleagues and I have created two CITES-II databases, a clinical trauma sample ($n = 60$) and a representative sample of high school girls ($n = 151$). For the clinical trauma sample, Cronbach alpha values for the scales are Reexperiencing (.87); Avoidance, (.76); and Hyperarousal (.89). For the high school girls sample, alpha values are Reexperiencing (.86); Avoidance (.91); and Hyperarousal (.90). In addition to including all symptom criteria for a DSM-IV-TR PTSD diagnosis, the CITES-II PTSD items are followed by three items designed to assess perceived functional impairment of relationships with family and friends, and school performance.

The CITES-II—Parent Report version (CITES-II-PR; Wolfe, 2000) comprises the CITES-II PTSD and Social Reactions items. The CITES-PR has 24 PTSD items, 6 Social Support items, and 8 Negative Reactions items. Based on a sample of children and adolescents referred to a trauma-focused mental health clinic ($n = 122$), internal consistency alpha values were .91, .80, and .81, respectively. Based on 52 individuals administered both the CITES-II and the CITES-PR, the total PTSD scores correlated significantly ($r = .47$). As expected, parent-reported PTSD symptoms correlated significantly with the Negative Reactions ($r = .30$) scale. Unexpectedly, parent-reported PTSD symptoms also correlated positively with the Social Support scale ($r = .28$). Perhaps children who experience PTSD subsequent to negative life events are more likely to provide and to recall social support given to themselves and to others.

The Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001) is a commonly used parent report questionnaire that assesses a broad spectrum of child adjustment problems. Although the CBCL was not designed

to assess PTSD, many of the items reflect PTSD symptoms. In an effort to document PTSD symptoms via parent report, Wolfe and colleagues (1989) selected 20 CBCL items that matched PTSD diagnostic criteria. Compared to the standardization sample, parents of sexually abused children endorsed PTSD items five times more frequently. Wolfe and Birt (1997) compared individual CBCL items across three samples: sexually abused, clinic-referred (but not sexually abused), and the CBCL standardization sample. Nineteen of the 20 items were more common in the sexually abused sample compared to the standardization group, and 11 of the 20 items differentiated between the sexually abused and the clinic-referred groups. Ruggiero and colleagues (2000) investigated the psychometric properties of the 20 CBCL PTSD items. The CBCL PTSD scale significantly discriminated between PTSD and no PTSD sexual abuse cases. CBCL PTSD scale scores were higher among sexually abused victims compared to a general school sample but did not differentiate between the sexual abuse sample and outpatient psychiatric controls. Fourteen items either correlated significantly with the number of PTSD symptoms reported during diagnostic interviews or significantly differentiated between sexually abused victims who either met or did not meet PTSD diagnostic criteria. Wolfe and Birt (2005a) modified the CBCL PTSD scale to include the 14 items identified by Ruggiero and colleagues. Thus, the CBCL PTSD scale now comprises the following items: Argues a lot, difficulty concentrating, obsessive thoughts, clings to adults, too guilty, secretive, moody, unhappy, withdrawn, fears doing something bad, feels persecuted, nervous, nightmares, and too fearful. Based on a mixed sample of sexual abuse victims, agency referred youth, and community controls, Cronbach's alpha value for the 14 items was .86. For the sexual abuse sample, the correlation between the CITES-R PTSD scale and the CBCL PTSD scale was .28 ($p < .001$). To examine the discriminative validity of the PTSD CBCL scale, the CITES-R was used to determine PTSD status for the sexual abuse sample. For the sexual abuse sample, CBCL PTSD scores were higher among those with PTSD compared to those who scored low on PTSD symptoms. Furthermore, CBCL PTSD scores among sexual abuse victims

were predicted by factors that tend to predict PTSD via other assessment strategies, including having experienced physical abuse in addition to the sexual abuse, and reports of extreme peritraumatic reactions at the time of the sexual abuse.

Assessing Dissociation

Current assessment strategies for childhood dissociation are limited (Silberg, 2000). Regardless of age, dissociative symptoms are very difficult to identify through typical psychological assessment strategies, because dissociated individuals are required to self-report on phenomena that affect their own continuity of consciousness, thus impairing their capacities for self-awareness and self-monitoring. In addition to these general difficulties, the assessment of dissociation in childhood is further complicated by several factors (Friedrich, 2002; McElroy, 1992; Ogata, Silk, & Goodrich, 1990; Putnam, 1997): (1) Relative to adults, children have a limited capacity to report on behavioral, cognitive, and emotional states; (2) relative to adults, they have a poorer sense of continuity in their experience, behavior, and the flow of time; (3) child dissociation presents subtly in childhood relative to adulthood, perhaps due to its diagnostically confounded nature with normative childhood dissociative experiences and other childhood disorders (such as oppositional problems, PTSD, MDD, or schizophrenia); and (4) given that one's sense of self and identity are not formed until late adolescence, dissociative disorders that are more directly related to identity and self (e.g., dissociative identity disorder [DID]) may manifest only subtly and progressively during later childhood and adolescence.

Parent/Caregiver Report

The Child Dissociation Checklist (CDC; Putnam, 1990; Sidran Traumatic Foundation, 2000b) was developed for use with children and adolescents ages 5–14. Parents report dissociative symptoms displayed by their child over the past 12 months, with the response options *Very true*, *Somewhat or sometimes true*, and *Not true*. Several dissociative symptoms are assessed, including imaginary friends, different identities, moodiness, forgetfulness, thought absorption, and “spaciness.” Based on

an initial psychometric evaluation of the CDC, the 20-item scale yielded one score, with a Cronbach's alpha of .91 (Putnam, Helmers, & Trickett, 1993), and a 1-year test-retest reliability of .84 for sexually abused children and .79 for controls. The CDC total score discriminates between maltreated and nonmaltreated children, and between children with DID and those with other dissociative disorders and normal controls (Macfie et al., 2001; Putnam et al., 1993). Collin-Vézina and Hébert (2005) found that a history of sexual abuse increased eightfold the odds of pathological levels of dissociation on the CDC. As well, higher scores have been associated with more extensive abuse history (Putnam & Peterson, 1994). Norms are available based on modest samples for sexually abused, dissociative, and community youth ages 6–14 years. High CDC total scores have been linked with younger age, family dysfunction, and hypnotizability (Ohan et al., 2002).

Because of the breadth of the symptoms included on the CDC, clinical interpretation of the total CDC score can be difficult. Six conceptually defined domains have been identified (Feindler, Rathus, & Silver, 2003; Putnam & Peterson, 1994): Dissociative Amnesia, Rapid Shifts in Demeanor and Abilities, Spontaneous Trance States, Hallucinations, Identity Alterations, and Aggressive or Sexualized Behavior. Psychometric properties and norms for the individual scales are not available. To aid in the clinical interpretation of the CDC, Zayed and colleagues (2006) conducted a series of psychometric analyses to examine scale content and structure. Based on group comparisons (sexually abused, clinic-referred/nonabused, and community control boys and girls) and a principal component analysis, the scale content was reduced to 14 items that produced three scales: Forgetful/Confused (Cronbach's alpha = .67; e.g., Child is unusually forgetful or confused about things that he or she should know), Absorption/Fantasy Proneness (alpha = .74; e.g., Child has vivid imaginary companion or companions; child may insist that the imaginary companion is responsible for things that he or she has done), and Identity/Self-Disturbance (Cronbach's alpha = .79; e.g., Child refers to him- or herself in the third person when talking about self, or at time insists on being called by a different name). Group comparisons revealed that all three scales differentiate between sex-

ual abuse victims and community controls, but not between sexual abuse victims and other agency-referred youth.

Self-Report of Dissociation

MEASURES SUITABLE FOR CHILDREN

The Child Dissociation Checklist—Child (CDC-C; Wolfe & Birt, 2002) was developed as a self-report version of the CDC, with language appropriate for children as young as 8 years. Zayed and colleagues (2006) conducted a series of psychometric analyses that resulted in a 17-item version that yields three scales: Forgetful/Confused (Cronbach's alpha = .67), Spaciness/Daydreaming/Fantasy (Cronbach's alpha = .74), and Identity/Self (Cronbach's alpha = .79). The Identify/Self scale was psychometrically sound only for the adolescent sample, suggesting that these personality dimensions are less well formulated or less often self-identified by children. As with the parent report version, although the scales differentiated between sexually abused and the community comparison samples, the sexually abused group did not differ from other agency-referred youth.

The Children's Perceptual Alteration Scale (CPAS; Evers-Szostak, 2002; Evers-Szostak & Sanders, 1992), drawn from the adult self-report Perceptual Alteration Scale (Sanders, 1986), is another self-report scale for children ages 8–12 years. Although the scale yields one total score, the items reflect six aspects of dissociation: Automatic Experiences, Imaginary Playmates, Amnesia, Loss of Time, Heightened Monitoring, and Loss of Control over Behaviors and Emotions. Internal consistency was reported to be good for a clinical sample but moderate for a nonclinical sample (Ohan et al., 2002). Rhue, Lynn, and Sandberg (1995) compared CPAS results for sexually abused, physically abused, and nonabused children. Although the total score distinguished between physically abused and nonabused children, it did not identify sexual abuse victims. The scale differentiated between children with and without mental health problems, and also correlated positively with measures of fantasy and imagination. Ohan and colleagues (2002) noted that some of the CPAS items are general and not specific to dissociation (e.g., I am hungry; I cannot sit still; I don't like going to

school), and recommended caution in interpreting individual items.

MEASURES SUITABLE FOR ADOLESCENTS

The *Adolescent Dissociative Experiences Scale* (A-DES; Armstrong, Putnam, Carlson, Libero, & Smith, 1997; Sidran Traumatic Stress Foundation, 2002a; Smith & Carlson, 1996) is an adolescent version (ages 11–21 years) of the adult Dissociative Experiences Scale (DES; Bernstein & Putnam, 1986; Van IJzendoorn & Schuengel, 1996). The 28-item A-DES yields a total score, as well as four conceptually derived subscale scores: Dissociative Amnesia, Absorption and Imaginative Involvement, Passive Influence, and Depersonalization/Derealization. However, a principal component analysis with a community sample failed to support a four-factor structure (Farrington, Waller, Smerden, & Faupel, 2001). Internal consistency for the total score was .91, and the subscale alpha values ranged from .64 to .83. Test–retest reliability at a 2-week interval was .77. Norms are available based on a diverse but modest-size sample (Ohan et al., 2002), and a French Canadian version is available. The A-DES discriminates between clinically referred traumatized youth, including samples of physically and sexually abused youth, and nontraumatized youth (Armstrong et al., 1997; Farrington et al., 2001; Svedin, Nilsson, & Lindell, 2004). As well, the A-DES has good sensitivity (80%) and specificity (74%) in detecting dissociative disorders with both clinic-referred and nonclinical samples. Interestingly, Prohl, Resch, Parzer, and Brunner (2001) found that A-DES scores correlated with declarative memory scores.

Direct Observation for Preschool-Age Children

The Attachment Story Completion Task (ASCT; Bretherton, Ridgeway, & Cassidy, 1990) was designed to elicit responses reflecting the attachment relationship between child and parent. Children are told the beginning of stories, with the aid of dolls and props, and are asked to complete the story. Five story-stems are used: (1) parent as an authority figure (story depicts a child that spilled his or her juice); (2) parent as comforter (child falls off a rock and hurts his or her knee); (3) parent as protector (child calls for parents at night thinking he or she has seen a monster); (4) separation of the child from his or her parents (par-

ents leave for a trip, leaving the children with their grandmother); and (5) the reunion (child and parents reunite the next day). The ASCT takes about 25 minutes to administer and is videotaped for later coding. Macfie and colleagues (2001) developed 15 codes within six domains designed to capture dissociation in children's narrative story-stem completions. The six domains include Disruptions in Memory, Disruptions in Perception, Disruptions in Identity, Inconsistent Parents, Difficulty with Loss, and Controllingness. Kappas ranged from .65 to 1.00, with a mean kappa of .86. Twelve of the 15 codes correlated significantly with the CDC total score, and were used to form a total narrative dissociation score. With a sample of 79 preschool children (ages 3–5), narrative dissociation correlated significantly with the parent-completed CDC ($r = .68$) and with a CBCL Dissociation scale ($r = .46$) (Ogawa et al., 1997). Cronbach's alpha was .79. As evidence of discriminant validity, and to address concerns that measures of dissociation simply assess proneness toward behavior problems, the narrative dissociation scores correlated significantly more strongly with the CDC than with the majority of the CBCL scales. As well, physically and sexually maltreated children demonstrated more dissociation than did the nonmaltreated group. Maltreated and community control children were tested twice, with a 1-year interval. Whereas sexually and physically abused children showed an increase in dissociative behaviors over time, neglected and nonmaltreated children showed no changes.

Assessing Sexual Problems in Children

Sexual behavior is generally private and not readily reported by children. Thus, assessment of children's sexual behavior has typically relied on parent report (Kendall-Tackett et al., 1993). However, as children grow older, parents know less about their children's sexual behaviors. Thus, parent reports of children's sexual behaviors typically yields the most accurate information, whereas adolescent reports are more reliable and valid.

The Child Sexual Behavior Inventory (CSBI; Friedrich, 1997), a 38-item, parent report measure, is designed to assess child sexual behaviors such as self-stimulation, sexual aggression, gender role discrepancies, and personal boundary violations. The CSBI, appropriate for children ages 2–12 years, is rated on a 4-point scale

for the previous 6-month period. In addition to a total CSBI score, two other scale scores are provided: Development-Related Sexual Behavior and Sexual Abuse Specific Items (Feindler et al., 2003). Norms for age and gender are provided, and the CSBI is available in French, Spanish, German, and Swedish, in addition to English. Internal consistencies for the total score ranged from .82 for a nonclinical sample and .93 for a clinical sample. Test-retest reliability was .85 for both 1-month and 3-month intervals. In the normative sample, young children were rated as displaying more sexual behaviors than older children (Friedrich et al., 1992). In fact, less sexual behavior is typically reported for each year after age 5 (Friedrich, 1997). Another study found that 26 of the 35 items were endorsed significantly more often for sexually abused children than for the normative sample (Friedrich et al., 1992). The CSBI discriminates between sexually abused and nonabused children more reliably than the CBCL Sexual Problems scale and is more strongly related to sexual abuse characteristics (including type of abuse, number of perpetrators, and use of force).

The Adolescent Clinical Sexual Behavior Inventory (ACSBI; Friedrich et al., 2004) was designed for clinical use to assess sexual risk taking, nonconforming sexual behaviors, sexual interest, and sexual avoidance/discomfort. Items were created to assess high-risk behaviors pertinent to adolescent physical and mental health concerns such as early-onset sexual behavior, unprotected intercourse, sexual victimization, multiple partners, running away from home, heightened sexual interest, sexual avoidance, fear or discomfort around the opposite sex, sexual aggression, and prostitution (Friedrich et al., 2004). The 45-item checklist has three response options (*Not true*, *Somewhat true*, and *Very true*) with consideration of the previous 12 months. A parent report version (ACSBI-P) that mirrors the adolescent self-report version (ACSBI-S) was also developed. Based on principal component analyses, the ACSBI yields five scores: Divergent Sexual Interest (5 items; alpha = .65; e.g., owns pornography); Sexual Knowledge/Interest (10 items; alpha = .84; e.g., is very interested in the opposite sex); Sexual Risk/ Misuse (10 items; alpha = .77; e.g., gets used sexually by others); Concerns about Appearance (4 items; alpha = .68; e.g., is unhappy with looks); and Fear/Discomfort (5 items; alpha = .45; e.g., has no friends of

the opposite sex). The ACSBI-P also yields the same five scores with some variation in item content: Divergent Sexual Interest (9 items; alpha = .81; e.g., has been accused of sexually abusing another person); Sexual Knowledge/Interest (13 items; alpha = .76; e.g., flirts with other teens or adults); Sexual Risk/Misuse (8 items; alpha = .79; e.g., has unprotected sex); Concerns about Appearance (4 items; alpha = .65; e.g., is concerned about looking just right); and Fear (7 items; alpha = .39; e.g., does not like to shower or bathe). Internal consistencies were .86 for the self-report total score and .84 for the parent total score. One-week test-retest reliability for the ACSBI-S with a sample of adolescent inpatients was .74. The parent and self-report versions of the ACSBI correlated .50 for the total scores. Both versions significantly correlated with the Adolescent Sexual Concerns Questionnaire (Hussey & Singer, 1993) and the TSCC Sexual Concerns scales (Briere, 1996). With some slight variations in prediction patterns across the five scales, both the parent- and self-report versions were linked with histories of physical and sexual abuse, family problems, and negative life events.

BEST PRACTICES FOR ASSESSING SEXUALLY ABUSED YOUTH

Reason for Referral

The first consideration when assessing CSA victims is to determine the purpose of the assessment and the questions to be asked. In many cases, CSA victims are referred to identify how the abuse affected them and to provide direction for the types of interventions needed to help them recover. This typically occurs in the context of mental health services, but it can also occur in the context of legal proceedings, such as child welfare matters, custody and access disputes, civil litigation, and victim compensation applications. In most cases, adjustment problems have instigated the referral, but in some cases, caregivers and social workers want a “checkup” to determine the impact of the abuse and explore ways to prevent future adjustment problems. In some cases, youth are referred for assessment because of other problems, such as conduct problems or intentional self-harm. Because of the child’s CSA history, questions arise as to whether the abuse contributed to the development or exacerbation of the problem. Thus, assessments for CSA may focus

specifically on the effects of the abuse or be part of a broader assessment that addresses a number of adjustment concerns.

Even if the original assessment was not intended for legal purposes, assessment reports are often requested or subpoenaed for such proceedings. Prior to initiating an assessment, all parties should be informed of limits of confidentiality, particularly the possibility that the report might be subpoenaed by a judge. Other limits of confidentiality, including report of the abuse, should also be reviewed. Issues relevant to legal proceedings should be considered. For instance, if new details about maltreatment were reported by the youth during the course of the assessment, then care should be taken to document both the context of the disclosure and the youth's verbatim statements, and subsequent reports to CPS. This is important to avoid potential allegations that the disclosures were in some way "led" by assessment questions, misinterpreted by the assessor, or in some way mishandled in terms of child protection mandates. Care should also be taken to document all sources of information, and to interpret assessment information in line with knowledge of CSA-related research.

Start with Standard Good Assessment Strategies

Psychological assessment of children and youth require some basic components. Positive rapport is essential to all assessments, but is particularly important for CSA victims and their families. Families who have undergone CPS and justice system investigations are often wary of mental health services, and children may fear yet another interview about the abuse. Exploration of child and family concerns, and their goals at the outset of the assessment, may be helpful, and assessors should take time to explain the assessment process and how assessment information is used to assist with planning services. To understand the impact of CSA on children, it is best to assess the "whole child," not just the sexual abuse; that is, take time to learn about the children's interests, strengths, friends, and family. Although much of the focus of assessment is on mental health problems, the goals of mental health interventions include positive adjustment and personal growth. Knowing the child's strengths and interests identifies areas on which to build resilience and competence, and helps the child and family feel hopeful and balanced about mental

health services. This chapter has focused on CSA-specific types of information. However, other basic information is required, including child developmental history, academic adjustment, and family and social relationships. Past efforts toward resolving problems should be explored, both within the family and through mental health services, including methods that have been successful and unsuccessful, and perceptions of the reasons behind these outcomes.

Build an Assessment Protocol

Individual assessors tend to establish preferred assessment methods and strategies. The purpose of this chapter is not to recommend specific assessment tools, but to provide information about the assessment methods available for establishing an assessment protocol. Given the breadth and complexity of issues inherent in assessing CSA victims, an assessment approach is recommended that is multi-gating, multivariate, multi-informant, and multi-method. Multi-gating refers to using broad-band assessment tools to guide more specific areas of inquiry. Broad-band assessments include interviews, questionnaires, and personality measures that span multiple factors. For instance, the CBCL (Achenbach & Rescorla, 2001) provides an excellent overview of both child competencies and behavioral and emotional problems. As well, diagnostic interviews, such as the Diagnostic Interview for Children and Adolescents-IV (Reich, Welner, & Herjanic; 1997) and the Diagnostic Interview Schedule for Children (Shaffer et al., 1996), provide a thorough investigation of common mental health problems. Available computer-administered versions of these interviews for parent and adolescent completion enhance feasibility within clinical settings. Once specific mental health issues are identified from these broad-band assessments, more narrow-band evaluations can be conducted. That said, these broad-band assessment tools are often not sensitive to some of the specific effects of CSA. Thus, it is recommended that for identifying symptoms and for diagnostic purposes, broad-band assessment tools be supplemented with measures that independently assess PTSD and sexual problems.

The multivariate aspects of assessment protocols refer to four domains: (1) background, (2) symptoms, (3) psychological processes, and (4) family and other social supports and stress-

ors. By assessing these four domains, the child's problems may be conceptualized in terms of antecedents and consequences of the maltreatment and adversity, and identified child and family factors may serve as objectives and goals for interventions. The multi-informant and multi-method aspects of an assessment protocol provide a layered strategy for ensuring a thorough evaluation and guard against biases stemming from different informants or methods. Assessment strategies should include the child and the child's primary caregivers, and when possible and relevant, information from social workers, therapists, and teachers. For background information, it is often helpful to gather information from multiple sources (charts, CPS workers, parents, and sometimes the children themselves), because it is unlikely that any single source presents a full account of all relevant information. As well, inconsistencies from different sources are not uncommon and may call for clarification. Whenever CPS is involved in a case, it is often helpful to invite the primary worker to participate in the assessment process. CPS workers can clarify custodial status and the provisions of supervisory orders, and provide information about past and ongoing child welfare concerns, often with detail that is not readily available from CPS reports, which may not reflect the most recent events relevant to the case.

Although parents generally provide a good assessment of externalizing types of problems, parents with mental health problems sometimes overreport child problems and may underreport symptoms in other circumstances (e.g., during custody and access or child welfare proceedings (Friedrich, 2002; Sourander et al., 2006). Teacher reports can provide an unbiased alternative assessment of adjustment problems and provide additional information about the child's academic and social adjustment. For sexual problems, parents are typically the best informants for sexualized behaviors of children (who often deny anything sexual), but adolescents are typically the better informants for themselves, because parents are often unaware of their sexual activities, and adolescents are less hesitant than children to report sexual issues. PTSD symptoms are best reported by the child or adolescent, because many symptoms are cognitive in nature. However, some youth may wish to avoid having their PTSD symptoms detected (as part of the avoidance aspect of PTSD); thus, parental re-

ports provide an alternative source of information, particularly about the more observable aspects of PTSD. Likewise, youth tend to be the best informants of other internalizing symptoms, but some children may under- or over-report their symptoms (Friedrich, 2002). Varying assessment methods can help to ensure that information drawn from children is consistent and reliable. Whereas self-report measures are very helpful, supplementing the assessment protocol with projective and observational tools may provide checks against method biases.

Assessing PTSD and Event-Related Issues with CSA Victims

One of the three symptoms domains of PTSD is avoidance, and avoidance of thoughts and conversations related to an identified trauma is a commonly endorsed symptom within that domain (Wolfe & Birt, 2005a). Thus, it is important to establish rapport before delving into these sensitive issues. As well, it is often helpful in the beginning to schedule assessment tasks with less sensitive measures (e.g., ways of coping) before moving to more sensitive measures (abuse-related PTSD). Open-ended questions about CSA-related issues typically do not yield detailed responses, because youth are often reluctant to discuss CSA, and they generally do not have a framework to conceptualize their behavioral and emotional thoughts, feelings, and symptoms in relationship to their abuse experiences. Therefore, abuse-specific questionnaires can be very helpful. The CITES-II asks respondents to remember their abuse experiences (but they are not asked to retell what happened) and to answer the questions with that set of events in mind. Children and adolescents appear to tolerate the questions well, though because of the different sections, completion of the full CITES-II sometimes takes more than one session. Because the CITES-II identifies the specific trauma and includes items that cover all DSM-IV-TR PTSD diagnostic criteria, the diagnostic process is facilitated (a diagnostic algorithm is provided). Detailed information about abuse-related attribution, social reactions, and coping is relevant to intervention. In some cases, children may not have fully disclosed their abuse, may have recanted their allegations, or the suspected abuse has not yet been disclosed. Questionnaires such as the TSCC (Briere, 2006a) can help to identify

trauma-related symptoms, because a designation of a specific event is not required. The TSCC also provides a broad overview of additional symptoms often associated with CSA and other traumatic events, and may serve as a screening tool for more in-depth assessments.

Assessment throughout the Intervention Process

Like the assessment process, interventions for CSA victims tend to be multidimensional, to address multiple problems, and often require long-term involvement (see Wolfe [2006] for an overview of interventions with CSA victims). Assessment information is essential in developing an effective treatment and intervention plan, and can help the clinician triage and prioritize treatment objectives. Once a treatment plan is in place, it is important to monitor progress of specific objectives on an ongoing basis, through tailored methods such as parent or child daily monitoring of symptoms and clinician sessional ratings of progress toward goals. Once a specific set of goals is met, new goals and objectives may be set and monitored, with a continuation of the process until the child's mental health difficulties are addressed in full. For example, for a sexually abused child with sexual behavior problems, a treatment priority might be decreasing inappropriate sexual behaviors with other children. Multiple sessions are required to address those problems, and tailored monitoring strategies may be put in place until the sexualized problems are under control. At that point, other problems may be considered as a second stage of intervention, such as addressing the child's PTSD symptoms, which also may be monitored until symptoms are resolved.

SUMMARY AND CONCLUSIONS

This chapter provides an overview of issues related to CSA, including epidemiological findings, situational correlates of sexual abuse, and the impact of sexual abuse on victims. The findings reviewed provide a framework for assessing sexually abused children for both clinical and research purposes. The research indicates that sexual abuse is a serious negative life event that has great potential to set in motion a lifetime of adjustment problems. A number of mental health problems are clearly linked with sexual abuse, including PTSD, dissociation, de-

pression, sexuality problems, and risk for subsequent revictimization. Additional problems are likely not only influenced by the sexual abuse experience but also linked with the emotional, familial, and social contexts associated with sexual abuse. For example, eating disorders and intentional self-harm appear to be disproportionately represented among sexual abuse victims, but the link with these disorders is the negative emotional states and dysphoria associated with the abuse. As well, behavioral and conduct problems have links with the sexual abuse, but the links are likely through depression and PTSD symptoms such as hyperarousal, as well as a dysfunctional family and social contexts that often accompany sexual abuse.

There are clearly great individual differences in risk for developing mental problems subsequent to sexual victimization. Understanding the effects of sexual abuse requires consideration of many layers of contributing factors that are interrelated in complex ways. Sexual abuse itself constitutes a heterogeneous set of circumstances, including different acts, perpetrators, types of coercion, and frequencies and durations. Although these factors are related to sexual abuse sequelae, research suggests that children's perceptions of abuse severity have much more to do with subsequent impact than specific abuse factors. Furthermore, children's perceptions of abuse severity do not necessarily correspond to the severity dimensions typically assessed by researchers (i.e., abusive acts, coercion, relationship to perpetrator). This suggests that either researchers have not yet found a way to define abuse severity that reflects children's experiences, or that individual differences in the ways children experience negative life events such as sexual abuse have much to do with the child's resilience. It is possible that children's perceptions of their sexual abuse are influenced by factors other than the abuse itself, such as postdisclosure stressors related to family reactions, involvement with CPS and the legal system, and the experience of other forms of maltreatment and subsequent sexual victimization. It is also possible that children's ways of coping with sexual abuse reflect premorbid coping tendencies; that is, well-adjusted children who have good coping skills and good family support may cope more effectively at the time of the abuse, perceive less threat and helplessness, act in effective ways to minimize the probability of further abuse or negative impact,

and subsequently experience fewer negative mental health outcomes. But children with poor self-esteem, who rely on avoidant, internalizing, or externalizing forms of coping and have distant, nonsupportive familial relationships may react at the time of the sexual abuse with great horror and helplessness, may fail to disclose their abuse, and may therefore experience repeated episodes of abuse. Further longitudinal research is needed with large representative samples to investigate how premorbid adjustment and coping factors affect the impact of sexual abuse. The good news on this front is the success of several large-scale research projects that have assessed both mental health and histories of negative life events, including sexual abuse, thus providing methodological templates for future prospective longitudinal studies. These findings have important implications for developing prevention programs that promote healthy coping when children face serious, negative life events, including but not limited to sexual abuse.

Over the past decade, the field has been enhanced by the development and refinement of a number of tools to assess CSA victims. In particular, we now have a number of tools that assess PTSD, dissociation, and sexuality problems at different developmental points. As well, numerous tools that are now available assess both details about sexual abuse and details of other childhood maltreatment, adversities, and family-related problems. Our tool kit now also includes measures that assess children's perceptions and attributions about their abuse and their family situation. Clinically, these tools may be used as part of a more comprehensive assessment of victim adjustment that is multi-gating, multitrait, multimethod, multi-informant, ensuring that all appropriate symptoms are assessed, that results do not just reflect method variance, and that the perspectives of multiple people involved in a child's life are considered.

PART VII

Problems of Adolescence

Eating Disorders

Eric Stice
Carol B. Peterson

Eating disorders are psychiatric disturbances involving abnormal eating behaviors, maladaptive efforts to control shape and weight, and disturbances in perceived body shape. Three eating disorder syndromes are recognized in the literature: anorexia nervosa, bulimia nervosa, and binge-eating disorder. These eating disorders commonly emerge during adolescence and can result in severe subjective distress, functional impairment, morbidity, and mortality.

We first define these eating disorders, with a focus on diagnostic criteria, associated clinical features, descriptive epidemiology, psychiatric comorbidity, etiology, and young adult outcomes. Next, we discuss the assessment and diagnoses of eating disorders, including general assessment considerations, critical assessment domains, and methods for selecting measurement instruments and integrating assessment data. Finally, we review questionnaire measures and diagnostic interviews that we believe are most feasible and ecologically useful in most assessment and clinical settings, as well as those supported by reliability and validity data.

DEFINITIONS OF THE DISORDERS

Anorexia Nervosa

Diagnostic Criteria

The diagnostic criteria for anorexia nervosa include extreme emaciation (less than 85% of expected weight for height and age), intense fear of gaining weight or becoming fat despite a low body weight, disturbed perception of weight and shape, undue influence of weight or shape on self-evaluation or denial of the seriousness of the low body weight, and amenorrhea in postmenarcheal females (American Psychiatric Association [APA], 1994). Table 16.1 provides a more detailed operationalization of the diagnostic symptoms for anorexia nervosa from the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). A distinction is made between a restricting type of anorexia nervosa, in which the person does not regularly engage in binge eating or purging (self-induced vomiting or laxative–diuretic use), and a binge eating–purging type of anorexia nervosa, in which the person does engage in these behaviors. This distinction is

TABLE 16.1. DSM-IV-TR Criteria for Anorexia Nervosa

-
- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
 - B. Intense fear of gaining weight or becoming fat, even though underweight.
 - C. Disturbance in the way one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
 - D. In postmenarcheal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)

Specify type:

Restricting Type: during the current episode of Anorexia Nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

Binge-Eating/Purging Type: during the current episode of Anorexia Nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

Note. From American Psychiatric Association (2000). Copyright 2000 by the American Psychiatric Association. Reprinted by permission.

based on the observation that individuals with the binge-purge type of anorexia nervosa have elevated personal and family histories of obesity and higher rates of impulsive behaviors, including stealing, drug abuse, self-harm, and mood lability, than individuals with the restricting type of anorexia nervosa (Garner, Vitousek, & Pike, 1993).

Although the diagnostic criteria for anorexia nervosa appear straightforward, they can be challenging to implement (Commission on Adolescent Eating Disorders, 2005). With regard to criterion A, because children and adolescents are undergoing physical maturation, it can be difficult to determine whether a particular individual is actually at or below the 85th percentile for body weight. The most logical solution is to use age- and sex-adjusted norms to determine the weight percentile, but these

can be rather challenging to locate. Complicating matters is the necessity to adjust for height when considering weight, which is most typically done by focusing on the body mass index (BMI = kg/m²). In addition, the weight and height norms are continuously changing as the prevalence of overweight and obesity increase in the general population. With regard to criterion B, younger individuals and those who are not motivated for treatment may deny that they fear weight gain, despite engaging in behaviors clearly designed to prevent weight gain and that clearly suggest a fear of gaining weight. One possible solution to this difficulty would be to reformulate this diagnostic criterion in terms of typical weight control behaviors, so that it would not be necessary to rely on unobservable cognitions for making diagnoses. Criterion D is somewhat controversial, because several studies have found that individuals who meet all of the diagnostic criteria for anorexia nervosa except amenorrhea do not differ from those who meet all of the diagnostic criteria (e.g., Garfinkel et al., 1996). In addition, the fact that certain forms of birth control produce seemingly regular menstrual cycles in those who would not otherwise experience them, whereas other forms of birth control can cause functional amenorrhea complicates matters further. These considerations suggest that this may be a less useful criterion for anorexia nervosa.

Associated Clinical Features

There are several common clinical features associated with anorexia nervosa, including a relentless pursuit of thinness and overvaluation of body shape that usually result in extreme dietary restriction and high levels of physical activity (Fairburn & Harrison, 2003). Consequent to this state of semistarvation, individuals experience mood disturbances, preoccupation with food, and ritualistic and stereotyped eating (Wilson, Becker, & Heffernan, 2003). Anorexia nervosa is also associated with the highest rates of suicidal ideation and mortality of any psychiatric condition (Herzog et al., 2000; Newman et al., 1996). According to the clinical literature (Slade, 1982), anorexia nervosa is also commonly associated with a need for control and dysfunctional relationships with family members, although it is unclear whether this is a cause or consequence of this eating disorder. Because of the extreme

pursuit of thinness that characterizes individuals with anorexia nervosa, the eating disorder is often perceived as a personal accomplishment rather than a psychiatric disorder in need of treatment. Thus, individuals with anorexia nervosa are often brought to treatment by concerned family members or friends and are typically very resistant to treatment, which invariably involves weight restoration.

Common physical presenting symptoms include yellowish skin (due to hypercarotenemia), lanugo (fine, downy hair), hypersensitivity to cold, hypotension, bradycardia, and other cardiovascular problems (Wilson et al., 2003). Purging behaviors may cause enlargement of salivary glands and erosion of dental enamel. Most importantly, dehydration and electrolyte imbalance resulting from chronic purging may lead to serum potassium depletion and consequent hypokalemia, which increases risk of renal failure and cardiac arrhythmia. Osteopenia may also result from malnutrition and decreased estrogen secretion.

Epidemiology, Course, and Periodicity

Epidemiological studies that primarily have relied on diagnostic interviews suggest that between 1.4 and 2.0% of girls and women experience anorexia nervosa, and that between 0.1 and 0.2% of boys or men experience this condition during their lifetime (Favaro, Ferrara, & Santonastaso, 2003; Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993; Lewinsohn, Striegel-Moore, & Seeley, 2000; Woodside et al., 2001). Community-recruited samples indicate that the rates of subthreshold or partial-syndrome anorexia nervosa range between 1.1 and 3.0% for adolescent girls (Lewinsohn et al., 2000; Stice, Presnell, & Bearman, 2007). Point prevalence rates range between 0.3 and 0.7% for full-threshold anorexia nervosa and between 0.0 and 0.4% for subthreshold anorexia nervosa among adolescent females, but the rates for males were too low to detect in epidemiological samples (Commission on Adolescent Eating Disorders, 2005).

Retrospective data suggest two peak periods of risk for onset of anorexia nervosa: age 14 and age 18 (APA, 1994). The fact that these two peak periods of risk correspond to the developmental transitions from grade school to high school and from high school to post-high school roles (e.g., going to college or assuming full-time jobs) suggests that developmental

stressors may precipitate onset of this condition among at-risk individuals. In addition, the fact that eating disorders more broadly tend to emerge after pubertal development suggests that there may be something about physical maturation of secondary sexual characteristics or concomitant increases in the female gender role internalization that increases risk for eating pathology, though the precise mechanisms that underlie this effect are unclear.

The course and outcome of this condition are highly variable (Wilson et al., 2003). Some afflicted individuals stage a complete and lasting recovery after only one episode of anorexia nervosa. Other individuals oscillate between marked weight loss and hospitalization, and periods of restoration of normal weight. Still others show weight restoration but experience bulimia nervosa or some other eating disorder not otherwise specified (ED NOS). Finally, a sizable proportion of afflicted individuals never recover from this eating disorder.

Although much attention has focused on ethnic differences in eating disorders, to date there is little evidence of ethnic differences in the rates of eating disorder symptoms and only limited evidence of ethnic differences in risk factors for eating disorders (Shaw, Ramirez, Trost, Randall, & Stice, 2004; Striegel-Moore, Wilfley, Pike, Dohm, & Fairburn, 2000). The one consistent ethnic difference that has emerged is that African Americans report less body dissatisfaction than their European American counterparts (Smolak & Striegel-Moore, 2001).

Psychiatric Comorbidity

Very few studies have examined the rates of comorbid psychiatric disorders among children and adolescents with anorexia nervosa relative to those without this eating disorder. In addition, virtually nothing is known about comorbidity in males, because the rates of eating disorders are extremely low. However, one study that collapsed across the various eating disorders suggested that men with eating disorders show very similar psychiatric comorbidity to that of women with eating disorders (Woodside et al., 2001). Moreover, many studies examining comorbidity in any age group use treatment-seeking samples, which are typically biased toward finding elevated comorbidity relative to population levels, because each psychiatric condition that an individual has in-

creases the odds of treatment seeking (Berkson, 1946). Another limitation of our knowledge base is that many studies have reported lifetime comorbidity, rather than concurrent comorbidity, and it is not clear that the former really should be conceptualized as comorbidity. From a clinical perspective, greater weight should be given to studies reporting concurrent comorbidity because these are the comorbid conditions that should be assessed with the greatest care among individuals with anorexia nervosa presenting for assessment or treatment.

Lewinsohn, Hops, Roberts, Seeley and Andrews (1993), one of the few groups to have collected psychiatric diagnostic data from a large cohort of community-recruited adolescents, provided detailed information about the rates of comorbid conditions among individuals with anorexia nervosa (personal communication with J. Seeley, January 2006). Relative to the base rates observed in the larger sample of female adolescents, those with anorexia nervosa had elevated rates of dysthymia (5 vs. 44%), bipolar disorder (3 vs. 33%), and oppositional defiant disorder (3 vs. 22%). However, individuals with anorexia nervosa did not show elevated rates of bulimia nervosa, major depression, conduct disorder, attention-deficit/hyperactivity disorder, substance use disorders, social phobia, simple phobia, agoraphobia, posttraumatic stress disorder, panic disorder, obsessive-compulsive disorder, separation anxiety, generalized anxiety disorder, or borderline personality disorder. Newman and colleagues (1996), another group that has collected psychiatric diagnostic data from a large cohort of community-recruited adolescents, also provided detailed information about the rates of comorbid conditions in the past year among individuals with anorexia nervosa (T. Moffitt, personal communication, October 2001). Relative to the base rates observed in the larger sample of female adolescents, those with anorexia nervosa had elevated rates of agoraphobia (50 vs. 5%), simple phobia (25 vs. 13%), dysthymia (25 vs. 4%), marijuana dependence (50 vs. 4%), and antisocial personality disorder (1 vs. 25%). In comparison to the base rates observed in the larger sample of female adolescents, those with anorexia nervosa had lower rates of obsessive-compulsive disorder (0 vs. 7%), social phobia (0 vs. 12%), and alcohol dependence (0 vs. 5%). It was noteworthy that the rates of major depression were similar among the large sample of adolescents relative

to those with anorexia nervosa (21 vs. 25%). However, these estimates should be interpreted with care, because there were only four individuals with anorexia nervosa in the past year from the Newman sample and only nine from the Lewinsohn sample.

We were able to locate a study on a community-recruited sample of individuals with anorexia nervosa that examined the rates of personality disorders. Although it lacked a weight-matched control group, there was evidence that adult females with anorexia nervosa showed elevated rates of narcissistic, dependent, avoidant, and obsessive-compulsive personality disorders, but did not show particularly elevated rates of paranoid, schizoid, schizotypal, antisocial, borderline, or histrionic personality disorders (Gillberg, Rastam, & Gillberg, 1995).

Although there appear to be no comparable data from treatment-seeking samples of adolescents with anorexia nervosa, one large study of adults seeking treatment for anorexia nervosa likewise suggested that the current rates of several disorders were elevated relative to current prevalence data available from epidemiological studies of similar-age participants (e.g., Garfinkel et al., 1995). Herzog, Keller, Sacks, Yeh, and Lavori (1992) found that the rates of current major depression (37%), obsessive-compulsive disorder (5%), panic disorder (7%), and phobic disorder (15%) were substantially higher than the lifetime prevalence rates observed in epidemiological studies. However, Herzog and associates found that the rates of alcohol and drug use disorders (both were 0% in this sample) among treatment-seeking adults were lower than the lifetime prevalence rates observed in epidemiological studies.

Collectively, results suggest that individuals with anorexia nervosa often show elevated rates of mood, anxiety, and substance use disorders. However, the inconsistencies across studies suggest that caution should be used when interpreting these findings, particularly because of the low base rate of anorexia nervosa in the population and the limited data available from adolescent samples.

Etiology

Although there are numerous theories regarding the etiological processes that promote the development of anorexia nervosa, almost no prospective studies have investigated factors that predict subsequent onset of anorexic pa-

thology or increases in anorexic symptoms, and there have been no prospective tests of multivariate etiological models. Thus, surprisingly little is currently known about the risk factors for anorexic pathology or how they work together to promote this pernicious eating disturbance. Prospective studies are essential to determining whether a putative risk factor is a precursor, concomitant, or a consequence of eating pathology.

Theorists have suggested a wide variety of risk factors for anorexia nervosa, including norepinephrine abnormalities, serotonergic abnormalities, childhood sexual abuse, negative life events, low self-esteem, perfectionism, need for control, disturbed family dynamics, internalization of the thin ideal, dietary restraint, and mood disturbances (Fairburn & Harrison, 2003; Kaye, Klump, Frank, & Strober, 2000; Wilson et al., 2003). These findings are largely based on cross-sectional studies that have compared individuals with and without anorexia nervosa (Commission on Adolescent Eating Disorders, 2005). However, because of the cross-sectional design of most of the studies in this literature, it is not possible to confirm whether they temporally preceded the development of anorexia nervosa, or whether they might have been a result of experiencing this pernicious eating disturbance.

Nonetheless, we were able to locate two prospective studies that examined risk factors for anorexia nervosa. In one study, which used the Swedish psychiatric inpatient registry, girls who were born prematurely (particularly those who were small for gestational age) and those born with cephalhematoma (a collection of blood under the scalp of a newborn) were at elevated risk for developing anorexia nervosa (Cnattingius, Hultman, Dahl, & Sparen, 1999). These particular obstetrical complications appear to be relatively specific to anorexia nervosa, given that they do not predict onset of schizophrenia or onset of affective or reactive psychosis (Cnattingius et al., 1999). The authors suggested that subtle brain injury at birth might result in feeding difficulties that increase risk for the onset of anorexia nervosa. Another possibility is that eating pathology in the mothers resulted in a premature birth and small gestational size of the infants because of malnourishment (Commission on Adolescent Eating Disorders, 2005). A second prospective study that tested predictors of subsequent onset of threshold or subthreshold anorexia nervosa

found that girls with the lowest relative weight and those with extremely low scores on a dietary restraint scale at baseline, when they averaged 13 years of age, were at increased risk for future onset of anorexic pathology over a 5-year period (Stice, Presnell, & Bearman, 2007). In contrast to expectancies, early puberty, perceived pressure to be thin, thin-ideal internalization, body dissatisfaction, depressive symptoms, and deficits in parental and peer support did not predict onset of anorexic pathology; however, these null findings should be interpreted with care because of the low base rate of this outcome. Unfortunately, we were unable to locate any additional prospective studies that focused on predicting onset of anorexic pathology or increases in anorexia nervosa symptoms: All of the other studies that focused on this eating disorder collapsed across anorexic and bulimic pathology (e.g., McKnight Investigators, 2003; Patton, Johnson-Sabine, Wood, Mann, & Wakeling, 1990; Santonastaso, Friederici, & Favaro, 1999), rendering it difficult to determine whether these risk factors are specific to each of these two eating disorders.

It is probable that genetic factors contribute to the development of anorexia nervosa, but twin studies have produced conflicting results, with heritability estimates ranging from 0 to 70% for anorexia nervosa and from 0 to 83% for bulimia nervosa (Fairburn, Cowen, & Harrison, 1999; Kaye et al., 2000). Other genetic findings are likewise conflicting. For example, in one study the concordance rate for monozygotic twins was greater than that for dizygotic twins (Treasure & Holland, 1989), but another observed findings in the opposite direction (Walters & Kendler, 1995). Similarly, studies that have tried to identify specific receptor genes associated with anorexia nervosa have produced highly inconsistent results that have not been replicated (e.g., Hinney et al., 1998). The large range in parameter estimates suggests fundamental problems with sampling error, resulting from small samples, the reliability of diagnostic procedures, or statistical models used to estimate genetic effects. It therefore appears premature to draw conclusions regarding the degree of genetic heritability of anorexia nervosa at this time.

Young Adult Outcomes

Research suggests that among adolescents with anorexia nervosa, 50–70% will recover, 20%

will show improvement but continue to exhibit residual symptoms, and 10–20% will not recover from this eating disorder (Commission on Adolescent Eating Disorders, 2005). Although these recovery figures appear promising, it is not uncommon for recovery to take up to 10 years (Strober, Freeman, & Morrell, 1997). In addition, those showing residual symptoms often exhibit abnormalities in weight, eating behaviors, body image, and menstrual functioning, and disturbances in psychosocial functioning. Furthermore, relapse is common after discharge from inpatient treatment, occurring in approximately 30% of the cases (Strober et al., 1997). There is also evidence that many patients with anorexia nervosa, particularly of the restricting subtype, develop binge eating and eventually satisfy criteria for bulimia nervosa after sufficient weight gain (Eddy et al., 2002). (Few individuals with bulimia nervosa show subsequent onset of anorexia nervosa.)

Anorexia nervosa also has one of the highest mortality rates of any psychiatric disturbance; approximately 6% of patients diagnosed with this disorder die per decade of illness, and anorexia nervosa patients are 12 times more likely to die than women of similar age in the population (Keel et al., 2003; Sullivan, 1995). The most common causes of death are acute starvation and suicide. The suicide rate for anorexia nervosa is 57 times greater than that for the general population (Keel, Fulkerson, & Leon, 1997).

Bulimia Nervosa

Diagnostic Criteria

The diagnostic criteria for bulimia nervosa include recurrent episodes (at least two episodes per week for the previous 3 months) of uncontrollable consumption of large amounts of food, recurrent use (at least twice weekly for the previous 3 months) of compensatory behavior to prevent consequent weight gain (e.g., self-induced vomiting, laxative abuse, diuretic abuse, fasting, or excessive exercise), and undue influence of weight and shape on self-evaluation (APA, 1994). Table 16.2 provides a more detailed operationalization of DSM-IV diagnostic symptoms for bulimia nervosa. If these symptoms occur exclusively during a period of time in which the individual satisfies diagnostic criteria for anorexia nervosa, the lat-

TABLE 16.2. DSM-IV-TR Criteria for Bulimia Nervosa

-
- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 - (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
 - (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
 - B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
 - C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
 - D. Self-evaluation is unduly influenced by body shape and weight.
 - E. The disturbance does not occur exclusively during episodes of Anorexia Nervosa.

Specify type:

Purging Type: during the current episode of Bulimia Nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Nonpurging Type: during the current episode of Bulimia Nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Note. From American Psychiatric Association (2000). Copyright 2000 by the American Psychiatric Association. Reprinted by permission.

ter diagnosis is given precedence because of the treatment implications; for those with anorexia nervosa, weight restoration is a key clinical goal. During binge episodes, individuals with bulimia nervosa (and binge-eating disorder) typically consume between 1,000 and 2,000 calories, which usually involve foods with high fat and sugar content (Walsh, 1993; Yanovski et al., 1992). Bulimia nervosa is typically associated with marked feelings of guilt and shame regarding eating behaviors, which are often kept secret from friends and family (Wilson et al., 2003). One benefit is that this shame makes it easier to engage individuals with bulimia

nervosa in treatment than is the case for individuals with anorexia nervosa, although the average patient has bulimia nervosa for 6 years before seeking treatment (Fairburn & Harrison, 2003). Similar to individuals with anorexia nervosa, those with bulimia nervosa often present with rigid rules regarding eating and an overvaluation of thinness.

The diagnostic criteria for bulimia nervosa may also be somewhat difficult to interpret (Commission on Adolescent Eating Disorders, 2005). The diagnostic criteria for binge eating, criterion A, has specific requirements regarding the amount of food typically consumed during a binge episode (larger than most people would eat), the duration of the binge episode (in a discrete period of time), and subjective experience of the episode (a sense of a lack of control over eating). It can be difficult to determine with certainty whether each of these conditions is satisfied for a particular individual. For example, certain clients may endorse uncontrollable binge eating in a discrete period of time but report eating a quantity of food that is not larger than what most people eat (e.g., two medium bowls of cereal). Because many clients exhibit a relatively chaotic eating pattern, it is often difficult to determine whether the reported eating episodes simply represent meals of a typical content at atypical times, or whether they truly represent clinically significant binge eating. Other clients, particularly males, may endorse eating an amount of food that is clearly larger than what most people eat (e.g., two large pizzas) but may deny that they experienced a lack of control over their eating. Criterion B requires that individuals endorse recurrent and inappropriate compensatory behaviors used to prevent weight gain. Although certain of these behaviors are discrete and easy to quantify, such as self-induced vomiting, others can be very difficult to operationalize, such as fasting and excessive exercise. A large proportion of adolescent girls endorse excessive exercise for weight control purposes, but on further probing it becomes clear that the exercise is not particularly excessive (e.g., doing 50 sit-ups or taking a 15-minute walk). It can also be difficult to determine whether the exercise is specifically used to compensate for overeating or simply part of a healthy lifestyle. It can also be challenging to determine when use of laxatives or diuretics becomes "misuse." Criterion C requires that individuals report engaging in binge eating and compensatory behaviors an average

of twice weekly for 3 months, but there is evidence that individuals slightly below this frequency and duration threshold report similar impairment and comorbidity to that of persons above this threshold (Garfinkel et al., 1995). Last, criterion D stipulates that self-evaluation be unduly influenced by weight and shape, but this criterion is endorsed by a large portion of adolescent girls and may be difficult to separate from body dissatisfaction. These ambiguities suggest that it might be beneficial to use more behavioral criteria for bulimia nervosa, or that clear decision algorithms should be developed for widescale use.

Clinical Features

There are several common clinical features of bulimia nervosa. This eating disorder is typified by rigid rules regarding eating and by dysfunctional cognitions about body shape and weight, as is the case with anorexia nervosa. Individuals with bulimia nervosa are also often secretive about their eating disturbances because of shame and guilt over these behaviors. It is not uncommon for parents and peers to be unaware of the disordered eating. In contrast to anorexia nervosa, individuals with bulimia nervosa are typically distressed about their eating behavior and are receptive to treatment, although approximately one-third of these individuals are fearful about giving up these behaviors and show a limited response to treatment. In addition, individuals with bulimia nervosa are typically in the average weight range. Laboratory-based investigations have revealed that during binge-eating episodes, individuals with bulimia nervosa primarily consume carbohydrates and fats (47 and 40% respectively; Walsh, 1993). Community-recruited samples indicate that bulimia nervosa is also associated with an increased risk for suicide attempt (Newman et al., 1996).

Bulimia nervosa may be associated with physical complaints, including fatigue, headaches, and enlarged salivary glands secondary to recurrent vomiting, and erosion of dental enamel from gastric fluids (Wilson et al., 2003). Electrolyte abnormalities (hypokalemia and hypochloremia) from frequent purging can result in cardiac arrhythmias and arrest. Regular use of laxatives may also result in dependence and withdrawal upon discontinuation, and also cause colon damage.

Epidemiology, Course, and Periodicity

Epidemiological studies suggest that between 1.1 and 4.6% of girls and women experience bulimia nervosa, and between 0.1 and 0.2% of boys or men experience this condition during their lifetime (Favaro et al., 2003; Garfinkel et al., 1995; Lewinsohn et al., 1993, 2000; Woodside et al., 2001). Community-recruited samples indicate that for adolescent females, the rates of subthreshold or partial-syndrome bulimia nervosa range between 2.0 and 5.4% (Lewinsohn et al., 2000; Stice et al., 2007). Point prevalence rates range between 0.7 and 1.5% for full-threshold bulimia nervosa, and between 0.0 and 1.2% for subthreshold bulimia nervosa among adolescent females, but the rates for males were too low to detect in epidemiological samples (Commission on Adolescent Eating Disorders, 2005). Although eating disorders such as bulimia nervosa are much more rare in males, some evidence suggests that male athletes may be at elevated risk for eating disorders (Wilson et al., 2003). Prospective epidemiological studies indicate that the peak period of risk for onset of full- and subthreshold bulimia nervosa is between 14 and 19 years of age for females (Lewinsohn et al., 2000; Stice et al., 2007).

Results in community-recruited samples suggest that bulimia nervosa typically shows a chronic course characterized by periods of recovery and relapse, whereas subthreshold bulimic pathology shows less chronicity (Bohon, Muscatell, Burton, & Stice, 2005; Fairburn, Cooper, Doll, Norman, & O'Connor, 2000). One large study followed a community-recruited cohort of 102 adolescent girls and young women with full-threshold bulimia nervosa for 5 years (Fairburn et al., 2000). Results indicated that afflicted individuals often showed marked initial improvement, followed by gradual improvement. By the end of this 5-year study, 15% of the participants still met diagnostic criteria for full-threshold bulimia nervosa, 2% met criteria for anorexia nervosa, and 34% met criteria for ED NOS. Findings also indicated instability in the course shown by this cohort; each year approximately 33% showed symptom remission, and 33% showed relapse. A second study that followed 101 community-recruited adolescent girls with full- or subthreshold bulimia nervosa indicated that 54% of the participants with bulimia

nervosa recovered over the 1-year follow-up, and that 45% of the participants with subthreshold bulimia nervosa recovered over this follow-up period (Bohon et al., 2005). In another community-recruited study, 40% of women with bulimia nervosa showed recovery over a 1-year follow-up (Grilo et al., 2003).

Psychiatric Comorbidity

As described previously, limited data are available regarding psychiatric comorbidity among adolescents with eating disorders, including bulimia nervosa. Lewinsohn and colleagues (1993), one of the few groups with comorbidity data from a large cohort of community-recruited adolescents, provided information about the rates of comorbid conditions among individuals with bulimia nervosa (J. Seeley, personal communication, January 2006). Compared to the base rates observed in the larger sample of female adolescents, those with bulimia nervosa showed elevated rates of major depression (60 vs. 89%), dysthymia (6 vs. 17%), bipolar disorder (3 vs. 11%), and conduct disorder (2 vs. 11%). However, individuals with bulimia nervosa did not show elevated rates of simple phobia, social phobia, agoraphobia, overanxious disorder, panic disorder, posttraumatic stress disorder, generalized anxiety disorder, separation anxiety, obsessive-compulsive disorder, oppositional defiant disorder, attention-deficit/hyperactivity disorder, substance use disorders, or borderline personality disorder. Moffitt and associates (Newman et al., 1996) also provided detailed information about the past-year prevalence of comorbid conditions among individuals with bulimia nervosa from a community-recruited sample of adolescents (T. Moffitt, personal communication, October 2001). Relative to the base rates observed in the larger sample of female adolescents, those with bulimia nervosa had elevated rates of agoraphobia (22 vs. 5%), social phobia (22 vs. 12%), major depression (66 vs. 22%), dysthymia (22 vs. 4%), alcohol dependence (33 vs. 5%), marijuana dependence (22 vs. 4%), and antisocial personality disorder (11 vs. 1%). The rates of the remaining major psychiatric diagnoses were roughly equivalent in young women with and without bulimia nervosa. These estimates should be interpreted with care, because there were only nine individuals with bulimia nervosa in the past year from the

Newman sample, and only 18 from the Lewinsohn sample.

It is noteworthy that in one large, community-recruited sample of adolescents and adults (Garfinkel et al., 1995) relative to comparison participants without bulimia nervosa, those with current bulimia nervosa had much higher current prevalence rates of major depression (2 vs. 20%), any anxiety disorder (8 vs. 33%), social phobia (4 vs. 29%), simple phobia (4 vs. 18%), agoraphobia (2 vs. 13%), panic disorder (1 vs. 11%), generalized anxiety disorder (1 vs. 4%), and alcohol dependence (1 vs. 4%). More confidence may be placed in these estimates, because there were 55 individuals with bulimia nervosa in the Garfinkel and colleagues sample. Although there appear to be no comparable data from treatment-seeking samples of adolescents with bulimia nervosa, one large study of adults seeking treatment for this eating disorder likewise suggested that current rates of several disorders were elevated relative to current prevalence data available from epidemiological studies of similar-age participants (e.g., Garfinkel et al., 1995). Specifically, Herzog and associates (1992) found that the rates of current major depression (32%) and substance use disorders (5%) were substantially higher than the lifetime prevalence rates observed in epidemiological studies. However, the rates of obsessive-compulsive disorder (1%), panic disorder (0%), and phobic disorder (9%) were generally similar to the rates of these conditions found in epidemiological studies.

Thus, findings from both community-recruited and treatment-seeking samples suggest that individuals with bulimia nervosa often show elevated rates of mood disorders, anxiety disorders, and substance use disorders. However, the inconsistency in the findings across studies suggests that these results should be interpreted with care.

Etiology

According to the general sociocultural model of bulimia nervosa, an internalization of the socially sanctioned thin ideal for females combines with direct pressures for females thinness (e.g., weight-related teasing) to promote body dissatisfaction, which in turn is thought to increase the risk for the initiation of dieting and for negative affect and conse-

quent bulimic pathology (Cattarin & Thompson, 1994; Garner, Olmsted, & Polivy, 1983; Polivy & Herman, 1985; Stice, 2001). This body dissatisfaction is thought to lead females to engage in dietary restraint in an effort to conform to this thin ideal, which paradoxically increases the likelihood of the initiation of binge eating. Dieting also entails a shift from a reliance on physiological cues to cognitive control over eating behaviors, which leaves the individual vulnerable to overeating when these cognitive processes are disrupted. Body dissatisfaction is also theorized to contribute to negative affect, which increases the risk that these individuals will turn to binge eating to provide comfort and distraction from negative emotional states.

Consistent with the sociocultural model, thin-ideal internalization, perceived pressure to be thin, body dissatisfaction, dietary restraint, and negative affect have been consistently found to increase the risk for future onset of bulimic symptoms and bulimic pathology in prospective studies (Field, Camargo, Taylor, Berkey, & Colditz, 1999; Killen et al., 1994, 1996; Stice, Killen, Hayward, & Taylor, 1998). Experiments have confirmed that a reduction in thin-ideal internalization, body dissatisfaction, and negative affect have produced the expected decreases in bulimic symptoms but have failed to provide support for dietary restraint (for a review, see Stice, 2002). For example, randomized trials have found that assignment to a weight loss diet results in decreases in binge eating and bulimic symptoms (Klem, Wing, Simkin-Silverman, & Kuller, 1997; Presnell & Stice, 2003). A number of other risk factors have received support in a few prospective studies, such as deficits in social support, substance abuse, and elevated body mass, but other hypothesized risk factors for bulimic pathology have not received support in prospective studies, including early menarche and temperamental impulsivity (Stice, 2002).

There is also some evidence that early feeding problems may increase the risk for future binge eating and bulimic symptoms. Marchi and Cohen (1990) found that digestive problems and pica in early childhood were associated with subsequent bulimic symptoms during adolescence. Another study found that initial elevations in body mass and longer duration of infant sucking in the first year of life predicted emergence of overeating and vomiting during

middle childhood (Stice, Agras, & Hammer, 1999), although these variables have not been shown to predict onset of DSM-IV binge eating or bulimia nervosa.

A variety of hypotheses have been offered regarding biological variables that may increase risk for onset or persistence of bulimia nervosa (Kaye et al., 2000). However, we were unable to locate any prospective or experimental tests of these hypotheses. In addition, it is almost certain that genetic factors contribute to the development of bulimia nervosa, but twin studies have produced conflicting results, with heritability estimates ranging from 0 to 83% for bulimia nervosa (Bulik, Sullivan, & Kendler, 1998; Fairburn et al., 1999; Kaye et al., 2000). Furthermore, studies of specific receptor genes associated with bulimia nervosa have produced inconsistent results that have not been replicated (e.g., Hinney et al., 1998). Thus, it appears premature to draw conclusions regarding the degree of genetic heritability of bulimia nervosa at this time.

Young Adult Outcomes

Approximately 40–75% of adolescents and adults with bulimia nervosa recover within a 5-year period and the remaining patients often show improvements in their symptoms (Commission on Adolescent Eating Disorders, 2005). However, the relapse rates are very high, with about one-third of patients relapsing within 1 year of recovery. In addition, many patients with bulimia nervosa exhibit residual symptoms after they no longer meet full diagnostic criteria for this eating disorder and show continued impairments in physical and psychosocial functioning (Fairburn et al., 2000). The mortality rate for bulimia nervosa is less than 1% (Keel, Mitchell, Miller, Davis, & Crow, 1999).

Furthermore, prospective studies have found that threshold and subthreshold bulimia nervosa increase the risk for future onset of depression, suicide attempts, anxiety disorders, substance abuse, obesity, and health problems (Johnson, Cohen, Kasen, & Brook, 2002; Stice, Cameron, Killen, Hayward, & Taylor, 1999; Stice, Hayward, Cameron, Killen, & Taylor, 2000; Striegel-Moore, Seeley, & Lewinsohn, 2003). For example, approximately 40% of individuals with bulimia nervosa will eventually meet diagnostic criteria for major depression,

even if they recover from their eating disorder (Fairburn et al., 2000).

Binge-Eating Disorder

Diagnostic Criteria

Binge-eating disorder is listed in DSM-IV (APA, 1994) as a provisional eating disorder diagnosis that requires further study, and as an example of eating disorder not otherwise specified. This eating disorder involves (1) repeated episodes (at least 2 days per week for previous 6 months) of uncontrollable binge eating characterized by certain features (e.g., rapid eating, eating until uncomfortably full, eating large amounts of food when not physically hungry, eating alone because of embarrassment, and feeling guilty or depressed after overeating), (2) marked distress regarding binge eating, and (3) the absence of regular compensatory behaviors (APA, 1994). Table 16.3 provides a more detailed operationalization of the provisional diagnostic symptoms for binge-eating disorder from DSM-IV. If these symptoms occur exclusively during a period of time in which the individual satisfies diagnostic criteria for anorexia nervosa or bulimia nervosa, these latter diagnoses are given precedence.

The diagnostic criteria for binge-eating disorder may also be difficult to apply. As with the criteria for bulimia nervosa, it can be challenging to determine whether purported binge episodes truly involve the consumption of an objectively large amount of food and truly involve a subjective loss of control over eating. Also, similar to bulimia nervosa, certain individuals, particularly males, may not endorse the features that reflect subjective distress regarding the binge eating, even though the binge eating may be severe. Also, few data demonstrate that the particular cutoff points regarding the frequency (twice weekly) or duration (for 6 months) optimally differentiate between individuals with and without clinically meaningful binge-eating disorder. In addition, it is often difficult for individuals to provide an accurate frequency of binge-eating episodes, because they are not punctuated by discrete compensatory behaviors (self-induced vomiting). Individuals with binge-eating disorder often report overeating continuously throughout the day (i.e., grazing), which is why it is necessary to focus on the frequency of binge-eating days

TABLE 16.3. DSM-IV-TR Research Criteria for Binge-Eating Disorder

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
- (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
 - (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B. The binge episodes are associated with three (or more) of the following:
- (1) eating much more rapidly than normal
 - (2) eating until feeling uncomfortably full
 - (3) eating large amounts of food when not feeling physically hungry
 - (4) eating alone because of being embarrassed by how much one is eating
 - (5) feeling disgusted with oneself, depressed, or very guilty after overeating
- C. Marked distress regarding binge eating is present.
- D. The binge eating occurs, on average, at least 2 days a week for 6 months.
Note: The method of determining frequency differs from that used for Bulimia Nervosa; future research should address whether the preferred method of setting a frequency threshold is counting the number of days on which binges occur or counting the number of episodes of binge eating.
- E. The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise) and does not occur exclusively during the course of Anorexia Nervosa or Bulimia Nervosa.

Note. From American Psychiatric Association (2000). Copyright 2000 by the American Psychiatric Association. Reprinted by permission.

rather than binge-eating episodes for diagnostic purposes.

Clinical Features

Relatively little is known about the common clinical features of binge-eating disorder, particularly during childhood and adolescence. However, studies of adults suggest that this condition often results in marked weight gain and onset of obesity (Fairburn et al., 2000).

Thus, binge-eating disorder is often associated with medical complications related to obesity, including high blood pressure, adverse lipoprotein profiles, diabetes mellitus, atherosclerotic cerebrovascular disease, coronary heart disease, colorectal cancer, reduced lifespan, and death from all causes (Dietz, 1998; Fontaine, Redden, Wang, Westfall, & Allison, 2003). In addition, individuals with binge-eating disorder often present with marked shame and guilt about their eating behaviors, which is associated with significant psychological distress.

Epidemiology, Course, and Periodicity

Epidemiological studies suggest that between 0.2 and 1.5% of girls and women experience binge-eating disorder, and between 0.9 to 1.0% of boys and men experience this condition during their lifetime (Cotrufo, Barretta, Monteleone, & Maj, 1998; Favaro et al., 2003; Hoek & van Hoeken, 2003; Kjelsas, Bjornstrom, & Gotestam, 2004). Community-recruited samples indicate that for adolescent females, the rate of subthreshold binge-eating disorder is 1.6% (Lewinsohn et al., 2000; Stice et al., 2007). Point prevalence rates range between 0.6 and 0.7% for full-threshold binge-eating disorder, but the rates for males were too low to detect in epidemiological samples (Commission on Adolescent Eating Disorders, 2005). To the best of our knowledge, there are no prospective data on the higher risk periods for onset of binge-eating disorder, although prospective studies have found that the peak period of risk for onset of DSM-IV–defined binge-eating episodes tends to occur between ages 16 and 18 years (Stice et al., 1998, 2007). However, retrospective data from clinical samples suggest that binge-eating disorder often shows a somewhat later age of onset relative to both anorexia nervosa and bulimia nervosa (Commission on Adolescent Eating Disorders, 2005).

Community-recruited natural history studies suggest that binge-eating disorder often shows a high remission rate over time, with nearly 50% of cases showing recovery by 6-month follow-up (Cachelin et al., 1999) and approximately 80% of cases showing recovery by 3- to 5-year follow-up (Fairburn et al., 2000; Wilson et al., 2003). However, some studies revealed that many of these individuals developed ED NOS or continued to show some residual

symptoms, as is the case with other eating disorders. In addition, Fairburn et al. (2000) found that the rate of obesity increased from 20 to 39% over this 5-year study.

Psychiatric Comorbidity

To the best of our knowledge, no studies have examined the rates of psychiatric disorders among children and adolescents with and without binge-eating disorder, which is perhaps not surprising given that this most recently recognized eating disorder has a relatively later age of onset. In the only study of non-treatment-seeking adult individuals that used a control group, Telch and Stice (1998) found that women with binge-eating disorder did not show significantly higher rates of major depression, bipolar disorder, dysthymia, substance abuse or dependence, panic disorder, agoraphobia, social phobia, or obsessive-compulsive disorder than weight-matched comparison women (although participants with binge-eating disorder did report elevated lifetime rates of major depression). Telch and Stice also found that individuals with binge-eating disorder did not show significantly elevated rates of avoidant, dependent, obsessive-compulsive, passive-aggressive, self-defeating, paranoid, schizotypic, schizoid, histrionic, narcissistic, borderline, or antisocial personality disorders relative to weight-matched controls. In a parallel study of individuals seeking weight loss treatment, women with binge-eating disorder reported significantly higher rates of current major depression (25%) relative to weight-matched comparison participants (6%), but the two groups did not differ in terms of current bipolar disorder, dysthymic disorder, post-traumatic stress disorder, agoraphobia, panic disorder, social phobia, specific phobia, or generalized anxiety disorder (Fontenelle et al., 2003). The most likely explanation for the evidence of elevated rates of comorbid current major depression in the treatment-seeking sample, but not in the non-treatment-seeking sample, is that treatment-seeking samples are biased toward finding elevated comorbidity (Berkson, 1946). Consistent with this interpretation, the rate of current major depression was 16% in another sample (Wilfley et al., 2000) of treatment-seeking individuals with binge-eating disorder, relative to the 5% rate observed in the non-treatment-seeking sample examined by Telch and Stice (1998).

Thus, it appears that individuals with binge-eating disorder do not typically show the elevated rates of mood, anxiety, and substance use disorders documented for anorexia nervosa and bulimia nervosa, although there is evidence that individuals with binge-eating disorder may show elevated rates of depression in treatment-seeking populations. However, these findings should be generalized to adolescents with caution, because all of these estimates are from samples of adults.

Etiology

To date there have been relatively few theories regarding the etiological processes that promote binge-eating disorder, but those that have been proposed conceptually overlapped with etiological theories put forth for bulimic pathology (Vogeltanz-Holm et al., 2000). Prospective studies have provided evidence that initial elevations in body mass, body dissatisfaction, dietary restraint, negative affect, and emotional eating increase the risk for future onset of binge eating (Stice, Presnell, & Spangler, 2002; Stice et al., 1998; Vogeltanz-Holm et al., 2000).

Young Adult Outcomes

Little is known about the young adult outcome associated with binge-eating disorder. However, in one community-recruited natural history study, individuals with binge-eating disorder often manifested onset of obesity (Fairburn et al., 2000). These findings converge with evidence indicating that binge eating is a risk factor for obesity onset (Stice et al., 2002). Furthermore, low self-confidence, diminished energy level, and discrimination from teachers and peers have been found to present significant obstacles to achievement in school and other pursuits among overweight adolescents (Gortmaker, Must, Perrin, & Sobol, 1993; Morrill, Leach, Shreeve, Puhl, & Brownell, 2001).

Eating Disorder Not Otherwise Specified

In addition to the three widely recognized eating disorders noted earlier, DSM-IV also allows for the diagnosis of eating disorder not otherwise specified (ED NOS; APA, 1994). This category includes subdiagnostic levels of anorexia nervosa, bulimia nervosa, and binge-eating dis-

order (Fairburn & Harrison, 2003). For example, an individual who only uses compensatory behaviors an average of one time per week (versus two times per week) but meets all other diagnostic criteria for bulimia nervosa probably warrants a diagnosis of ED NOS. The ED NOS category also includes partial-syndrome eating disorders. For instance, an individual who does not evidence uncontrollable binge eating but nonetheless engages in weekly compensatory behaviors may warrant a diagnosis of ED NOS. Finally, the ED NOS category includes other atypical eating disorders, such as food avoidance or refusal, rumination (chewing food and then spitting it out), or pica (eating nonfood items) exhibited during adolescence and adulthood.

ED NOS is particularly important during childhood and adolescence, because nearly half of individuals in this developmental period who seek treatment for eating pathology do not meet full diagnostic criteria for anorexia nervosa or bulimia nervosa (Fisher, Schneider, Burns, Symons, & Mandel, 2001; Williamson, Gleaves, & Savin, 1992). The clinical features vary greatly for ED NOS.

Relatively little is known about the prevalence, course, or periodicity of ED NOS. In one study a community-recruited sample of individuals with ED NOS showed a recovery rate of 59% over a 1-year follow-up (Grilo et al., 2003), suggesting that the course may be shorter than is the case for anorexia or bulimia nervosa. Little research has been conducted on psychiatric comorbidity in samples of individuals with ED NOS, or on etiological processes and young adult outcomes within the general eating disorder category.

There are certain concerns with the current criteria for ED NOS in DSM-IV (APA, 1994). First, nearly half of adolescents seeking treatment for eating pathology do not meet full diagnostic criteria for anorexia or bulimia nervosa (Fisher et al., 2001; Herzog, Hopkins, & Burns, 1993; Williamson et al., 1992). The fact that the diagnostic net is missing nearly half of adolescents who present for treatment clearly suggests that frequency criteria for certain symptoms are overly high and that diagnostic criteria for certain syndromes are overly narrow. With regard to the former, a large portion of individuals presenting for treatment do not satisfy the frequency criteria for binge eating and compensatory behaviors for bulimia nervosa and binge-eating disorder diagnoses.

With regard to the latter, the fact that many individuals presenting for treatment have symptom compositions that fall outside the diagnostic criteria for anorexia nervosa, bulimia nervosa, and binge-eating disorder suggests the need to recognize the diversity of symptom presentation for these eating disturbances. For example, many adolescent males endorse recurrent, uncontrollable eating binges but do not satisfy criteria for binge-eating disorder, because they do not report distress and guilt over their eating behavior. Although ED NOS can be applied to these cases, because the patients, their parents, and reimbursement parties often do not consider these disturbances as serious as a full-threshold diagnosis, treatment or proper case management is often hampered.

Another limitation of the current diagnostic criteria is that there is no requirement that the eating disturbances cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, as is the case for other psychiatric disorders, such as major depression. It is our understanding that this criterion was not originally included because many patients with clinically significant anorexia nervosa and bulimia nervosa deny distress or impairment. However, this criterion would be particularly useful for determining whether a diagnosis of ED NOS is warranted for individuals who do not quite meet full diagnostic criteria for another eating disorder. Such an amendment to the diagnostic criteria would also be potentially useful if a decision were made to relax the frequency requirements or symptom combination requirements we discussed previously. However, it might not be prudent to include the requirement of clinically significant distress or impairment in the diagnostic criteria for anorexia nervosa given that many patients with this condition minimize their eating disturbance.

ASSESSMENT AND DIAGNOSIS OF EATING DISORDERS

General Assessment Considerations

The assessment of youth with eating disorder symptoms poses a number of challenges for the clinician. Adolescents with eating disorders are usually referred because of concerns about weight loss or symptoms that include binge eating, purging, fasting, extreme dietary restriction, and excessive exercise. At times, relatives

and school personnel express greater concern about these symptoms than do adolescents. Because individuals with eating disorders usually conceal their symptoms from others, many adolescents are symptomatic for lengthy periods of time before they seek treatment or are brought to treatment by their parents. Significant weight loss is usually apparent and tends to prompt parents' decision to pursue an evaluation. Occasionally, adolescents successfully hide their weight loss by wearing loose clothing. Some parents are aware of their child's weight loss but do not pursue treatment. Adolescents with eating disorders who are not underweight are often referred to treatment because they have been "caught" (e.g., self-induced vomiting, binge eating) or have admitted they are symptomatic. In most cases, parents are worried about their child's health and safety, and this concern is typically the main parental priority. Older adolescents may seek treatment on their own, without the family's knowledge.

One of the most difficult aspects of conducting these assessments is that many individuals with eating disorders are ambivalent about seeking treatment or refuse treatment altogether. Although treatment refusal is common among patients of all ages with eating disorders, it complicates the assessment of youth who are brought unwillingly to the evaluation by their parents. The accuracy of self-report in eating disorder assessment is compromised by a number of factors, including patients' minimization of symptoms to avoid treatment, lack of self-awareness or understanding, and cognitive biases that may affect accurate information recall (Anderson & Paulosky, 2004; Schacter, 1999; Vitousek, Daly, & Heiser, 1991). Malnourishment and nutritional deprivation may also impair concentration and memory (Keys, Brozek, Henschel, Mickelson, & Taylor, 1950).

The clinician should consider a number of factors in conducting the initial assessment and may choose to discuss some of these issues with parents by phone before the appointment. The issue of confidentiality is particularly problematic, because some youth are unwilling to disclose information to the clinician in front of the parents, or to share any information about themselves that they know will be revealed by the clinician to the parents. Parents often recognize this process and may be willing to relinquish their right to be told details about the

content of the interactions between the clinician and adolescent, as long as they are assured that the clinician will inform them of any information pertinent to their child's safety (e.g., medical instability, suicidal thoughts, self-injurious behaviors, substance abuse).

In general, one of the most crucial assessment and therapeutic strategies is establishment of a solid rapport that provides a foundation for treatment and facilitates the collection of more accurate assessment data (Peterson, 2005). For this reason, the clinician should attempt to devote at least part of the initial intake to meeting alone with the adolescent to understand his or her perspective and needs. Although some youth with eating disorders deny that they have problems with eating and weight, most are willing to admit that they are struggling with interpersonal problems, academic concerns, and even depressive symptoms. In contrast, some youth are readily willing to discuss their eating disorder symptoms in detail.

As described below, a number of empirically supported instruments may be used in the assessment of eating disorder symptoms. When administered carefully, these instruments may actually enhance rapport and improve the comprehensiveness and quality of assessment data. Many adolescents with eating disorders experience significant interpersonal isolation and are ashamed of at least some of their symptoms, particularly binge eating. The use of well-articulated questions during the intake, along with appropriate assessment measures, provides for adolescents a sense that the clinician understands them and their symptoms.

When conducting an eating disorder assessment interview, semistructured or unstructured, it is most effective to convey a combination of empathy, curiosity, and patience (Miller & Rollnick, 2002; Peterson, 2005). This stance may be challenging in the face of open hostility, withdrawal, or acute medical instability, but it is nonetheless essential to building a sense of trust. When the clinician encounters anger and resistance, it is helpful to consider the source of these feelings, and to express empathy and curiosity to the adolescent. Fear is often the driving force behind this type of hostility, because most adolescents with eating disorders are terrified that they will be forced to change their eating and gain weight. The clinician can explore these possibilities with the adolescent during the initial interview (e.g., "I sense that

you don't want to be here talking with me. Before I start asking you questions, let's start with your feelings about coming here today") to gradually begin the process of building rapport.

Eating disorder assessment interviews should be characterized by detailed questioning and frequent clarification (Fairburn & Cooper, 1993). Probing in detail is especially helpful to elicit accurate data and to communicate the clinician's knowledge of eating disorder patterns. For example, if an adolescent reports eating an apple for lunch, the clinician can express interest in the size of the apple, whether the apple was peeled, and how much of the apple was actually consumed. When obtaining information about the types and amounts of food eaten during a binge-eating episode, the clinician can ask, "What else did you eat?"—even after the adolescent has described the consumption of an unusually large amount of food. Once again, such a question serves to elicit accurate data, as well as convey to the adolescent that the clinician understands the nature of binge eating and is not shocked or negatively judgmental about how much food has been eaten.

In summary, the clinical assessment of eating disorders may be challenging for a number of reasons, including the need to address concerns of all family members, the importance of conducting a detailed evaluation, and the high likelihood of encountering inaccurate self-reported data. The goal of the clinician is to express empathy, patience, and curiosity regardless of hostility, anxiety, or denial that may be conveyed by adolescents or their family members. The importance of rapport in eating disorder assessment and treatment cannot be overemphasized, and the assessment phase provides a critical opportunity for the gradual development of trust and honesty.

Assessment Domains

The clinical assessment of eating disorders is multidimensional, incorporating medical, psychological and behavioral, nutritional, interpersonal, and psychosocial factors. Careful assessment in each of these domains is essential for establishing an accurate diagnosis, ensuring medical stability, and devising an effective treatment plan. Eating disorder assessment and treatment often involve a multidisciplinary team, including a psychologist, a psychiatrist, a pediatrician, and a dietician. If different profes-

sionals conduct various components of the assessment, then it is crucial that they communicate with each other and are in agreement about the assessment information and treatment plan.

Medical Evaluation

Youth with eating disorders may experience a wide range of medical problems, some of which can be both acutely and chronically dangerous (Roerig, Mitchell, Myers, & Glass, 2002). A thorough medical evaluation should be conducted as soon as possible after the initial assessment (for detailed reviews, see Pomeroy, 2004; Society for Adolescent Medicine, 1995), especially for individuals who are significantly underweight and/or purging. Blood testing for hypokalemia is particularly crucial. The medical evaluation typically informs the most immediate question of medical stability and whether the adolescent requires hospitalization.

One aspect of the medical condition that is often assessed by the mental health clinician is height and weight, because this information is needed to determine the percentage of ideal body weight as well as the BMI (kg/m^2 ; see the National Institutes of Health BMI website, nhlbisupport.com/bmi/, for calculating BMI values). These data are often required immediately to make an eating disorder diagnosis, as well as to provide preliminary information about the degree of emaciation in underweight adolescents. Self-reported height and weight should be confirmed by actual measurement, and if possible the adolescent should be weighed in a gown. Some adolescents deliberately provide misinformation about their height and weight to avoid treatment, as a way of insisting that they are "fine"; others give inaccurate information unintentionally.

Although obtaining height and weight is an important component of the initial assessment, many individuals with eating disorders find this aspect of the evaluation highly distressing. The clinician should be aware of adolescents' concerns and be as sensitive as possible about the weighing procedure. Individuals with eating disorders typically weigh themselves frequently or avoid weighing themselves out of fear or distress (Fairburn & Cooper, 1993). Asking explicitly how the adolescent feels about being weighed may help this process, as

well as providing the option of a “blind weight,” in which the adolescent neither sees nor hears the actual number. As important as it is to be sensitive to the adolescent’s needs in the weighing process, the clinician must also be vigilant about the possibility of deception (e.g., adding weights to the pocket of the gown, drinking large amounts of fluid prior to weighing).

Psychological and Behavioral Variables

Assessment of psychological and behavioral variables is necessary to determine eating disorder and comorbid psychopathology diagnoses. This domain includes core eating disorder symptoms, comorbid Axis I and Axis II symptoms, developmental history, and other aspects of psychological functioning. In addition to establishing diagnosis, evaluating each of these factors is necessary to determine the treatment plan and intervention priorities.

Psychological and behavioral variables may be assessed with a combination of interviews and self-report instruments. In clinical settings, the interview is typically unstructured; however, the use of interviews such as the Eating Disorder Examination (EDE; Fairburn & Cooper, 1993; described below) provides a number of advantages to the clinician, yields more comprehensive and higher quality assessment data, and potentially enhances rapport (Peterson, 2005).

COMPENSATORY BEHAVIORS

The adolescent should be asked about the current and past frequency and duration of compensatory behaviors, including self-induced vomiting, fasting, excessive exercise, and abuse of laxatives and diuretics. Determining type and amount of laxatives and diuretics is also important. The clinician should also ask about the use of syrup of ipecac to induce vomiting, because it is particularly dangerous and can cause cardiomyopathy and organ dysfunction (Pomeroy, 2004). Other types of compensatory behaviors are less common but can occur, including manipulation of insulin in individuals with diabetes and the abuse of thyroid medication (APA, 1994). Although not part of the criteria, diet pill use and caffeine abuse are also important behaviors to assess and may impact the adolescent’s medical status.

BINGE EATING

Among the eating disorder symptoms, binge eating is perhaps one of the most difficult to assess accurately (Wilson, 1993). Because DSM-IV requires that an episode comprise both an unusually large amount of food and a subjective sense of lack of control to be considered a binge, both of these constructs must be evaluated to determine the presence and frequency of binge eating. A number of researchers have observed that whereas the correlation between questionnaire and interview-based estimates of compensatory behaviors are generally high (e.g., Peterson & Miller, 2005), the concordance between these types of assessments for binge eating is more modest. The main source of inconsistency between self-reported and interview-based estimates of binge eating appears to be clinician raters’ higher threshold for what is considered objectively or unusually large compared to individuals with eating disorders, who place more emphasis on the subjective experience of loss of control in labeling their eating as a binge (Beglin & Fairburn, 1992; Telch, Pratt, & Niego, 1998).

Because of limitations in the accuracy of written self-report data in assessing binge eating, interviews are generally essential to determine the presence and frequency of this symptom. The EDE (Fairburn & Cooper, 1993), a particularly effective method of assessing binge eating (Wilson, 1993), may be used by the clinician to determine the frequency of different types of binge eating. The EDE distinguishes between objective bulimic episodes, in which the amount of food consumed is large according to a clinical rater and the individual experiences a sense of loss of control, and subjective bulimic episodes, in which the individual experiences a sense of loss of control and feels that he or she has overeaten, but does not consume an objectively large amount of food. Although the clinical significance of the size distinction in binge-eating episodes is unclear and a topic of debate (Keel, Mayer, & Harnden-Fischer, 2001; Niego, Pratt, & Agras, 1997; Pratt, Niego, & Agras, 1998), it is nonetheless crucial to determine the size of the binge-eating episodes to make an accurate DSM-IV diagnosis.

As described earlier, careful and detailed probing is especially important when asking about binge-eating episodes. The clinician should ask for several examples of the types and amounts of food consumed during binge-

eating episodes and never express shock or dismay about the amount of food consumed. Careful questioning about the subjective sense of loss or lack of control is also important and potentially challenging. Translating this construct into more concrete terms may be helpful, for example, by asking adolescents if they felt they could not resist eating food that was available, felt unable to stop eating once they started, or experienced a sense of being driven or compelled to eat (Fairburn & Cooper, 1993).

BODY IMAGE

Body image is a multidimensional construct that includes a number of different components, both perceptual and cognitive (Thompson, 2004). Effective assessment often integrates questionnaire and interview data to establish a comprehensive evaluation of body image (for detailed reviews, see Thompson & Gardener, 2002; Thompson, Roehrig, Cafri, & Heinberg, 2005). Aspects of body image include dissatisfaction with weight and/or shape; overvaluation of shape and/or weight in self-evaluation; body image distortion (i.e., misperception of body size or body parts); preoccupation with weight and shape, ideal weight and shape; and behavioral phenomena, including checking, rituals, and avoidance.

Because of the complexity of body image, the clinician should attempt to prioritize which aspects are most relevant and important to assess, particularly aspects of body image that are essential to establish a DSM-IV diagnosis: fear of weight gain, body image distortion, and overvaluation of shape and weight in self-evaluation. Fear of weight gain is generally straightforward to assess through direct questioning, although it should be noted that some individuals with anorexia nervosa fear becoming fat, whereas others fear any type of weight gain. Body image distortion is particularly difficult to measure (Thompson & Gardener, 2002). A number of devices have been used in research studies to assess the perceptual accuracy of individuals with eating disorders, and a meta-analysis suggests that, on average, samples of participants with eating disorders do overestimate their size and shape to a greater extent than do those without eating disorders (Cash & Deagle, 1997). However, these measures are generally impractical for clinical use, and questionnaire methods are not generally

effective for assessing body image distortion. Fortunately, many individuals with eating disorders are able to describe this phenomenon and admit that their perception of their bodies shifts dramatically depending on their mood, stress level, and recent food consumption. Some adolescents will agree that others perceive their bodies as thinner than they do. Body image distortion can also be inferred when an emaciated individual insists that he or she is obese (Peterson, 2005).

Although the overvaluation of shape and weight in determining self-evaluation is included in the criteria for both anorexia nervosa and bulimia nervosa, this abstract construct is challenging to assess, particularly in adolescents. Self-evaluation may be assessed using questionnaires, although the complexity of understanding self-definition and the self-awareness required to respond to these questions may result in inaccurate self-report data among adolescents. Whether using the EDE or an unstructured interview, the clinician can attempt to make self-evaluation more concrete by asking the adolescent to construct a list or pie chart to depict different components (e.g., school, relationships, work) and their importance (Fairburn & Cooper, 1993).

Other aspects of body image, although not included in the diagnostic criteria, are nonetheless core features of eating disorders and are important to address during assessment and treatment. In addition to interviews, a number of questionnaires assess body dissatisfaction and distress. Preoccupations, rituals, checking, and avoidance may also be evaluated using questionnaires or interviews. The Body Shape Questionnaire (Cooper, Taylor, Cooper, & Fairburn, 1987) and the Multidimensional Body-Self Relations Questionnaire (Brown, Cash, & Mikulka, 1990) are two measures with considerable psychometric support and clinical utility.

COMORBID PSYCHOPATHOLOGY

As described earlier, the high rates of comorbid psychopathology in eating disorders make this an important focus of assessment, especially symptoms of mood, anxiety, substance use, and personality disorders. Semistructured instruments such as the Structured Clinical Interview for DSM-IV (SCID; Spitzer, Williams, Gibbon, & First, 1990) and the Schedule for Affective Disorders and Schizophrenia for School-Age

Children (K-SADS; Puig-Antich & Chambers, 1983) can provide a thorough and comprehensive method of evaluating comorbidity. Written questionnaires that measure these types of symptoms are also clinically useful, although the clinician should be aware of potential “false positives” that can arise in the context of eating disorder symptoms. On mood disorder questionnaires, for example, adolescents with eating disorders typically endorse disturbances in eating and weight that may or may not be symptoms of depression. Semistarvation symptoms may also mimic clinical depression (Keys et al., 1950). On measures of anxiety, scores are often elevated due to anxiety that is specifically focused on weight, shape, and eating. For these reasons, data assessing comorbid psychopathology may need to be interpreted with caution for individuals with eating disorders.

PERSONALITY

Assessing personality in adolescents with eating disorders is important in several respects. First, the high rates of comorbid personality disorders make them crucial to assess, although assigning accurate Axis II diagnoses in younger adolescents can be quite difficult and may need to be provisional (see Shiner, Chapter 17, this volume). Other than accurate assignment of Axis II symptoms, assessment of personality dimensions provides important information for understanding aspects of the eating disorder (e.g., perfectionism, impulsivity) and formulating a treatment plan. Although less is known about personality and adolescents with eating disorders, individuals with restricting anorexia nervosa have been found to have elevations on measures of constraint, anxiety, and perfectionism; individuals with bulimia nervosa and the bulimic subtype of anorexia nervosa have elevated scores of impulsivity and affective instability (Cassin & von Ranson, 2005; Vitousek & Manke, 1994). Instruments that measure personality may be useful components to assess eating disorders and guide treatment plans, although they generally provide limited information about eating disorder diagnoses.

Nutrition

Collaborating with a dietician who has experience with adolescents with eating disorders is often beneficial to the mental health professional. As part of the assessment and treatment

team, the dietician can focus on obtaining a careful dietary assessment (Rock, 2005) and devising meal plans. If such collaboration is not possible because of limited personnel or financial resources, the mental health clinician may include a nutritional evaluation as part of the comprehensive assessment (Brunzell & Hendrickson-Nelson, 2001; Rock, 2005).

Regardless of whether a dietician is included on the assessment team, the clinician should nonetheless ask detailed questions about current and past eating patterns, including the frequency and contents of meals and snacks, “rules” about eating (avoiding certain types of foods, calorie limits, etc.), and attempts at dietary restriction. Several methods may be used to evaluate eating habits, including unstructured interviews; standard interviews, including the EDE; dietary recalls (e.g., asking the adolescent to describe in detail types and amounts of food eaten during the past 24 hours); and written food records. Unfortunately, self-reported food intake is highly inaccurate regardless of the eating disorder diagnosis (Bandini, Schoeller, Dyr, & Dietz, 1990), and the clinician should be aware of this limitation in interpreting these types of data.

Interpersonal and Psychosocial Functioning

Assessing interpersonal and psychosocial functioning is an important aspect of assessment, because these factors are potentially causal and are also negatively affected by eating disorder symptoms. The level of detail of data collected within this assessment domain depends on several factors, including the age of the adolescent, whether the adolescent is living with the family, and the degree and scope of psychosocial impairment. Decisions about interpersonal and psychosocial assessment also depend on the treatment. For example, in interpersonal psychotherapy (IPT; Fairburn, 1997), the first phase of treatment involves a detailed assessment of interpersonal relationships in the context of eating disorder symptoms and developmental history. Family-based psychotherapy (e.g., Lock, le Grange, Agras, & Dare, 2001) requires a greater emphasis on family assessment during the initial phase.

Regardless of the type of treatment implemented, the clinician should obtain information about the adolescent’s developmental history, including significant events, academic functioning, trauma experiences, and social re-

relationships. Family history, especially of obesity and eating, mood, substance use, and anxiety disorders is also important to determine. Asking the adolescent to describe friendships and dating experiences is helpful for establishing rapport, assessing the developmental level of psychosocial functioning, evaluating the degree of impairment, determining social support resources, and formulating treatment goals. Specific questions relevant to eating disorder symptoms and peer relationships include whether the adolescent has been teased (especially about weight and shape), participation in activities in which weight and shape are emphasized (e.g., dance, gymnastics, wrestling), and the extent to which other members of the adolescent's peer group have had eating disorder symptoms.

Family assessment may be conducted with both unstructured interviews and self-report questionnaires (for a review, see le Grange, 2005). For family-based assessments, it is crucial to include all members of the cohabitating family in the assessment phase, as well as during treatment (Lock et al., 2001). Research investigations often rely on observational methods for family assessments, but these approaches are generally impractical in clinical settings.

Selecting Instruments and Integration of Assessment Data

Decisions about instrument selection depend on a number of variables, including the type of clinical setting (e.g., hospital-based vs. outpatient), the treatment orientation (e.g., family-based therapy vs. individual psychotherapy), and the age of the adolescent, because some assessment instruments are not appropriate for younger adolescents. The clinician should also consider the cost of administering and scoring, as well as the potential time burden on the adolescent and family members (Peterson & Mitchell, 2005). An important consideration in instrument selection is the extent to which an assessment measure increases the comprehensiveness and quality of the data, without creating undue time or financial burden. Self-report questionnaires may also provide more in-depth information about eating disorder symptoms, including body image, compensatory behaviors, and cognitions related to eating. The reliability and validity of each instrument is a primary concern, and the clinician should be

especially careful about selecting assessment measures that have been validated with adolescent samples.

Because of the multidimensional nature of eating disorders assessment, the clinician must often integrate various sources of information at the conclusion of the evaluation, including data from interviews, questionnaires, charts, and food records, as well as reports from other professionals. In integrating these data, the clinician should examine them for inconsistencies (e.g., discrepant information between the parents and the adolescent) and consider potential limitations in the accuracy of the data, including social desirability, inaccurate recall, and minimization of symptoms to avoid treatment. Because of the difficulty in obtaining accurate information in the initial phase (Vitousek, Daly, & Heiser, 2001), the clinician continues to gather and revise assessment data throughout the course of treatment.

ASSESSMENT INSTRUMENTS

A wide variety of self-report questionnaires and diagnostic interviews have been developed to assess eating pathology. For our purposes in this chapter, we focus on assessment devices that we believe are the most feasible and ecologically useful in most assessment and clinical settings, as well as those supported by reliability and validity data. It should be clearly noted, however, that most of the psychometric data for these scales are from samples of adolescents or young adults; very few data are available from samples of children. Although eating disorders are rare among preadolescent children, many of the measures reviewed below are probably too complex for administration to children, particularly the self-report questionnaire measures.

Questionnaire Measures

Two broad types of questionnaires assess eating pathology: one assesses general psychological disturbances often associated with eating disorders, and the other directly assesses eating disorder symptoms from DSM-IV. Both types of questionnaires have their uses in assessment and treatment settings. However, research suggests that questionnaires may provide inaccurate assessments of eating disorder symptoms relative to diagnostic interviews (Fairburn & Beglin,

1994; Wilfley, Schwartz, Spurrell, & Fairburn, 1997), presumably because interviews provide an opportunity for assessors to clarify the meaning of terms (e.g., “binge eating” and “excessive exercise”). Accordingly, unless it is unfeasible to conduct a diagnostic interview, we recommend that questionnaires be used as screening devices or to provide adjunctive information to data gathered through interviews (particularly for children). In addition, we have found that questionnaires yield the most accurate data when an office staff or research assistant is available while individuals complete the measures and when the questionnaires are immediately checked for completeness and errors (again, particularly for children).

Eating Disorder Examination–Questionnaire

The Eating Disorder Examination–Questionnaire (EDE-Q; Fairburn & Beglin, 1994), a 36-item questionnaire version of the EDE interview (Fairburn & Cooper, 1993), assesses the diagnostic symptoms of anorexia nervosa and bulimia nervosa, but not binge-eating disorder. The EDE-Q also contains subscales that assess features commonly associated with eating disorders: Restraint, Eating Concern, Shape Concern, and Weight Concern. Other investigators have created a continuous bulimic symptom composite score by averaging across the diagnostic items from this scale (e.g., Stice, 2001).

With regard to reliability, Luce and Crowther (1999) found that the Restraint, Shape Concern, Weight Concern, and Eating Concern subscales showed adequate internal consistency in a sample of late adolescent girls (mean $\alpha = .86$). The 2-week test–retest reliability coefficient for items assessing the frequency of eating disorder behaviors were $r = .68$ for binge eating, $r = .92$ for vomiting, $r = .65$ for laxative misuse, and $r = .54$ for diuretic misuse, and the 2-week test–retest coefficients for the subscales were $r = .81$ for Restraint, $r = .94$ for Shape Concern, $r = .92$ for Weight Concern, and $r = .87$ for Eating Concern (Luce & Crowther, 1999). The bulimic symptom composite has been found to possess adequate internal consistency (mean $\alpha = .85$) and 3-week test–retest reliability ($r = .89$) in several samples of adolescent girls (Stice, 2001; Stice, Mazotti, Weibel, & Agras, 2000; Stice, Trost, & Chase, 2003).

With regard to validity, agreement across the EDE-Q and EDE versions of the Restraint,

Shape Concern, Weight Concern, and Eating Concern subscales for adult women was moderately high (mean $r = .76$; Black & Wilson, 1996; Fairburn & Beglin, 1994). Although the EDE-Q assesses symptoms of anorexia nervosa and bulimia nervosa, few studies have examined agreement between diagnoses with this scale and those with validated structured interviews, and we could not locate any that reported the kappa agreement between the two methods. Agreement between the EDE-Q and the EDE is generally good for the presence of vomiting and laxative misuse (mean Kendall's tau-b = $.87$), but lower for the presence of binge eating (mean Kendall's tau-b = $.42$; kappa = $.47$) across community and clinical samples of adults (Black & Wilson, 1996; Fairburn & Beglin, 1994; Mond, Hay, Rodgers, Owen, & Beumont, 2004; Wilfley et al., 1997). Studies have suggested that the concordance between the EDE and EDE-Q in terms of the frequency of bulimic symptoms tended to be higher, ranging from a high of $.98$ to a low of $.35$ (mean $r = .62$; Sysko, Walsh, & Fairburn, 2005). The agreement between the EDE and EDE-Q in terms of the frequency of binge eating was higher when more detailed instructions were provided relative to those given in the basic EDE-Q (Celio, Wilfley, Crow, Mitchell, & Walsh, 2004). There is evidence that the Restraint, Shape Concern, Weight Concern, and Eating Concern subscales of the EDE-Q are also sufficiently sensitive to detect effects of prevention interventions (Celio et al., 2000; Stewart, Carter, Drinkwater, Hainsworth, & Fairburn, 2001). The bulimic symptom composite from the EDE-Q has also been found to be sensitive to detecting change in bulimic symptoms in response to prevention programs (Stice, Mazotti, et al., 2000; Stice et al., 2003). In contrast, results in one study suggested that the EDE-Q may not provide accurate estimates of symptom change among individuals receiving treatment (Sysko, Walsh, & Fairburn, 2005). The EDE-Q has also been found to distinguish between women with and without eating disorders, with a sensitivity of $.83$ and a specificity of $.96$ (Mond et al., 2004). However, the EDE-Q Restraint scale has not shown a significant inverse correlation with objectively measured caloric intake in community and patient samples (Stice, Fisher, & Lowe, 2004; Sysko, Walsh, Schebendach, & Wilson, 2005), which suggests that it is not a valid measure of actual dietary restriction.

In summary, there is reasonable evidence regarding the internal consistency, test–retest reliability, and sensitivity of the EDE-Q for use with adolescents. However, there is relatively limited evidence of criterion validity for this scale, and most of these data were from adult samples. Normative data for adolescent girls are available for this scale, which should facilitate the use of the EDE-Q in clinical settings (Carter, Stewart, & Fairburn, 2001). Because the EDE-Q is easy to administer and score, it may be useful clinically to provide more detailed information about eating disorder symptoms, although it should not be used in lieu of a diagnostic interview.

Eating Disorder Diagnostic Scale

The Eating Disorder Diagnostic Scale (EDDS; Stice, Telch, & Rizvi, 2000) is a 1-page, 22-item self-report screening measure that assesses DSM-IV diagnostic criteria for anorexia nervosa, bulimia nervosa, and binge-eating disorder. This scale yields provisional diagnoses of these three eating disorders. In addition, the items can be averaged to form a continuous eating disorder symptom composite score.

In terms of reliability, the internal consistency for the overall symptom composite was adequate (mean $\alpha = .87$; Stice, Fisher, & Martinez, 2004; Stice, Orjada, & Tristan, 2006; Stice & Ragan, 2002; Stice, Telch, et al., 2000). The 1-week test–retest kappa coefficient was .95 for anorexia nervosa, .71 for bulimia nervosa, and .75 for binge-eating disorder diagnoses; the 1-week test–retest correlation for the symptom composite was .87 (Stice, Telch, et al., 2000).

In terms of validity, the EDDS evidenced acceptable agreement with EDE diagnoses for anorexia nervosa ($\kappa = .93$), bulimia nervosa ($\kappa = .81$), and binge-eating disorder ($\kappa = .74$) in a sample of adolescent girls and women (Stice, Telch, et al., 2000). Reasonable diagnostic agreement was also observed in a sample of primarily adolescent girls ($\kappa = .78$; Stice, Fisher, et al., 2004). The EDDS symptom composite has also been found to detect preventive intervention effects in three independent controlled trials (Stice, Fisher, et al., 2004; Stice, Orjada, et al., 2006; Stice & Ragan, 2002). With regard to predictive validity, elevated scores on the EDDS symptom composite were found to moderate the pre- to postintervention effects of an eating disorder

prevention program (Stice, Fisher, et al., 2004). In addition, elevated scores on this symptom composite were found to predict future onset of binge eating, compensatory behaviors, and depression among initially nonafflicted individuals (Stice, Fisher, et al., 2004).

In summary, the EDDS shows promise as a brief survey designed solely to assess eating disorder symptoms and render provisional diagnoses. This scale is easy to administer and score, and takes less than 10 minutes to complete, which suggests that it might be useful for screening patients in clinical settings and monitoring change in response to preventive and treatment interventions. However, a disadvantage is that relatively less psychometric evidence has accumulated for the reliability and validity of this questionnaire. As with other survey measures, it should not be used in lieu of a diagnostic interview.

Eating Disorder Inventory–2

The Eating Disorder Inventory–2 (EDI-2; Garner, 1991) is a 91-item scale that assesses features commonly associated with anorexia nervosa and bulimia nervosa but does not provide diagnoses for eating disorders. This measure has 11 subscales including Bulimia, Body Dissatisfaction, Drive for Thinness, Perfectionism, and Impulse Regulation. Eight of these subscales remained unchanged from the previous version of this measure, and three new subscales have been added.

The EDI-2 has been found to have adequate internal consistency for women (range, .69–.92) and men (range, .57–.82) from community samples (McCarthy, Simmons, Smith, Tomlinson, & Hill, 2002; Spillane, Boerner, Anderson, & Smith, 2004). However, there is evidence that the new subscales have somewhat lower internal consistency coefficients among clinical samples of women (Eberenz & Gleaves, 1994). Research suggests that the eight subscales from the original EDI, which are also included in the EDI-2, possess adequate internal consistency and test–retest reliability (Anderson & Paulosky, 2004).

The EDI-2 has been found to discriminate significantly between individuals with and without eating disorders (Garner, 1991; Nevenon & Broberg, 2001; Schoemaker, Verbraak, Breteler, & van der Staak, 1997). For instance, in one study, the Bulimia subscale correctly classified 97% of individuals with

bulimia nervosa from general psychiatric controls (Schoemaker et al., 1997). Certain EDI-2 subscales have also been found to predict drop-out from eating disorder treatment (Fassino, Daga, Piero, & Rovera, 2002).

The EDI-2 is widely used clinically and may be helpful for assessing personality features, as well as a full range of eating disorder symptoms, both at intake and in assessing change over the course of treatment. Because this scale does not provide a direct assessment of the frequency of eating disorder symptoms or provide DSM-IV eating disorder diagnoses, it may be most useful as an adjunct to a diagnostic interview such as the EDE.

Diagnostic Interviews

There are several structured psychiatric interviews that generate DSM-IV (APA, 1994) diagnoses of anorexia nervosa, bulimia nervosa, and binge-eating disorder among adults, but few have been evaluated with children and adolescents.

Eating Disorder Examination

The EDE (Fairburn & Cooper, 1993), a 34-item, semistructured psychiatric interview that assesses the diagnostic criteria for anorexia nervosa and bulimia nervosa, also contains subscales that assess features commonly associated with eating disorders—Restraint, Eating Concern, Shape Concern, and Weight Concern—as well as behavioral and eating patterns.

The EDE subscales have consistently been found to have moderately high internal consistency among community and clinical samples of adult women (range, .68–.83; Fairburn & Cooper, 1993; Mond et al., 2004). The diagnostic items assessing eating behaviors have been found to have high test–retest reliability over a 2- to 7-day period (range, .82–.97) in women with eating disorders, although the agreement for subjective binge eating was much lower (number of binge days = .40; number of binge episodes = .33; Rizvi, Peterson, Crow, & Agras, 2000). This study also found that the subscales showed adequate 2- to 7-day test–retest reliability (range, .71–.76; Rizvi et al., 2000). The interrater agreement (as assessed by coding audiotapes of interviews) was high for the diagnostic items assessing eating behaviors (range, .90–.99) and for the subscales (range, .92–1.00; Rizvi et al., 2000). A

Spanish-language version of the EDE has been found to have similar test–retest and interrater reliability coefficients with Hispanic women recruited from the community, with the exception of the test–retest and interrater reliability for objective binge-eating episodes (kappas = .37 and .56, respectively; Grilo, Lozano, & Elder, 2005).

The EDE has been found to discriminate reliably between individuals with and without eating disorders, and between individuals with anorexia nervosa and those with bulimia nervosa (Fairburn & Cooper, 1993). The EDE is also sufficiently sensitive to detect intervention effects among women treated for anorexia nervosa (Pike, Walsh, Vitousek, Wilson, & Bauer, 2003), bulimia nervosa (Agras, Walsh, Fairburn, Wilson, & Kraemer, 2000; Walsh et al., 1997), and binge-eating disorder (Wilfley et al., 2002). However, Sysko, Walsh, Schebendach, & Wilson (2005) found that the EDE Restraint subscale was not significantly correlated with observed caloric intake of a yogurt shake in a laboratory setting by young women with anorexia nervosa or nondisordered control women of normal weight during two separate sessions, suggesting that this measure is not a valid measure of actual dietary restriction.

Emerging evidence supports the reliability and validity of a Child Adaptation of the EDE (ChEDE; Watkins, Frampton, Lask, & Bryant-Waugh, 2005). The subscales of the ChEDE evidenced satisfactory internal consistency (range, .80–.91), and interrater consistency was also excellent in a sample of 8- to 14-year-old girls (range, .91–1.0; Watkins et al., 2005). With regard to validity, the subscales were able to distinguish among children with anorexia nervosa, children with bulimia nervosa, and those without eating disorders. They were not able to distinguish between children with bulimia nervosa and control children, however (Watkins et al., 2005).

Another group has developed a semistructured interview, loosely adapted from the EDE, for diagnosing eating disorders among adolescents (Stice, Burton, & Shaw, 2004). This 39-item interview, the Eating Disorders Diagnostic Interview (EDDI), focuses solely on diagnosing anorexia nervosa, bulimia nervosa, and binge-eating disorder over the past year and also provides an overall eating disorder symptom composite. Research with adolescents has indicated that the symptom composite shows adequate

internal consistency (mean alpha = .91) and 1-month test–retest reliability ($r = .88$; Stice, Burton, et al., 2004; Stice, Presnell, Groesz, & Shaw, 2005; Stice, Shaw, Burton, & Wade, 2006). This scale also has acceptable interrater agreement (kappa = .86), as assessed by completely independent interviews (rather than ratings of recorded interviews), and 3- to 5-day test–retest reliability in an adolescent sample (kappa = .96; Stice, Shaw, et al., 2006). This scale has shown predictive validity for future onset of obesity, depression, and substance abuse (Stice, Burton, et al., 2004; Stice, Presnell, Shaw, & Rohde, 2005), as well as sufficient sensitivity to detect intervention effects from randomized prevention and treatment trials with adolescents and young adults (Burton & Stice, 2006; Stice, Presnell, Shaw, et al., 2005; Stice, Shaw et al., 2006).

In summary, the EDE is a useful clinical interview for assessing eating disorder behaviors and associated features. The instrument has extensive reliability and validity data supporting its use among adult women, and there are adaptations that appear to be reliable and valid for use with children and adolescents. Although it has primarily been used in research settings, it may be beneficial for assessment in clinical settings as well.

Other Measures for Diagnosing Eating Disorders

Two other diagnostic interviews deserve mention that also appear to be reliable and valid, although relatively less psychometric research has investigated these measures, particularly with child and adolescent samples. First, the Structured Interview for Anorexic and Bulimic Disorders (SIAB-EX) has been found to have impressive internal consistency, interrater reliability, criterion validity with the EDE, and discriminant validity (Fichter, Herpertz, Quadflieg, & Herpertz-Dahlmann, 1998; Fichter & Quadflieg, 2001b). The SIAB-EX has also shown good agreement with a self-report version of this instrument (Fichter & Quadflieg, 2001a). The Interview for Diagnosis of Eating Disorders–IV (IDED-IV) has also shown excellent internal consistency, interrater reliability, and concurrent validity (Kutlesic, Williamson, Gleaves, Barbin, & Murphy-Eberenz, 1998). A unique feature of the IDED is that it was specifically devised to provide diagnoses of binge-eating disorder and it also provides broad coverage of ED NOS symptoms.

It is noteworthy that all of the questionnaires and interviews with adequate evidence of reliability and validity in assessing eating pathology have collected data solely from children or adolescents. In contrast, the Children's Eating Behavior Inventory (CEBI; Archer, Rosenbaum, & Streiner, 1991) was designed to be completed by parents. This questionnaire measures eating and mealtime problems in children ages 2–12 years. It contains 40 items that gather information regarding the child's food preferences, food refusal, behavioral compliance during meals, and feeding skills. The CEBI has shown satisfactory internal consistency, test–retest reliability, discriminant validity, and sensitivity to treatment interventions (Archer et al., 1991).

USE OF ASSESSMENT IN THE CONTEXT OF TREATMENT

The primary aim of assessment at the initial evaluation is to establish an accurate diagnosis and to determine the scope and severity of eating disorder and associated symptoms to formulate a detailed treatment plan. For example, if the clinician determines that the appropriate diagnosis for a particular patient is the binge-purge subtype of anorexia nervosa, then the treatment will target binge eating and compensatory behaviors, in addition to dietary restriction, excessive exercise, and body image disturbance (which would more likely be the primary focus for an individual with the restricting subtype of anorexia nervosa). If scores on a body dissatisfaction questionnaire are extremely high, the clinician may choose to focus on this type of distress early in treatment. If co-occurring symptoms of mood or anxiety are severe, the therapist may consider an adjunctive intervention including medication. Thus, the priorities of treatment are strongly influenced by the initial assessment and diagnostic information.

The selection of assessment instruments in the context of treatment depends on the type of treatment to be implemented. As described earlier, family-based and interpersonal treatments require a greater assessment focus on interpersonal variables and family patterns. Assessment in cognitive-behavioral therapy (Fairburn et al., 1993; Garner, Vitousek, & Pike, 1997) is influenced by the intervention itself, which incorporates the active assessment of behaviors

and cognitions as a focus of treatment. In cognitive-behavioral therapy, the patient is asked to keep a written food log or diary. Early in treatment, in the context of nutritional rehabilitation, the main emphasis of this type of self-monitoring is the frequency and content of food consumed, as well as precipitants of problematic eating patterns. For example, review of the food diaries during the therapy sessions may reveal that purging episodes usually occur in certain places or at certain times of day. These data then influence the implementation of behavioral strategies to alter symptoms. Later in treatment, an increasing focus is placed on monitoring cognitions and thought patterns, along with eating patterns. Thus, the content of the self-monitoring varies in the course of treatment. Although many patients are at first skeptical about the use of food diaries, this type of written self-monitoring is a powerful component of treatment. It provides valuable data to review in the psychotherapy session, develops the adolescent's self-awareness as he or she monitors patterns and antecedents, and it has been found to be a therapeutic intervention for altering eating disorder symptoms, independent of psychotherapy (Agras, Schneider, Arnow, Raeburn, & Telch, 1989).

Regardless of the type of treatment, repeatedly administering assessment instruments throughout the course of treatment may be useful for ongoing planning, monitoring progress, and maintaining motivation. For example, a short battery of questionnaires to assess eating disorder and associated symptoms, including depression, may be administered on a weekly or monthly basis and reviewed by the therapist and adolescent patient together to evaluate progress. Adolescent patients often find the process of comparing current questionnaire responses to previous ones quite compelling, and they are often unaware of their progress until they observe this type of concrete change in assessment scores. Similarly, reviewing earlier food diary information may be helpful to both the therapist and the adolescent as treatment progresses.

In addition to monitoring progress, assessment data obtained throughout treatment may also highlight areas of continued struggle that require increased therapeutic focus. For example, if the adolescent patient reports that weight and shape continue to be a primary source of self-evaluation, or that he or she fre-

quently engages in body checking rituals during the second stage of cognitive-behavioral therapy, then the therapist may modify the treatment to target these body image problems (Fairburn et al., 1993). Assessment measures, in addition to less structured interview questions, may be used to obtain a more comprehensive evaluation of symptoms and to prioritize treatment goals appropriately. Recent data also suggest that adult individuals with bulimia nervosa who ultimately respond to cognitive-behavioral therapy abstain from or significantly reduce purging by the fourth week of treatment (Agras, Crow, et al., 2000; Fairburn, Agras, Walsh, Wilson, & Stice, 2004). Although these rapid response data are based on adult samples and have not been replicated in adolescents, the clinician should nonetheless consider supplementing or altering treatment for patients who report limited reductions in purging symptoms on food logs, recall, or questionnaires by the fourth week of cognitive-behavioral treatment.

In addition to treatment planning and modification, assessment data may be useful to the clinician for documentation. Reviewing questionnaires that have been administered repeatedly may be helpful in the context of consultation or supervision. In addition, questionnaire data may be used in certain cases to document the need for ongoing treatment to third-party payors.

In summary, although assessment data are used initially to determine diagnosis and treatment goals, they are valuable to the clinician throughout the course of treatment. Repeated administration of a standard set of questionnaires provides quantitative data for both the clinician and the adolescent to monitor change. In addition, the ongoing use of assessment instruments may not only help the clinician to modify treatment appropriately but may also be useful for documentation purposes.

SUMMARY

Eating disorders in youth are serious conditions complicated by medical and psychiatric comorbidity. Accurate diagnosis of eating disorders is important for appropriate referrals and treatment planning, but this can be challenging with children and adolescents because of the complexity of the criteria and limitations in the accuracy of self-reported data. We

recommend a multidimensional approach to eating disorder assessment, with a focus on medical, psychological, behavioral, nutritional, interpersonal, and psychosocial components. Assessment and treatment of adolescents with eating disorders often involve multidisciplinary team members who communicate regularly. In the initial evaluation, the clinician uses interview-based methods (both unstructured and semistructured) with the adolescent and, if appropriate, with his or her family members. The primary concern initially is to ensure that the adolescent is medically stable, and this question often informs the first phase of treatment. Self-report questionnaires are valuable for the assessment of eating disorder and comorbid symptoms, although they may not yield accurate data for certain symptoms that require clinical ratings, including binge eating. In addition to providing initial information for diagnosis and treatment planning, assessment instruments may be clinically useful for measuring quantitative change in symptoms over the course of treatment.

Personality Disorders

Rebecca L. Shiner

At times, individuals' personalities significantly interfere with their day-to-day functioning and generate internal distress and misery; this is true for youths, as well as for adults. Child psychologists and psychiatrists who routinely treat such personality difficulties need a means of conceptualizing and assessing them. Personality difficulties may be a primary focus in treating some youth, but in nearly all cases, clinicians must be attentive to patients' individual differences in emotional, cognitive, and interpersonal functioning. The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV, American Psychiatric Association [APA], 1994) acknowledges the central importance of personality by including a set of personality disorder diagnoses on Axis II. Each personality disorder in the diagnostic manual is seen as "an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment" (p. 629). This chapter elaborates the processes through which clinicians may best assess such personality disturbances in youth.

THE CASE FOR ASSESSING PERSONALITY PATHOLOGY IN ADOLESCENT PATIENTS

In assessing youth, it is essential for clinicians to consider the possibility of personality pathology; this is the most important take-home message of this chapter! In other words, it is important to consider the possibility of a personality disorder in all youth who are assessed, not just in those cases in which the youth has prototypical and obvious features of a personality disorder.

At present there is ambivalence about diagnosing personality disorders in youth, both in the DSM-IV and in the psychiatric and psychological fields at large. DSM-IV cautions clinicians to be careful about diagnosing children and adolescents with a personality disorder except in "those relatively unusual instances in which the individual's particular maladaptive personality traits appear to be pervasive, persistent, and unlikely to be limited to a particular developmental stage or an episode of an Axis I disorder" (APA, 1994, p. 631). This explicit hesitance to diagnose personality disorders in youth may arise from several sources (Freeman & Rigby, 2003; Westen & Chang, 2000). At the time when DSM-IV was written,

there was a notable lack of data on early manifestations of personality disorders. There are also ongoing concerns about diagnosing youth with potentially stigmatizing disorders that are viewed as long-lasting, difficult to treat, and severe. Finally, personalities of youth are often seen as being “under construction” during childhood and adolescence, and therefore too unstable to have lasting significance. Clinicians may avoid assigning an Axis II diagnosis to their adolescent patients. In a study by Westen, Shedler, Durrett, Glass, and Martens (2003), practicing psychologists and psychiatrists were asked to report on a particular adolescent patient in their practices. Although only 28.4% of patients were assigned an Axis II diagnosis, 75.3% of the patients met criteria for an Axis II diagnosis based on their clinicians’ reports of Axis II symptoms.

Over the last decade, a number of researchers have marshaled evidence that personality pathology does, indeed, occur in youth and that the pathways leading to adult personality disorders sometimes begin in childhood (Bleiberg, 2001; Cohen & Crawford, 2005; Johnson, Bromley, Bornstein, & Sneed, 2006; Johnson, Bromley, & McGeoch, 2005; Kernberg, Weiner, & Bardenstein, 2000; Westen & Chang, 2000). There has been an upsurge of empirical research on the adolescent manifestations of personality disorders in particular and on personality in adolescence more generally. This new research (reviewed in the next section of this chapter) points to several compelling reasons clinicians ought to assess personality disorders in their adolescent patients. First, personality pathology in adolescents is not rare and often poses considerable risks for development, including potential high-risk behaviors, emergence of Axis I disorders, and impairment in important life domains (e.g., academic achievement, relationships, work). Second, personality difficulties are not necessarily transient phenomena in adolescence given that pathological personality traits are already moderately stable by adolescence. Third, in light of more recent knowledge about personality change and the treatment of personality disorders in adults, a diagnosis of a personality disorder in adolescence need not be seen as consigning a youth to a permanent life of difficulty. Fourth, careful personality assessment may point to strengths youth possess that can be tremendous assets in treatment. Fifth, treat-

ment ultimately may need to focus on personality change, even if a personality disorder is not the primary diagnosis. Many Axis I disorders likely represent varying manifestations of underlying personality pathology (Westen & Bradley, 2005). Thus, effective treatment may need to target personality change or, in the case of some newer cognitive-behavioral therapies (e.g., Hayes, Follette, & Linehan, 2004), may need to enhance patients’ strategies for coping effectively with personality tendencies that may be difficult to change.

A final important reason to assess personality pathology is perhaps less obvious: the potentially large costs of misdiagnosing youth with other disorders, when a personality disorder diagnosis would be more appropriate. In some cases, well-meaning clinicians may search for another disorder to explain a youth’s difficulties because of intentional or unrecognized attempts to avoid labeling the youth with a personality disorder. McClellan and Hamilton (2006) recently presented such a composite case of a 15-year-old girl, Abigail. In this illustrative case, Abigail had exhibited a range of serious symptoms for many years, including self-mutilation, explosive outbursts, alcohol and substance abuse, and self-reports of hearing voices. Her psychosocial history was characterized by maltreatment and repeated foster placements. Abigail had received a range of diagnoses, including “bipolar disorder, schizoaffective disorder, major depression with psychotic features, PTSD [posttraumatic stress disorder], conduct disorder, and substance abuse” (p. 490) and had subsequently been prescribed a wide range of psychotropic medications. Finally, she was more appropriately diagnosed with borderline personality disorder and treated with dialectical behavior therapy (DBT; Linehan, 1993a, 1993b). This case illustrates well the problem of incorrectly diagnosing a youth with a mood, anxiety, or psychotic disorder when a personality disorder diagnosis may be more accurate; incorrect diagnosis can lead to improper prescription of medications and the absence of treatment that appropriately targets the key symptoms. Certainly, it is important for clinicians to continue to be cautious about diagnosing youth with a personality disorder, because of the potential cost of stigmatization, but it is important also to recognize the costs of not diagnosing a personality disorder when it is present.

OVERVIEW OF THE CHAPTER

This chapter proceeds in five sections, the first of which articulates the two different means of conceptualizing personality pathology—as diagnostic categories and as pathological personality dimensions. The second section reviews recent research on personality disorders in youth, including prevalence, course, comorbidity, impairment, and etiology. The third section provides a set of basic underlying principles for assessing personality disorders. The fourth section outlines a set of procedures for conducting an assessment of personality disorders, including types of measures to use, information to gather, use of assessment for treatment planning and monitoring, and presentation of assessment information to patients and families. The fifth section describes and evaluates measures that can be used to assess personality pathology in youth and provides recommendations for specific measures to use. The chapter concludes with suggestions for future research on assessment of personality pathology.

MANIFESTATIONS OF PERSONALITY PATHOLOGY: DIAGNOSTIC CATEGORIES AND PERSONALITY TRAIT DIMENSIONS

DSM-IV Diagnoses

The DSM-IV provides an overarching framework for what constitutes a personality disorder. According to this general framework, personality disorders comprise deviant patterns of inner experience and behavior in at least two of the following four areas: “(1) cognition (i.e., ways of perceiving and interpreting self, other people, and events); (2) affectivity (i.e., the range, intensity, lability, and appropriateness of emotional response); (3) interpersonal functioning; (4) impulse control” (APA, 1994, p. 633). Skodol (2005) has fleshed out what these four areas often include. *Cognition* typically manifests as disturbances in how patients view themselves and others, for example, over-inflated self-views or unduly negative views of the self, profound mistrust or alienation toward others, or tendencies to idealize or devalue others. Cognition also includes deviant thinking about the world, such as expectations for perfectionism or odd, delusional beliefs. *Affectivity* involves a wide range of disturbances in patients’ typical emotions, including

both restricted emotional experience and excessively intense and labile emotions. The emotions that are disturbed include the full gamut of human emotions—sadness, anxiety, anger and irritation, joy and pleasure, and love and affection. Difficulties in *interpersonal functioning* typically involve problems with one or both of the two main dimensions of interpersonal behavior: agency (ranging from dominance and self-assuredness to submission) and communion (ranging from affiliation and warmth to detachment and coldheartedness) (Wiggins & Trobst, 1999). Finally, several personality disorders involve problems with *impulse control*—either deficits in self-control (poor planning, thinking without acting, poor self-regulation of behavior and emotions) or excessive levels of self-restraint and inhibition of healthy impulses.

These deviant personality patterns are further defined by DSM-IV in several ways (APA, 1994, pp. 630–631). In making a personality disorder diagnosis, clinicians must evaluate personality difficulties in the context of the person’s culture; a personality disorder diagnosis is warranted only in cases in which the patterns deviate from what is typically expected in that cultural context. Furthermore, the patterns must be enduring, inflexible, and pervasive across many contexts in the person’s life. The patterns are expected to have started at least by adolescence or early adulthood. Like many other DSM-IV disorders, the personality patterns must be distressing to the person or cause impairment in important areas of daily life, such as social relationships, school, or work. Finally, the pattern must not be better accounted for as a consequence of an Axis I condition, a medical condition, or the use of some substance.

In addition to this general framework for defining the presence of a personality disorder (PD), DSM-IV outlines diagnostic criteria for 10 specific PDs, grouped into three clusters: *Cluster A*, odd or eccentric—paranoid PD, schizoid PD, and schizotypal PD; *Cluster B*, dramatic, emotional, or erratic—antisocial PD, borderline PD, histrionic PD, and narcissistic PD; and *Cluster C*, anxious or fearful—avoidant PD, dependent PD, and obsessive-compulsive PD (APA, 1994, pp. 629–630). Two additional PD diagnoses are included in the DSM-IV appendix for further study: depressive PD and passive-aggressive or

negativistic PD. The primary features of the 12 personality disorders are described in Table 17.1. DSM-IV also provides the option of diagnosing personality disorder not otherwise specified (PD NOS), for those cases in which the general PD criteria are met and PD symptoms are present, but the person does not fulfill the criteria for any specific PD in the manual. The three clusters into which the diagnoses are grouped were not derived empirically; rather, they were created to help clinicians mentally group the disorders into those that share some descriptive features.

DSM-IV offers some cautions that are specific to diagnosing PDs in children and adolescents under the age of 18, who are diagnosed with personality disorders by the same set of criteria as adults; for youth under age 18, the patterns must have been present at least a year (APA, 1994, p. 631). Youth under 18 may not be diagnosed with antisocial PD, however (p. 647). Typically, youth with antisocial behavior are diagnosed with conduct disorder instead, and conduct disorder with onset before age 15 is required for an adult diagnosis of antisocial PD (p. 650). Although youth under age 18 cannot be formally diagnosed with antisocial PD, there is robust evidence that they can still exhibit the psychopathic personality traits and behaviors associated with this diagnosis, such as manipulateness, lack of empathy, and impulsiveness (Kotler & McMahon, 2005; Lynam & Gudonis, 2005; Salekin & Frick, 2005). Because the presence of psychopathic tendencies in youth has implications for treatment, the assessment of psychopathy is discussed later in this chapter.

Alternative Dimensional Models of Personality Pathology

A key issue in conceptualizing personality pathology is whether it is most validly described as categorical patterns or variations on dimensional traits. This issue is discussed in some detail here, because it has important ramifications for the assessment of personality pathology in youth.

The model of PDs adopted in DSM-IV is a categorical one; the PDs are each seen as distinct patterns that differ qualitatively from both normal personality functioning and each other. The validity of this categorical system has been challenged on a number of fronts (reviewed in Oldham & Skodol, 2000; Trull

& Durrett, 2005; Widiger & Mullins-Sweatt, 2005). The PDs co-occur within patients at a rate that is much higher than would be expected if the disorders were truly distinct, categorical entities with distinct etiologies. The existing PD diagnoses also do not provide adequate coverage of the range of personality pathology that patients exhibit. As a result, PD NOS turns out to be the most common PD diagnosis used in actual practice with adults (Verheul & Widiger, 2004), and it may be the most prevalent PD in both adolescents and adults (Johnson, First, et al., 2005).

Rather than defining personality pathology as categorical disorders, personality pathology may be more validly conceptualized within a dimensional framework. In a dimensional taxonomy, it is recognized that psychopathology involves variation in underlying dimensions of cognition, affect, and behavior. Implicit in such a model is the recognition that there is no clear-cut boundary between normal and abnormal functioning; in other words, in a dimensional model, PDs differ from normal-range personality quantitatively rather than qualitatively. A critical issue in the upcoming development of DSM-V is whether dimensional models of psychopathology should be included (Krueger, Watson, & Barlow, 2005; Rounsaville et al., 2002). In the specific case of PDs, a dimensional model would suggest that personality pathology represents maladaptive variants of personality traits that exist in the population as a whole.

A dizzying array of dimensional models has been proposed to describe personality pathology. In fact, one recent review of such models listed 18 alternative proposals (Widiger & Simonsen, 2005)! Fortunately, there is considerable overlap among many of these models, and it is possible to integrate many of them into an overarching taxonomy of personality pathology. In one model that is particularly well supported empirically (Markon, Krueger, & Watson, 2005; Trull & Durrett, 2005; Widiger & Mullins-Sweatt, 2005; Widiger & Simonsen, 2005), personality pathology can be defined along four overarching or higher-order dimensions. First, *Extraversion versus Introversion* measures the degree to which a person is outgoing, active and energetic, expressive, and emotionally positive. At the pathological extremes, this dimension taps exhibitionism (high end) and detachment, social avoidance, and excessive shyness (low end). Second, *Antagonism*

TABLE 17.1. DSM-IV-TR Personality Disorder Diagnoses: Essential Features and Links with Big Five Personality Traits

Diagnosis	Essential features ^a	Associated Big Five traits and facets ^b
Paranoid	Distrust and suspiciousness such that others' motives are interpreted as malevolent	N—Angry–Hostility (high); E—Warmth, Gregariousness (all low); O—Actions, Ideas (all low); A—Trust, Straightforwardness, Altruism, Compliance, Tender Mindedness (all low)
Schizoid	Detachment from social relationships and a restricted range of emotional expression	E—Warmth, Gregariousness, Assertiveness, Activity, Excitement seeking, Positive Emotions (all low); O—Feelings, Actions (all low)
Schizotypal	Acute discomfort in close relationships, cognitive or perceptual distortions, and eccentricities of behavior	N—Anxiety, Self-Consciousness (all high); E—Warmth, Gregariousness, Positive Emotions (all low); O—Ideas (high); C—Order (low)
Antisocial	Disregard for, and violation of, the rights of others	N—Angry–Hostility, Impulsivity (all high) and Anxiety, Self-consciousness (all low); E—Assertiveness, Activity, Excitement Seeking (all high); O—Actions (high); A—Trust, Straightforwardness, Altruism, Compliance, Modesty, Tender Mindedness (all low); C—Dutifulness, Self-Discipline, Deliberation (all low)
Borderline	Instability in interpersonal relationships, self-image, and affects, and marked impulsivity	N—Anxiety, Angry–Hostility, Depression, Impulsiveness, Vulnerability (all high); O—Feelings, Actions (all high); C—Deliberation (low)
Histrionic	Excessive emotionality and attention seeking	N—Self-Consciousness (low) and Impulsiveness (high); E—Gregariousness, Activity, Excitement Seeking, Positive Emotions (all high); O—Fantasy, Feelings, Actions (all high); A—Trust (high); C—Self-Discipline, Deliberation (all low)
Narcissistic	Grandiosity, need for admiration, and lack of empathy	N—Angry–Hostility (high) and Self-Consciousness (low); E—Warmth (low) and Assertiveness and Excitement Seeking (all high); O—Feelings (low) and Actions (high); A—Trust, Straightforwardness, Altruism, Compliance, Modesty, Tender Mindedness (all low)
Avoidant	Social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation	N—Anxiety, Self-consciousness, Vulnerability (all high) and Impulsiveness (low); E—Gregariousness, Assertiveness, Excitement Seeking, Positive Emotions (all low); O—Actions (low); A—Modesty (high)
Dependent	Submissive and clinging behavior related to an excessive need to be taken care of	N—Anxiety, Self-Consciousness, Vulnerability (all high); E—Assertiveness (low); A—Trust, Compliance, Modesty (all high)
Obsessive–compulsive	Preoccupation with orderliness, perfectionism, and control	N—Anxiety (high) and Impulsiveness (low); E—Excitement Seeking (low); O—Feelings, Actions, Ideas, Values (all low); C—Competence, Order, Dutifulness, Achievement Striving, Self-Discipline, Deliberation (all high)
Depressive (Appendix)	Depressive cognitions and behaviors	None provided
Passive–aggressive (negativistic; Appendix)	Negativistic attitudes and passive resistance to demands for adequate performance in social and occupational situations	None provided

^b N, Neuroticism; E, Extraversion; O, Openness to Experience; A, Agreeableness; C, Conscientiousness. The facets listed are those included in the NEO-PI-R (Costa & McCrae, 1992). The Big Five traits and facets associated with each personality disorder diagnosis are adapted from Lynam and Widiger (2001). Copyright 2001 by the American Psychological Association. Adapted by permission.

versus Compliance measures tendencies toward being hostile and cynical versus kind, modest, empathetic, honest, and trusting. At the pathological high end, this dimension taps mistrust and alienation, aggression, entitlement, and callousness. Third, *Constraint versus Impulsivity* measures tendencies to be responsible, attentive, persistent, orderly, high-achieving, and planful versus irresponsible, unreliable, careless, and to quit easily. At the pathological extremes, this dimension taps compulsivity and workaholism (high end), and impulsiveness, irresponsibility, and excessive risk taking (low end). Fourth, *Emotional Dysregulation versus Emotional Stability* measures individual differences in the experience of negative emotions. At the pathological high end, this dimension taps anxiousness, insecure attachment, identity problems, affective lability, feelings of worthlessness, and poor ability to cope with stress. It is not clear whether there is a pathological low end, but it may possibly involve an excessive lack of fear and anxiety (as in psychopathy). Each of these broad, higher-order dimensions in the proposed model includes a number of more narrow, lower-order dimensions that are sometimes called “facets” (e.g., Extraversion involves components such as activity level, gregariousness, and positive emotions). The lower-order components tend to covary, which is why they cohere to form a higher-order trait, but they differ enough that each lower-order component provides useful information about personality functioning.

Evidence for the proposed taxonomic framework comes from two primary sources: research linking normal-range personality traits, such as the Big Five, with personality disorders, and research delineating the structure of pathological personality trait dimensions. DSM-IV PD diagnoses may be described in terms of variation of normal-range personality traits, such as the Big Five (Costa & Widiger, 2002), which is a taxonomy of normal-range personality traits that has robust empirical support (John & Srivastava, 1999) and includes the following traits: Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness. Support for the proposed model of personality pathology also comes from research undertaken to determine the structure of pathological personality traits. Both Livesley (Livesley & Jackson, in press) and Clark (1993) created questionnaires designed to measure the full range of personality

pathology in adults. These personality pathology measures included a greater proportion and a broader range of negative personality descriptors than normal-range personality inventories, such as those measuring the Big Five. The higher-order structure obtained in these questionnaires is generally consistent with the proposed taxonomic framework, although some differences do emerge. Normal-range personality traits and pathological personality traits in adults appear to share a common structure of higher-order traits (Markon et al., 2005). Table 17.1 presents the Big Five traits and facets that experts rated as likely to be associated with each of the DSM PDs (Lynam & Widiger, 2001).

Thus, there is compelling support for a dimensional model of personality pathology as an alternative to the categorical system now in place. This work raises an important question for the assessment of personality difficulties in children and adolescents: Can youths’ personalities likewise be described validly with the proposed taxonomy of four higher-order traits? It is possible to give a tentative “yes” to this question. Children and adolescents manifest a set of Big Five traits similar to that of adults (Caspi & Shiner, 2006; Shiner, 2006); therefore, it is possible to use the Big Five traits to characterize youths’ personalities in a clinical setting. As with adults, there is some evidence that PDs in adolescence may be described using Big Five personality measures (De Clercq & De Fruyt, 2003; De Clercq, De Fruyt, & Van Leeuwen, 2004). Furthermore, De Clercq, De Fruyt, Van Leeuwen, and Mervielde (2006) have created a new questionnaire measure of pathological personality in youth (similar to those created by Livesley and Clark for adults) and have found that, as with adults, four higher-order traits emerge: Introversion, Disagreeableness, Compulsivity, and Emotional Instability. Thus, clinicians who assess PDs in youth have the option of assessing personality traits, as well as determining the presence of DSM-IV PD diagnoses.

OVERVIEW OF RECENT RESEARCH ON PERSONALITY DISORDERS IN YOUTH

Prior to the mid-1990s, there was very little empirical research on the nature and development of PDs in children and adolescents. Although there is still far less known about PDs

than about other disorders in youth, the last decade has seen a surge of interest. Consequently, some basic information is now available about personality pathology in adolescents, including data on prevalence, stability and course, comorbidity, life impairment, and etiology. This basic information has important implications for the assessment of PDs, because it points to crucial areas to assess. The recent research also overturns many incorrect assumptions about the nature of PDs and makes clear why it is essential that clinicians consider the possible presence of personality pathology in the youth they treat.

Prevalence and Gender

It is difficult to estimate the prevalence of PDs in both adolescents and adults, because there are not yet adequate epidemiological studies addressing this issue. Although epidemiological studies have determined prevalence rates for Axis I disorders, Axis II disorders have been excluded from these studies, with the exception of antisocial PD (Mattia & Zimmerman, 2001). For adolescents, the best available estimates of DSM-III-R and DSM-IV PDs derive from representative community or primary care samples. Prevalence estimates for having at least one PD have ranged from 6 to 17% in adolescents, with a median prevalence of 11% (Johnson, Bromley, Bornstein, & Sneed, 2006). Comparable large-scale studies with adults suggest prevalence rates of approximately 10–15% for at least one PD, and 1–2% for each specific PD diagnosis (Mattia & Zimmerman, 2001; Torgersen, 2005). Thus, there is good evidence that PDs are as prevalent in adolescence as in adulthood. In fact, PD traits and diagnoses may actually be more prevalent earlier in adolescence than during later adolescence, at which point prevalence appears to be quite comparable to that seen in adulthood (Johnson, Bromley, et al., 2006). PD rates in individuals presenting for treatment are, of course, likely to be higher.

As with general prevalence rates for PDs, epidemiological data on gender differences are lacking for both adolescents and adults. However, there is some evidence from adult community samples that although the overall prevalence rates for PDs appear to be roughly equal for males and females, some specific PDs may be more prevalent in one gender or the other (Morey, Alexander, & Boggs, 2005; Torgersen,

2005). Empirical findings are not entirely consistent with the information on gender in DSM-IV. Specifically, in adult community samples, schizoid PD, antisocial PD, and obsessive-compulsive PD may be more common in males, and histrionic and dependent PD may be more common in females (Morey et al., 2005; Torgersen, 2005). Consistent gender differences are not found in community samples for the other PDs, including borderline PD. Furthermore, findings of gender differences are often inconsistent across studies or modest in size. Very little is known about gender differences in community samples of adolescents, other than the consistent finding that conduct problems are more prevalent in samples of males (Moffitt, Caspi, Rutter, & Silva, 2001). In short, gender differences in PDs are not as common or as large in community samples as often assumed. Furthermore, even in the case of a disorder such as antisocial PD, where there is a clear male preponderance, many adolescent females still meet criteria for the diagnosis. Thus, it is important for clinicians to be vigilant about preventing preconceived ideas about gender differences from influencing their assessment of PDs and traits.

Course of Personality Disorders

DSM-IV makes a number of explicit assumptions about the stability and course of PDs. Specifically, DSM-IV describes PDs as *enduring* patterns, and these patterns need to have existed for at least a year to warrant diagnosis in youth under age 18. A number of recent longitudinal studies have examined the stability and course of PD diagnoses and symptoms in both youth and adults, and have found that the picture regarding stability is more complex than assumed. Furthermore, the results for PD diagnoses and symptoms may be understood in light of recent research on the stability of normal-range personality traits over time. Taken together, the findings for both PDs and normal-range personality traits are forcing a reanalysis of the picture of PDs presented in the DSM-IV.

Personality stability is itself a complex notion, because there are many different kinds of continuity and change. First, *rank-order stability* refers to the degree to which the relative order of individuals on a given trait or symptom is maintained over time, and it is typically measured through test–retest correlations on di-

mensional scores of some trait across two points in time. PD symptoms in adolescents and young adults display moderate levels of rank-order stability across time, often in the range of .40 to .65 (Cohen, Crawford, Johnson, & Kasen, 2005; Johnson, Bromley, et al., 2006), similar to the moderate levels of stability observed in adulthood (Grilo & McGlashan, 2005). These findings of moderate rank-order stability for personality disorder symptoms in adolescence are quite comparable to those found for normal-range personality traits in childhood and adolescence (Roberts & DelVecchio, 2000). The findings for personality pathology and normal personality converge on the conclusion that there is nothing transformative about the age of 18 with regard to stability of personality disorder symptoms; moderate stability is already apparent by adolescence.

Second, it is important to consider the *stability of PD diagnoses* over time. In other words, if a person meets criteria for a particular PD, is it likely that he or she will still warrant that diagnosis over time? Contrary to what might be expected from the DSM-IV, the stability of particular PD diagnoses appears to be relatively modest in both adolescent and adult samples (Cohen et al., 2005; Grilo & McGlashan, 2005; Johnson, Bromley, et al., 2006; Skodol, Gunderson, et al., 2005; Zanarini, Frankenburg, Hennen, Reich, & Silk, 2005). The relatively modest stability of PD diagnoses is due in part to the categorical system used; patients can shed a diagnosis because of crossing the arbitrary threshold set for the diagnosis. But the surprising remission rates seem to reflect more substantive processes as well. Recent longitudinal research with adults suggests that there are less stable and more stable aspects to PDs (Skodol, Gunderson, et al., 2005; Zanarini et al., 2005). The less stable aspects typically involve more acute behaviors, such as odd behavior or self-harm; in contrast, the more stable aspects involve personality traits underlying the condition (McGlashan et al., 2005). Finally, although rates of continuity may be low for specific PD diagnoses, there is some evidence that adolescent patients with a PD diagnosis may still be at higher risk of having *any* PD diagnosis over time (Chanen et al., 2004).

Third, *mean-level change* refers to increases or decreases in the average trait level of a population as a whole. In terms of mean-level

change, levels of PD symptoms appear to peak in early adolescence, then decline across the years of later adolescence and early adulthood (Cohen et al., 2005; Johnson, Bromley, et al., 2006). These findings are consistent with results for mean-level stability of normal personality traits. On average, Neuroticism decreases in young adulthood, and Agreeableness and Conscientiousness increase in young adulthood and middle age (Roberts, Walton, & Viechtbauer, 2006). Given that many PDs are characterized by high Neuroticism and low Agreeableness and Conscientiousness, it is not surprising that PD symptoms peak in adolescence and later improve. Thus, across the late adolescent and early adult years, there is on average a movement toward greater personality maturity.

The findings for mean-level changes may also help to account for why PD diagnoses are relatively unstable; individuals with PDs may experience the same maturing normative changes that occur in personality traits across the population. Despite the general improvements that typically occur in personality functioning, there may be some individuals whose PD symptoms worsen in adolescence and adulthood (Johnson, Cohen, Kasen, et al., 2000). These individuals particularly may be in need of treatment.

Comorbidity: Concurrent and Prospective Links with Axis I and Axis II Disorders

Comorbidity appears to be the rule rather than the exception for personality disorders. As noted previously, there tends to be a high level of comorbidity among the PDs in adults (Skodol, 2005). The same is true for adolescents: Comorbidity among PDs in adolescents is common (Cohen et al., 2005). There is also a high level of comorbidity between Axis I and Axis II disorders in both adults (Dolan-Sewell, Krueger, & Shea, 2001) and adolescents. All three clusters of PDs in adolescence show high rates of comorbidity with Axis I disorders, including depressive, anxiety, substance use, and disruptive behavior disorders (Cohen et al., 2005). Furthermore, earlier Axis I disorders predict heightened risk for later emergence and continuation of Axis II disorders into adulthood (Cohen et al., 2005; Lewinsohn, Rohde, Seeley, & Klein, 1997). The reverse is true as well: Earlier Axis II disorders predict greater

risk for early adult Axis I disorders, even after taking into account the presence of earlier Axis I and II disorders (Cohen et al., 2005; Daley et al., 1999). It appears that there is often a transaction between Axis I and Axis II disorders across the years from adolescence to adulthood, with Axis I disorders contributing to the expression of Axis II disorders and vice versa.

PD traits in childhood are similarly linked with Axis I symptoms (Mervielde, De Clercq, De Fruyt, & Van Leeuwen, 2005): Antagonism and low Constraint with externalizing symptoms and Emotional Dysregulation and low Extraversion with internalizing symptoms. These high rates of overlap between Axis I and Axis II conditions suggest that the two axes are not nearly as distinct as originally conceived. Furthermore, it is increasingly recognized that comorbidity may often be caused by something meaningful, namely, personality dimensions that underlie both Axis I and Axis II disorders (Clark, 2005).

Impairment Associated with Personality Disorders

Personality disorders cause youth to be vulnerable to the development of a variety of risky and harmful behaviors. PDs from clusters A and B in adolescence predict risks for adolescent and adult violence, including acts such as “arson, assault, breaking and entering, initiating physical fights, robbery, and threats to injure others” (Johnson, Cohen, Smailes, et al., 2000, p. 1406) even when possible confounding variables are taken into account. Adolescent PDs from all three clusters and those in the DSM appendix are also predictive of heightened risk of suicidal ideation or attempts in early adulthood (Johnson, Cohen, et al., 1999). Self-mutilation may also be present in youth with PDs, in the form of cutting, burning, or punching oneself. In a recent study of adult patients with borderline PD approximately one-third of the patients who had engaged in self-mutilation reported that they started harming themselves as children, and another one-third reported having started as adolescents (Zanarini et al., 2006). Finally, adolescents with PDs are at heightened risk for having a high number of sexual partners and high-risk sexual behaviors more generally (Lavan & Johnson, 2002).

Beyond the effects of PDs on symptomatology and risky behaviors, there is evidence that

adolescent PDs are associated with risks for problems with adaptation, both concurrently and into adulthood. Adolescent PDs and traits pose heightened risks for later conflicts with family members, as well as problems with romantic relationships, including stressful relationships, conflicts, low partner satisfaction, abuse, and unwanted pregnancy (Johnson, Bromley, et al., 2006). Adolescents with PDs also have heightened rates of problems in other domains of life, including difficulties in friendships, few social activities, poor educational achievement, and work difficulties (Bernstein et al., 1993; Johnson, First, et al., 2005). All of these findings for PDs are consistent with research on personality in childhood and adolescence more generally; youths’ personalities are predictive of many important life outcomes, including peer relationships, formation of romantic relationships, academic attainment, effectiveness at work, and health (Caspi & Shiner, 2006; Shiner, 2006). It should be emphasized that although adolescent PDs are associated with risks for impairment, not all youth with PDs in the community have clear-cut impairment (Cohen et al., 2005; Johnson, First, et al., 2005). Furthermore, the functioning in some youth with PDs improves as they age (Cohen et al., 2005).

In short, adolescent PDs are associated with risks for concurrent and future difficulties in many areas—Axis I disorders, high-risk behaviors (violence, suicide, risky sexual behavior), and life impairment. All of these same co-occurring problems are associated with PD NOS in adolescents as well (Johnson, First, et al., 2005). Although PD symptoms do appear to improve with age for some adolescents, the outcomes associated with these disorders can be quite serious for many youth.

The Etiology of Personality Disorders

Much of the early clinical interest in PDs in the 20th century arose from rich, complex psychodynamic theories about the origins of such disorders. Most of these etiological theories were based on clinicians’ discussions with patients about their early histories. Although these theories have spurred interest in PDs and have provided a basis for interventions, relatively little is known empirically about the developmental pathways leading to PDs (with the exception of antisocial PD). Nonetheless, there are

several promising leads for potential causes of PDs, including early temperament and personality traits based in part on genetics and adverse environmental experiences, particularly in the family.

Children's emerging temperaments and personalities are likely to play an important role in the emergence of personality pathology over time. Both temperament in early childhood and personality in later childhood and adolescence significantly overlap with the kinds of personality traits observed in adults (Caspi & Shiner, 2006; Rothbart & Bates, 2006; Shiner & Caspi, 2003). In early childhood, children manifest traits that tap differences in extraversion or surgency (positive emotions/pleasure), negative emotionality (fear/inhibition, irritability), and effortful control or constraint (attention); they also manifest temperament traits of activity level and soothability/adaptability (Caspi & Shiner, 2006). Thus, early in life children manifest individual differences in both their experiences of positive and negative emotions, and their ability to regulate their emotions and behavior. As children age, they display a wider range of traits, and by middle childhood these traits are structured like the Big Five traits observed in adults (Caspi & Shiner, 2006). In other words, by middle childhood, children continue to manifest individual differences in emotions (Extraversion and Neuroticism) and self-regulation (Conscientiousness), but they also manifest clear, individual differences in their prosocial versus antisocial orientation toward others (Agreeableness), and in their creativity and curiosity (Openness to Experience). There is some longitudinal evidence that childhood personality traits are predictive of later general PD symptoms; predictive childhood personality traits include introversion, low self-esteem, high emotionality, abrasiveness, immaturity, and not being goal-directed (Bernstein, Cohen, Skodol, Bezirgianian, & Brook, 1996; Cohen, 1996).

Children's early personalities shape their experiences of the environment through a number of important processes (Caspi & Shiner, 2006): the ways children are conditioned by their environments, the responses children evoke from the people in their lives, the ways children interpret their experiences, the ways children evaluate themselves and form a sense of identity, the environments that children "select" for themselves, and the ways children modify and manipulate their environments.

Youths' personalities can help explain why children exposed to relatively similar environments do not have the same outcomes—a phenomenon known as "multifinality." For example, a child who is intensely anxious and irritable and lacks good self-control is going to have a very different experience of parental divorce than a child who is emotionally stable and behaviorally restrained; these differences in the experience of divorce could then lead to differing outcomes for the children.

What are the origins of individual differences in personality? Behavior genetic research on normal-range temperament and personality traits has established that individual differences in these traits are moderately heritable; estimates of heritability are in the range of $.50 \pm .10$ in twin studies and somewhat lower (around $.30$) in adoption studies (Caspi & Shiner, 2006). It is interesting to note that temperament in infancy and early childhood is influenced by environmental experiences, not just by heredity (Emde & Hewitt, 2001); this research corrects common misconceptions that temperament is solely influenced by genes in infancy, and that the environment only becomes important later in life. Estimates of heritability for PD traits in adults are roughly similar in magnitude to those found for normal-range traits (Cloninger, 2005; Livesley, 2005). There is preliminary evidence for moderate heritability of PD features in a small study of children and adolescents (Coolidge, Thede, & Jang, 2001). Behavior genetic research also highlights the importance of environmental experiences as a determinant of personality differences (Caspi, Roberts, & Shiner, 2005); in nearly all behavior genetic studies, environmental differences account for a substantial portion of the variation in personality and temperament. One surprise emerging from this research, however, is that environmental experiences tend to create differences between children growing up in the same family rather than making siblings more alike (Caspi et al., 2005).

Although theories about the family origins of PDs abound, relatively few data addressed this issue until recently. There is now strong longitudinal evidence that childhood abuse (including sexual, physical, and verbal abuse) and neglect predict heightened risk for the later development of PDs (Johnson, Bromley, et al., 2005, 2006). In addition, maladaptive parenting more generally poses risks for the develop-

ment of PDs; such maladaptive parenting includes low parental affection or nurturing and aversive parental behavior (e.g., harsh punishment; Johnson, Cohen, Chen, Kasen, & Brook, 2006). Abuse, neglect, and poor parenting behavior may shape children's emerging personality pathology through a number of processes. Children who face these adverse experiences lack the socialization experiences that normally help children learn how to cultivate relationships, follow societal rules, and regulate emotions and behavior (Johnson, Bromley, et al., 2005, 2006). Many children who experience family adversity also develop insecure attachments and do not learn how to trust and engage appropriately with close others (Johnson, Bromley, et al., 2005, 2006). Beyond the family environment, sociocultural factors are also likely to influence the development of PDs; for example, personality pathology characterized by poor constraint may be fostered in social contexts that do not provide structure or firm limits on the expression of impulsivity (Paris, 2005a).

Early family adversity poses significant risks for the development of personality pathology, but it is crucial to recognize that early trauma and abuse may not be present in the histories of all youth with PDs. In fact, in the best longitudinal study of personality disorders to date, the Children in the Community Study, early trauma and/or abuse “do not account for all, or even most cases of PD observed in our longitudinal cohort” (Cohen et al., 2005, p. 482). Furthermore, even in cases of maltreatment, different children are affected differently. In one study, maltreated children whose genotype conferred low levels of monoamine oxidase A (MAOA) expression more often developed conduct disorder, antisocial personality, or violence than children with a high-activity MAOA genotype (Caspi et al., 2002). Temperament may also play a more central role in some pathways, whereas trauma may be more central in other ones (Nigg, Silk, Stavro, & Miller, 2005). Research has begun to yield some clues as to the origins of personality pathology, but the task remains for future research to lay out more clearly the varied pathways through which temperament is transformed through experience into PDs (Clark, 2005; Paris, 2003). Behavior genetic designs will be particularly helpful in elucidating the roles of both genetic and environmental contributors to personality pathology.

BASIC PRINCIPLES FOR ASSESSING PERSONALITY DISORDERS

This section reviews some basic recommendations or principles for assessing PDs in youth; most of these principles should be applicable to the assessment of PDs in adults as well. Many of these principles derive from current research on the nature of PDs in youth and adults; readers are referred the earlier section of this chapter for citations of studies that document these findings.

1. *Be careful to avoid unwarranted assumptions about the manifestations or causes of PDs.* This first principle, of course, applies to assessment of all psychological conditions, but it may be especially important in the diagnosis of PDs, in which the knowledge base is relatively shallower and untested theories may sometimes hold sway. Three examples serve to illustrate the kinds of faulty assumptions to avoid. First, although childhood abuse and neglect occur at higher-than-average rates in adolescents with PDs, longitudinal data show that not all youth with PDs have been maltreated in their past. Thus, although a history of abuse or neglect should be assessed, it should not be assumed. Second, although some PDs occur at higher rates in one gender than the other, all PDs can occur in both genders (e.g., a boy with borderline PD, or a girl with early signs of antisocial PD). Third, although many youth with PDs are highly impaired in multiple areas of adaptive functioning, not all youth with PDs are severely impaired. Thus, it is important to consider the possible presence of a PD even in youth who have some areas of competent functioning.

2. *Evaluate personality pathology comprehensively to ascertain the possible presence of more than one PD diagnosis.* In evaluating PDs through unstructured methods, clinicians may sometimes settle on a PD diagnosis, then fail to adequately evaluate the presence of other PD symptoms or disorders (Westen et al., 2003; Widiger & Samuel, 2005). This tendency is particularly problematic, because comorbid PDs are common in both youth and adults. Thus, by settling on one PD diagnosis without considering others, clinicians may overlook central aspects of a patient's personality that should be addressed in treatment. Regardless of what assessment methods they use, it is important that clinicians at

least screen for a comprehensive range of personality pathology.

3. *Consider the possibility of a personality disorder not otherwise specified (NOS) diagnosis.* The DSM-IV specifies that a PD NOS diagnosis is warranted when a patient exhibits the general features of a PD and has a number of PD symptoms but does not meet criteria for any specific PD. It would be easy to overlook the possibility of this diagnosis in conducting an assessment, yet PD NOS may be the most prevalent PD in youth. Furthermore, as described previously, PD NOS is as predictive of impairment and high-risk behavior as any of the other PD diagnoses; therefore, it needs to be treated on an equal basis. Because a PD NOS diagnosis is vague and provides little guidance for treatment, clinicians need to assess and specify which personality patterns are present and particularly troubling when assigning this diagnosis.

4. *Evaluate whether personality traits and behaviors are impairing and pathological patterns versus more normative manifestations of adolescence.* Although PD symptoms may peak in adolescence and be prevalent in patients, clinicians still need to carefully discriminate between pathological patterns and more typical adolescent personality tendencies. For example, a certain amount of insecurity about relationships, confusion about one's identity, and shifting of moods and emotions is common during adolescence. Clinicians need to draw on their knowledge of adolescent behavior to determine whether particularly patterns are non-normative. Questionnaire measures that are scored based on normative, national data are useful in this regard, as are the reports of informants who have experience with a range of adolescents (e.g., teachers).

5. *Be attentive to both acute symptoms and underlying personality patterns.* Newer models of PDs in adults indicate that PDs involve a mixture of both more acute, short-term problematic behaviors and more stable, long-term personality patterns (Skodol, Gunderson, et al., 2005; Zanarini et al., 2005). The acute behaviors may be brought on by current stress and may often be the reason for referral; for example, the patient may exhibit odd (e.g., paranoid ideation) or risky behaviors (e.g., suicidal ideation or behavior, violence, self-mutilation). In contrast, the more stable aspects involve more enduring personality patterns. The acute behaviors may be the most attention-grabbing

during an initial assessment, but it is essential to evaluate the enduring personality patterns carefully as well. The more enduring patterns are likely to provide clues to the causes of the more acute behaviors, and need to be addressed in treatment. It is also possible that the acute symptoms might be viewed as manifestations of an Axis I disorder, when they actually point to a more enduring personality pattern.

6. *Gather information from both the adolescents and others who know them well.* As with all child and adolescent disorders, it is critical for clinicians to obtain assessment information from other informants in addition to reports from the adolescent patients themselves. This is generally true when assessing children and adolescents, because different informants provide different information about them, and reports from different informants converge only modestly to moderately (Kamphaus & Frick, 1996). The need for varied informants may be especially acute in assessing PDs, however, because the disorders themselves may make it difficult for some patients to report on their functioning accurately (Klonsky, Oltmanns, & Turkheimer, 2002). Individuals with PDs may lack insight into their personality patterns, may not realize the effects of their behaviors, or may intentionally try to conceal some of their behaviors. Among adults, targets and informants agree only modestly about targets' personality disorders (Klonsky et al., 2002), and both self- and informant reports of PD symptoms provide incremental prediction of important outcomes (Klein, 2003; Ready, Watson, & Clark, 2002). Thus, informants and adolescents may have quite different perspectives on the adolescents' functioning, and these varied perspectives need to inform the assessment.

7. *Assess personality strengths as well as areas of difficulty.* In assessing PDs, it would be easy to focus entirely on areas of deficit—those aspects of youths' personalities that are causing difficulties and lead them to need treatment. Yet it is essential to assess areas of personality strengths as well; even the most troubled youth have areas of relative health in their personalities. These strengths are resources on which to draw in treatment, and a better appreciation of adolescents' individual strengths can sustain a sense of optimism in the adolescents themselves, in their caregivers, and in their treatment providers (Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998).

This sense of encouragement and optimism may be especially important in treating youth with PDs, who may become discouraged when treatment is difficult. Recent work in positive psychology suggests that focusing on and amplifying patients' character strengths may be a powerful complement to more traditional therapy focused on correcting deficits (Duckworth, Steen, & Seligman, 2005). One advantage to assessing personality traits rather than just PDs is that it yields information about both positive and negative traits.

RECOMMENDED PROCEDURES FOR ASSESSING PERSONALITY DISORDERS IN YOUTH

This section presents an overview of recommended procedures to follow in assessing PDs in youth. The purposes of assessment are varied; among the most important reasons are to establish a diagnosis, to formulate a case in order to plan for treatment, and to monitor treatment outcomes (Mash & Hunsley, 2005). This section considers these various purposes and recommends procedures for five aspects of assessment: (1) evaluating personality pathology, (2) obtaining other relevant information, (3) developing an effective treatment plan, (4) monitoring treatment outcomes, and (5) presenting results to adolescents and their families.

Evaluating Personality Pathology

Clinicians who assess PDs in adolescents face a formidable task, because the criteria for PDs are so wide-ranging and encompass so many different aspects of the adolescent's life. Two different types of measures are likely to be particularly helpful in gathering the information necessary to make a diagnosis: questionnaire measures and semistructured interviews. Questionnaire measures can first be administered to the adolescents and their parents to screen for the possible presence of personality pathology and to narrow down the range of personality difficulties that will require further assessment. The adolescents and their parents can then be interviewed (preferably through a semistructured interview) to determine more clearly what personality patterns are problematic. My discussion of the use of these two types of measures draws heavily on recommendations by Widiger and colleagues for assessing PDs in adults (Widiger, 2002; Widiger & Coker, 2002;

Widiger, Costa, & Samuel, 2006; Widiger & Samuel, 2005). A detailed discussion of specific questionnaires and semistructured interviews is presented in the next section.

Questionnaires

A very useful first step involves administering a self-report questionnaire to the adolescent and a separate questionnaire to his or her parent. Three different kinds of self-report omnibus questionnaires may be given to adolescents to assess personality pathology. First are measures that assess DSM-IV PD criteria in a fairly straightforward manner. Most of these are essentially screening measures that help to pinpoint which PDs require further assessment. Second are questionnaires that assess pathological personality traits that are related to but lack a clear one-to-one correspondence with the DSM-IV PDs. Third are questionnaires that assess normal personality traits that have clear relevance for the assessment of PDs. For parents, the first type of questionnaire—those that assess the DSM-IV criteria—is most appropriate, because it can be used without scoring according to norms. The latter two types of questionnaires require norms for scoring, and norms for parent reports are not available.

These different types of questionnaires vary in the information they provide. All three types of measures may potentially serve as useful screens to help determine whether to assess further for personality pathology, which PDs potentially may be skipped in a later interview, and which PDs will require more careful assessment. Although the questionnaires that assess DSM-IV PD symptoms serve most directly as screeners, the other types of questionnaires provide this sort of preliminary assessment as well. The pathological and normal-range personality trait measures serve an additional purpose: These questionnaires can help to flesh out personality patterns that are related to but not fully encompassed by the DSM-IV criteria. This is an important feature, because some clinically important aspects of personality pathology are not adequately covered by DSM-IV (Westen, 1997). These two types of questionnaires also have norms for scoring, which may be helpful in comparing the youth to adolescents in general. Finally, the normal-range personality questionnaires have the additional purpose of helping to highlight youths' personality strengths.

The questionnaires yield a rich picture of personality functioning, but they cannot be used to diagnose PDs for several reasons, the most obvious of which is that most of the recommended self-report questionnaires do not correspond exactly with DSM-IV Axis II criteria. Questionnaire measures agree only modestly with interview measures of personality (Zimmerman, 1994), in part because questionnaire measures typically overdiagnose personality pathology (Clark & Harrison, 2001; McDermut & Zimmerman, 2005). Finally, although questionnaires can pinpoint problematic personality patterns, they cannot determine the other important features of these patterns: their duration, onset, pervasiveness, and effects on patients' lives. Interviews are needed to investigate these other aspects of personality functioning.

Interviews

As noted earlier, the administration of questionnaires should be followed by interviews with adolescents and their parents. Two types of interviews may be used to assess personality disorders: unstructured and semistructured. In unstructured interviews, clinicians ask questions in the order that seems most appropriate, and the questions are typically not planned in advance (though it is likely that many clinicians typically follow a general order). In contrast, in a semistructured interview, clinicians ask a standard set of questions in a planned sequence. These questions are often followed up for clarification and elaboration. The responses to questions are scored in a structured manner. Clinicians are also usually required to score some aspects of the interview based on observations of the patient during the interview itself. Practicing clinicians tend to use unstructured interviews to assess PDs (Westen, 1997), whereas semistructured interviews are more often used in research. Semistructured interviews possess a number of advantages over unstructured interviews in assessing PDs (reviewed in Kaye & Shea, 2000; Rogers, 2003; Widiger et al., 2006): They result in more reliable diagnoses and ensure that the full range of personality pathology is considered and assessed carefully. Practicing clinicians may be hesitant to use semistructured interviews for a number of reasons, including the length of time involved, the potential formality and interference with rapport building, and the concern that patients

may have difficulty describing their personality patterns accurately and honestly. These concerns can potentially be addressed. Questionnaire measures help cut down the interview time by ruling out disorders that need not be assessed. An unstructured interview may be used initially to build rapport. Clinicians who are concerned about maintaining rapport or overcoming patients' reluctance to report problems may use one of the topically organized interviews. These topical interviews assess various areas of a patient's life (e.g., relationships, school) in a natural manner and may potentially help guarded patients be more forthcoming. Clinicians who are hesitant to use a semistructured interview are encouraged to read one nonetheless, because these interviews can help clinicians formulate questions to gather information on PDs.

As noted previously, parents should be interviewed about their children's personality patterns. The use of a PD screening questionnaire with parents helps to focus the parent interview on the relevant diagnoses. Particular attention should be paid to the parent report on Axis II diagnoses for which his or her adolescent may be a poor reporter. Some of the semistructured interviews have specific instructions for the use of informants, but all of these interviews may potentially be adapted for use with informants. The optimal way to combine informant and patient information to formulate adolescent PD diagnoses is unclear; the same is true for child and adolescent assessment more generally (Mash & Hunsley, 2005). Clinicians need to exercise considerable judgment in discerning which information yields the most valid picture of their adolescent patients' personality functioning.

Obtaining Other Relevant Information

A number of areas other than the adolescent's personality functioning are particularly important to assess in light of current research and theory on personality disorders in adolescence. These areas include the following:

Risky Behaviors

PDs in adolescence are associated concurrently and longitudinally with a number of risky behaviors: suicidality, violence, self-mutilation, and risky sexual behaviors. These troubling behaviors are likely to be the presenting problems

for many youth with PDs, but clinicians should assess for these behaviors even if they are not part of the presenting picture.

Childhood Temperament

Given that childhood temperament is likely to be an important contributor to later personality pathology (Shiner, 2005), it is important to assess adolescents' early-emerging personalities. Parents may be asked about their child's early behaviors—positive emotions, willingness to approach new situations, shyness, anxiety, irritability, sensitivity to sensory stimulation, ability to maintain attention, self-control, kindness, and aggression (Caspi & Shiner, 2006). The clinician may also ask parents about responses the child's temperament evoked in them and in others, to ascertain whether the child's temperament and parents' own needs and emotional responses set in motion a problematic pattern of interaction. Adolescents themselves may be asked about their early personalities. They may have insight into internal experiences of which their parents may be unaware. Even if adolescents' recollections are not veridical, their self-descriptions are likely to illuminate their early self-concepts.

Current and Past Context

It is important to evaluate the adolescent's context carefully, because it is possible that contextual factors contributed to the development of a PD, and it is quite likely that such contextual factors may be maintaining the problematic patterns. The context should be evaluated broadly, but particular attention should be given to the adolescent's relationships with family and with peers. Recent research has substantiated that child maltreatment and poor family functioning predict heightened risk for PDs in adolescence and adulthood, so it is important that these factors be evaluated. Relationships with peers, both in childhood and concurrently, should also be assessed. Relationships with parents and peers are likely to be especially powerful contributors to internalized views of the self and of the self in relation to others.

Cyclical Patterns

A careful assessment of personality pathology can pinpoint adolescents' interpersonal behav-

iors that may be problematic; these behaviors include aggressiveness and hostility, lack of assertiveness, excessive social avoidance and anxiety, too much openness and trust, lack of interpersonal connectedness, or excessive interpersonal sensitivity (Gude, Moum, Kaldestad, & Friis, 2000). Adolescents may be engaging in interpersonal behaviors that perpetuate their psychological difficulties. A vicious cycle may emerge in which an individual's interpersonal behaviors evoke reactions from others that inadvertently reinforce his or her maladaptive personality tendencies (Wachtel, 1994). For example, a narcissistic individual's desperate attempt to impress others could evoke rejection from others who find the person to be a braggart, which in turn reinforces his or her underlying sense of inadequacy (that may have fueled the bravado in the first place).

Developing an Effective Treatment Plan

After determining that an adolescent patient meets criteria for a PD or has significant PD features, clinicians face a daunting task—the development of an effective treatment plan. This task is complex for a number of reasons. A key reason is that there are not yet empirically supported treatments for treating adolescent PDs. Another challenge in treating adolescents with PDs is that they are often “complex cases” that involve some combination of significant comorbidity, risk for self-harm or harm to others, substance abuse, low motivation or lack of compliance with treatment, or a stressful social environment (Ruscio & Holohan, 2006). Despite the complexities of developing a treatment plan for this population of youth, two promising routes may be followed. The first is to adapt empirically supported treatments developed for adults with PDs. The second is to define clearly youths' pathological personality patterns and use treatments that have been effective for similar problems. These two methods are discussed in turn.

Empirically supported treatments for adults with PDs may be modified for use with adolescents. Several reviews have addressed the empirical evidence of effective treatments for adult PDs (Crits-Christoph & Barber, 2004; Fonagy, Roth, & Higgitt, 2005; Leichsenring & Leibling, 2003; Perry, Banon, & Ianni, 1999). According to these reviews, there are empirically supported treatments for several specific PDs and for mixed PDs. For adult

borderline PD, several treatment models have some support: schema-focused therapy (an integrative cognitive therapy; Giesen-Bloo et al., 2006); dialectical behavior therapy (DBT; an integration of cognitive-behavioral therapy and Zen mindfulness practices; see preceding reviews and Linehan et al., 2006); and psychodynamic treatment in a partial hospital program and outpatient setting (see reviews and Giesen-Bloo et al., 2006). Of these treatments, DBT has been adapted for use with adolescents (Miller, Rathus, & Linehan, 2006), and there is some preliminary empirical evidence that this treatment model may be effective with youth (Katz, Cox, Gunasekara, & Miller, 2004; Rathus & Miller, 2002). For avoidant PD, a number of behavioral treatments have proved effective in adults, including graded exposure and social skills training (see preceding reviews). Cluster C personality disorders have been treated effectively with both cognitive therapy and short-term psychodynamic therapy (see reviews and Svartberg, Stiles, & Seltzer, 2004). Finally, several forms of psychodynamic therapy have demonstrated effectiveness in treating adults with any PD diagnosis (see preceding reviews and Vinnars, Barber, Noren, Gallop, & Weinryb, 2005). In short, a number of psychodynamic, cognitive, behavioral, and integrative treatments may be adapted for use with adolescents.

Another option for devising a treatment plan is to define clearly the adolescent's pathological personality patterns and use empirically supported treatments that address similar problems in youth. Thus, in this case, the clinician is crafting a plan tailored to the needs of each individual adolescent patient. As Kazdin (2005) recently noted, "Knowing the symptoms and patterns that an individual has, working on and with these in treatment, and evaluating the impact of treatment is facilitated by leaving aside the term *disorder* and working on this child's characteristics" (p. 550). This means of developing a treatment plan may be particularly appropriate for PDs, given that the specific diagnoses possess questionable validity as discrete categories. Particular personality patterns, understood in the context of the youth's life, may be the best targets for treatment.

If clinicians conduct the sort of comprehensive personality assessment described in this chapter, then they will have a thorough understanding of their adolescent patients' problem-

atic personality patterns to address in treatment. By the end of the assessment, they should have a good understanding of youths' difficulties in the four areas included in the PD diagnoses: *cognitions*, *affectivity*, *interpersonal functioning*, and *impulse control*. Treatments that have demonstrated efficacy for these patterns in other disorders may then be tailored to the needs of a particular youth (for a discussion of how to adapt empirically supported treatments to complex cases, see Ruscio & Holohan, 2006). For example, cognitive-behavioral therapy developed to treat depression in youth might be adapted to address an adolescent's tendencies to misinterpret others' ambiguous behaviors as malevolent. Behavioral and family treatments developed to treat conduct disorder might be adapted to address an adolescent's difficulties with controlling his or her impulses. Clinicians need to be very thoughtful in adapting treatments in this way; behavior patterns that appear similar in Axis I and Axis II conditions could, in fact, arise from quite different sources. In other words, it is essential to attend to the motivations underlying adolescents' behaviors to ensure that the selected treatments are appropriate.

Monitoring Treatment Outcomes

Research on the course of PDs has implications for which behaviors to measure at baseline to track treatment effectiveness over time. This research suggests that clinicians should measure three different kinds of targeted behaviors at the start of treatment to track adolescents' treatment outcomes; these targets include (1) disturbed personality patterns, (2) any acute problematic behaviors (e.g., suicidality, violence, or self-mutilation), and (3) life impairment.

In light of the research distinguishing between acute and stable behaviors in PDs, it may be useful to measure the more acute behaviors separately from the more stable personality patterns. Support for this idea also derives from "third-wave" cognitive-behavioral treatments (Hayes et al., 2004), including DBT for borderline PD. These third-wave therapies often focus on helping patients learn new skills for coping with painful emotions and difficult personality tendencies, while also helping patients develop a sense of acceptance of their experiences. Although the therapies do not al-

ways explicitly address the issue of personality change, they implicitly acknowledge that some personality tendencies may be relatively resistant to change, and they help patients to focus on changing their maladaptive responses to these personality tendencies. Thus, it may be helpful to measure separately the acute behaviors that may respond more quickly to treatment, and the personality patterns that may require longer bouts of treatment. By measuring these targets separately, it is possible for clinicians to document different aspects of treatment effectiveness over time.

In addition to measuring personality-relevant behaviors, it is useful to measure patients' levels of impairment at baseline and over time to determine whether treatment has helped adolescent patients achieve better life adaptation. For children and adolescents with PDs, measuring impairment includes documenting adaptation in terms of academic achievement, peer relationships, and relationships with parents or other caregivers, as well as law-breaking behavior. One of the most troubling outcomes of PDs in youth is impairment in these domains, so it is important to assess whether treatment has helped youth achieve better adaptation in their day-to-day lives.

To measure these three different targets for treatment, several kinds of measures are recommended. To assess treatment impact on PD symptoms, clinicians might use one of the questionnaire measures of PDs (perhaps one of the shorter screening measures). To assess treatment impact on the more acute PD symptoms and impairment, other measures are needed. A prototypical example of such a measure is the Youth Outcome Questionnaire (Y-OQ; Burlingame, Wells, Lambert, & Cox, 2004), a brief parent report questionnaire that assesses child and adolescent functioning in a number of areas relevant to PD treatment: intrapersonal distress, somatic, interpersonal relations, social problems, behavioral dysfunction, and critical items (paranoid ideation, obsessive-compulsive behaviors, hallucinations, delusions, suicidal feelings, mania, and eating disorder issues). A measure such as the Y-OQ might be used to complement a measure more clearly focused on PD symptoms for treatment monitoring, because it assesses both acute symptoms (e.g., suicidal feelings, paranoid ideation, distress) and life adaptation/impairment

(e.g., interpersonal relations, social problems). Other measures that serve a similar purpose include the Adolescent Treatment Outcomes Module (ATOM; Kramer & Robbins, 2004), the Child and Adolescent Functional Assessment Scale (CAFAS; Hodges, 2004), and the Child Health Questionnaire (CHQ; Landgraf, 2004). The use of such measures permits a more comprehensive evaluation of treatment impact on adolescents' acute problems and day-to-day adaptation.

Presenting Results to Adolescents and Their Families

In presenting feedback about the assessment to youth and their parents, it is important to convey the main points of the case formulation, including the key problematic personality patterns, their potential causes, and the motivations underlying them. Adolescents and their parents are likely to find little of value in being given a specific PD diagnosis. In fact, there might be some potential harm in labeling adolescents with a specific PD when providing feedback to families. There is a great deal of misinformation about the nature of PDs, and youth and their parents might easily misinterpret diagnostic information. However, there is much to be gained by conveying to adolescents and their parents the basic points of the case formulation, particularly if the information is presented in a way that conveys an empathetic understanding of the adolescents' experience of the world. The results should be presented in a manner that minimizes defensiveness on the part of both adolescents and their parents. Presenting the case formulation gives adolescents and their parents an opportunity to suggest corrections to the formulation and to begin planning for treatment.

ASSESSMENT MEASURES

This section reviews a wide range of measures used to assess PDs, maladaptive personality traits, and normal-range personality traits in youth. Four general categories of instruments are presented: (1) questionnaire measures of PDs, maladaptive personality, and normal-range personality; (2) comprehensive semistructured interviews for personality disorders; (3) measures for assessing single PDs and

traits (borderline PD, narcissistic PD, and psychopathy); and (4) measures that are difficult to classify. Specific recommendations are offered for choosing among the omnibus questionnaires and semistructured interviews.

Many of the measures are the same as those used with adults (e.g., all of the semistructured interviews), and others have already been adapted from adult measures for use with adolescents. Readers are referred to several excellent general reviews of PD assessment in adults for more details on the adult-based measures: Clark and Harrison (2001); Kaye and Shea (2000); McDermut and Zimmerman (2005); Widiger and Coker (2002); Widiger, Costa, and Samuel (2006); Widiger and Samuel (2005). These reviews include some very useful adult assessment measures that are not discussed here but that may be modified for use with adolescents, such as the Dimensional Assessment of Personality Pathology—Basic Questionnaire (DAPP-BQ; Livesley & Jackson, in press), the Inventory of Interpersonal Problems—Personality Disorder scales (IIP-PD; Pilkonis, Kim, Proietti, & Barkham, 1996), and the Structured Interview for the Five-Factor Model of Personality (Trull & Widiger, 1997). Another measure not reviewed here, the Structural Analysis of Social Behavior (SASB; Benjamin, 1996; Benjamin, Rothweiler, & Critchfield, 2006), may be used to examine PDs in terms of patients' views of themselves, others, and their relationships with others. The SASB has received some use with adolescents.

Given the relatively limited amount of research on PDs in youth, it should not be surprising that information about the reliability and validity of many of these measures in youth is less than optimal. Ideally, wider knowledge of measures for assessing PDs in adolescents will spur more research in this area. When available, information on reliability and validity of the measures in adults is provided.

Omnibus Questionnaire Measures of Personality Disorders, Personality Pathology, and Normal-Range Personality Traits

As described previously, the recommended assessment procedure involves the administration of at least one questionnaire or screening measure prior to completing an interview. Table 17.2 presents the full names of the questionnaires reviewed in this section and outlines dif-

ferences in the number of items and scales, informants (self or parent), age range, rating format, and material covered (DSM-IV PD criteria, pathological personality traits, or normal-range personality traits). The table also includes information about whether the questionnaires assess conditions other than PDs and where to obtain the measures.

Nearly all of the measures described have already demonstrated adequate reliability (at least in terms of internal consistency). However, most of the measures have received relatively little scrutiny in terms of whether they validly assess PDs in adolescents. Although there may be valuable validity information examining the correlations of these measures with other relevant questionnaires, many measures lack validity data demonstrating their ability to predict life outcomes, treatment effectiveness, or interview-based diagnoses of personality disorders. A number of the questionnaires are derived wholly or in part from adult instruments that have demonstrated validity for assessing personality pathology. Because of the scant validity data for most of these measures, it is especially important that clinicians consider the questionnaire results to be preliminary and to follow up on these measures with careful interviewing.

Clinicians and researchers must do a bit of work to obtain relevant materials for using and scoring some of these measures, because many of the measures lack computerized scoring systems. In other cases, it is necessary to use norms obtained for older populations. It is to be hoped that this extra bit of upfront work will not deter researchers and clinicians from using some of the less easily accessible questionnaires.

The *Adolescent Psychopathology Scale* (APS; Reynolds, 1998) self-report measure assesses five DSM-IV PDs with items that are fairly close in content to DSM criteria: avoidant, obsessive-compulsive, borderline, schizotypal, and paranoid. The APS also assesses 20 Axis I disorders (including conduct disorder) and 11 psychosocial problems (e.g., problems with anger, interpersonal relationships, suicide, self-concept), and it includes four response style scales. The items are written at a third-grade level, and computer scoring is available. The manual presents data on reliability and validity in a large school-based norming sample and a clinical sample. These data indicated

TABLE 17.2. Omnibus Questionnaire Measures Assessing Personality Disorder Diagnoses, Personality Pathology, and Normal-Range Personality Traits

Instrument	No. of items/scales	Informants	Age range	Rating format	Material covered ^a	Non-PD scales ^b	Availability ^c
Adolescent Psychopathology Scale (APS; Reynolds, 1998)	346/40	Self	12 to 19	Varies	PD Dx and Path Pers	Yes	PAR

Schedule for Nonadaptive and Adaptive Personality—Youth version (SNAP-Y; Clark et al., 2003)	375/20	Self or parent	12 to 18	True-false	PD Dx and Path Pers	No	Author

^a Normal Pers, Normal-range personality traits; Path Pers, pathological personality traits; PD Dx, personality disorder diagnoses based on DSM-IV criteria.

^b Includes scales measuring constructs outside of personality disorders, pathological personality traits, or normal-range personality traits (e.g., Axis I disorders, impairment).

^c PAR, Psychological Assessment Resources; PA, Pearson Assessments.

good internal consistency and test–retest reliability for most of the scales, and preliminary validation in terms of content and convergent and discriminant validity with other measures. The APS has received relatively little empirical attention outside the initial studies presented in the manual. The measure appears initially promising, however, and warrants further empirical evaluation, particularly with regard to its validity for assessing PD diagnoses.

The *Assessment of DSM-IV Personality Disorders Questionnaire* (ADP-IV; Schotte & De Doncker, 1996) is a brief screening measure for PDs, with items created to assess each of the DSM-IV criteria for the 10 PD and 2 appendix diagnoses. Test takers rate themselves on a 7-point scale for each item in terms of how typical the described trait is for them; when they rate themselves as a “4” or higher on the trait, they then complete a follow-up rating on a 3-point Distress scale to describe how distressing and impairing the trait is. In approximately three out of four cases, test takers do not rate the traits as distressing even when significantly present (Schotte et al., 2004). The measure yields both dimensional scores and categorical assessments of the PDs, and is scored with an Internet application, which also produces a narrative description of the results. The ADP-IV has demonstrated good reliability, convergent validity with other PD questionnaire measures, and preliminary validity in terms of predicting any Axis II diagnosis on the Structured Clinical Interview for DSM-IV Axis II Disorders (SCID-II) in adult samples (reviewed in Schotte et al., 2004). The ADP-IV was used successfully in two studies of adolescents (De Clercq & De Fruyt, 2003; De Clercq et al., 2004); thus, it seems promising as a somewhat more detailed screening measure for PDs in adolescents.

The *Coolidge Personality and Neuropsychological Inventory for Children* (CPNI; Coolidge, 1998) was developed as a straightforward parent report measure of DSM-IV PDs (including the appendix diagnoses). The measure includes at least one item to assess each of the PD criteria, and the number of items per diagnosis ranges from 7 to 10. The CPNI also includes scales assessing a number of Axis I disorders, neuropsychological conditions, personality change due to a medical condition, hostility scales, other clinical scales, and critical items. In preliminary research, most PD scales were found to have adequate internal consistency

and test–retest reliability, but validation of the scales is very limited (Coolidge, Thede, Stewart, & Segal, 2002). Although there are norms for calculating *T*-scores, cutoff scores should not be used given the lack of validation research. However, given how closely the items are tied to the DSM criteria, it may be possible to use this measure to ascertain parent perceptions of which PDs should be assessed further.

The *Dimensional Personality Symptom Item Pool* (DIPSI; De Clercq et al., 2006) is a newly developed parent and self-report inventory to assess personality pathology in children and adolescents. The DIPSI was developed to explore the dimensional structure of personality pathology in youth, as has been done with adults (e.g., with the Schedule of Nonadaptive and Adaptive Personality, described below). As described in the section on dimensional models of personality pathology, in preliminary research on community and clinical youth samples, a number of lower-order scales were created, and four higher-order traits emerged: Introversion, Disagreeableness, Compulsivity, and Emotional Instability. The DIPSI is not suitable at this point for clinical use, but it is a very promising instrument for research on the development of personality pathology in childhood and adolescence.

The *Millon Adolescent Clinical Inventory* (MACI; Millon, Millon, Davis, & Grossman, 1994) is a widely used omnibus self-report measure that yields scores relevant to the 12 DSM-IV PDs, as well as facet scales for these. The MACI is based on Millon’s personality theory, which is strongly influenced by evolutionary theory (Millon & Davis, 1996). Although the theory relates to DSM PDs, it is not perfectly commensurate with the DSM system. The MACI yields several other types of scales as well: 8 for expressed concerns, 7 for clinical syndromes, and 3 modifying indices and 1 validity scale. A sixth-grade reading level is required. Computerized administration and scoring are available, as are interpretative reports and profiles. The measure has been found to be reliable, and preliminary validity data are available (Meagher, Grossman, & Millon, 2004). Further information on interpretation can be found in McCann (1999).

The MACI possesses both strengths and weaknesses. It is relatively efficient and easy for adolescents to complete and has the potential to yield a rich personality portrait that may provide useful targets for treatment. However,

because the instrument is based on both Millon's theories and DSM criteria, the instrument may yield diagnostic information that is not as closely tied to DSM-IV as that obtained through other instruments. To obtain maximum benefit from the measure, users need to have a full understanding of Millon's personality theory and the specific content of each scale; it is important to not rely simply on the names of the scales for interpretation. There may be problems with Millon's personality theory (Widiger, 1999) and with the scoring system used. Scores adjust for age and gender differences, and also take into account estimated base rates for psychopathology; these unusual scoring procedures may yield unsupported gender differences in scores and are questionable in light of the lack of firm epidemiological data on the prevalence of PDs in adolescents.

The *Minnesota Multiphasic Personality Inventory—Adolescent* (MMPI-A; Butcher et al., 1992) is a widely used omnibus self-report measure that yields a wide range of clinically relevant scales. The MMPI-A is based in large part on the MMPI adult measures. The MMPI-A has 10 clinical scales, 15 content scales (which have more homogeneous content than the clinical scales), 11 supplemental scales, and 7 validity scales. None of the scales corresponds directly to DSM-IV PD diagnoses, but they do provide information on a wide range of topics highly pertinent to personality pathology. A sample of potentially informative scales includes the following: Depression, Hysteria, Psychopathic Deviate, Paranoia, Schizophrenia, Social Introversion, Obsessiveness, Alienation, Anger, Cynicism, Conduct Problems, Low Self-Esteem, Social Discomfort, and Family Problems. In addition, the MMPI-A may be scored to yield the Personality Psychopathology Five (PSY-5; McNulty, Harkness, Ben-Porath, & Williams, 1997), a set of scales that describe personality pathology along five dimensions: Aggressiveness, Psychoticism, Constraint, Negative Emotionality/Neuroticism, and Positive Emotionality/Extraversion.

For most items, a sixth-grade reading level is required, but some items may require more advanced reading skills (Archer, 2004). Computerized administration and scoring are available, as are interpretative reports. The measure has been found to be reliable, and preliminary validity data are available (Archer, 2004, 2005), although much of the interpretation of the instrument is based on validity research on

the adult instruments. The biggest limitation of this instrument for assessing adolescent PDs is that, although the instrument assesses personality-relevant material, the scales do not specifically measure DSM-IV PDs, so clinicians would need to make links between the patterns observed on the MMPI-A and the diagnostic categories.

The *NEO-Personality Inventory—Revised* (NEO-PI-R; Costa & McCrae, 1992) is a widely used omnibus adult self-report measure of personality that assesses the Big Five higher-order traits (Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness), as well as 30 facets (six per Big Five trait). The NEO-PI-R is reliable (Costa & McCrae, 1992), and the Big Five model and this instrument have accumulated a vast literature demonstrating their predictive validity for individuals' adaptation and day-to-day behavior (Caspi et al., 2005). The NEO-PI-R may be computer scored, and interpretive reports are available. It has been used in a number of studies with adolescents as young as age 14 and with bright youth ages 12 and 13 (reviewed in Caspi & Shiner, 2006). The NEO-PI-R may be scored for use with adolescents by using the college-age norms. A new version of the NEO has been developed, the *NEO-Personality Inventory-3* (NEO-PI-3). This new measure is a more readable version of the NEO-PI-R and has replaced some of the more difficult items with simplified versions (McCrae, Costa, & Martin, 2005). Preliminary research with the NEO-PI-3 in a large sample of adolescents demonstrated that the measure is reliable in this sample for the Big Five traits and most of the facets (McCrae, Martin, & Costa, 2005); the measure also demonstrated a valid factor structure, and convergent and discriminant validity. A new study has found that the NEO-PI-3 may also be used with middle school-age students (Costa, McCrae, & Martin, in press). The NEO-PI-3 items can be obtained from Psychological Assessment Resources, and the new instrument may be scored for use with adolescents by using either the norms in McCrae, Martin and colleagues (2005) or NEO-PI-R college student norms.

As described in the section on dimensional models of personality pathology, the NEO-PI-R has been found to predict DSM-IV PDs (Costa & Widiger, 2002). The five higher-order traits measured in the NEO-PI-R map onto the higher-order pathological personality traits in

dimensional research on PDs. The facets of the NEO instruments provide particularly good coverage of variation in most PDs (Bagby, Costa, Widiger, Ryder, & Marshall, 2005; De Clercq & De Fruyt, 2003; De Fruyt, De Clercq, van de Wiele, & Van Heeringen, 2006; Miller, Reynolds, & Pilkonis, 2004), although there may be aspects of PDs not fully captured by the Big Five model (Skodol, Oldham, et al., 2005). The NEO-PI-R higher-order traits and facets provide a rich picture of a patient's personality functioning, including areas of difficulty and strength. An excellent example of the use of the NEO-PI-R (as well as other normal-range personality measures) in a clinical setting may be found in Singer (2005). The NEO-PI-R can also be scored using a prototype-matching procedure (Miller, Pilkonis, & Morse, 2004) or a simple summing procedure (Miller, Bagby, Pilkonis, Reynolds, & Lynam, 2005) to yield scores for DSM-IV personality diagnoses.

The *Personality Diagnostic Questionnaire-4+* (PDQ-4+; Hyler, 1994) is a version of two earlier measures (the PDQ and PDQ-R), which has been updated for DSM-IV. This brief screening measure assesses self-reports on each of the diagnostic criteria for DSM-IV PDs and those in the appendix. Scores for each PD are for the most part obtained by simply summing the number of criteria endorsed. The PDQ-4+ also includes two validity scales and an optional Clinical Significance scale, which is scored by having the administering clinician check on the duration, nonoverlap with Axis I conditions, and impairment and distress for each of the criteria endorsed. There is no manual for the instrument; however, a computer-assisted version is available. A substantial literature on earlier versions of this instrument suggests that it can be useful as a brief screening measure for PDs in adults; it tends to overdiagnose PDs, but it does not generally appear to miss "true" cases (Bagby & Farvolden, 2004). There is not yet enough research on the new version of the instrument to be able to establish cutoff scores for use as a screening measure (Bagby & Farvolden, 2004). The PDQ-4+ and its earlier versions have been used in a small number of studies with adolescents (e.g., Daley et al., 1999; Vito, Ladame, & Orlandini, 1999). In light of current evidence, the PDQ-4+ may potentially be used with adolescents as a brief screening measure for a later diagnostic interview.

The *Schedule of Nonadaptive and Adaptive Personality—Youth version* (SNAP-Y; Clark, Linde, & Simms, 2003) is an omnibus self-report measure of personality pathology adapted for youth from the Schedule of Nonadaptive and Adaptive Personality (SNAP; Clark, 1993) for adults. The SNAP was developed to assess criteria from DSM PD diagnoses, important aspects of other models of PDs, and some Axis I disorders that overlap potentially with PDs. Through empirical and rational means, the SNAP items were sorted to yield 12 scales that describe pathological personality traits (Mistrust, Manipulativeness, Aggression, Self-Harm, Eccentric Perceptions, Dependency, Exhibitionism, Entitlement, Detachment, Impulsivity, Propriety, and Workaholism) and three overarching temperament traits (Negative Temperament, Positive Temperament, and Disinhibition). The SNAP also includes five validity scales and can be scored to yield DSM-IV PD diagnostic information. The SNAP has strong psychometric characteristics and increasing support in terms of its validity as a measure of personality pathology (e.g., Melley, Oltmanns, & Turkheimer, 2002; Morey et al., 2003). In preliminary research with adolescents ages 12–18, the SNAP-Y has demonstrated evidence of good reliability, as well as structural validity and convergent-discriminant validity with the MMPI-A (Linde, 2002). The SNAP-Y may be scored using either the SNAP college student norms or the descriptive statistics presented in Linde (2002). Although the SNAP-Y requires further validation with adolescent samples, it appears to be a useful measure for obtaining both a more fine-grained look at adolescents' problematic and healthy personality patterns, and screening information for DSM-IV PDs.

Recommendations for Selecting Questionnaires

Assessors have a number of options in terms of youth self-report questionnaires to obtain information about problems in personality functioning. However, it is crucial to emphasize that all of these measures have received very little (if any) validation in terms of predicting interview-based PDs in adolescents; thus, all questionnaire-based findings are highly preliminary.

The selection of measures depends in part on other disorders that are being assessed and the

measures that are being administered to assess those other conditions. In most clinical contexts, it is unlikely that clinicians would be assessing only PDs given the high rates of comorbidity between Axis I and Axis II conditions. If clinicians are looking for measures that assess other conditions, as well as PD features, options include the APS and the MACI (recognizing, however, that the APS does not assess all PDs and the MACI scales do not correspond exactly to DSM disorders). Clinicians with extensive experience with the MMPI-A may use this instrument to generate hypotheses about relevant personality patterns, but this measure does not assess DSM PDs directly. In contrast, when more time can be devoted specifically to PD assessment, a number of self-report measures assess DSM PDs: the SNAP-Y, the ADP-IV, the PDQ-4+, and the Structured Clinical Interview for DSM-IV Axis II Personality Disorders—Screening Questionnaire (SCID-II-Q; First, Spitzer, Williams, & Gibbon, 1997; described in the next section under the SCID-II). The SNAP-Y has the advantage of providing a rich description of personality pathology more generally rather than DSM diagnoses only. Finally, when clinicians want a more complete picture of youths' personality difficulties and strengths, the NEO-PI-R and NEO-PI-3 are recommended; new scoring procedures may be used with these instruments to generate hypotheses about DSM PD diagnoses as well.

To obtain parent report on youths' personality disorder symptoms, the SNAP-Y, ADP-IV, PDQ-4+, and SCID-II-Q are recommended; these questionnaires may be used to pinpoint which PDs should be evaluated more carefully with diagnostic interviews.

Comprehensive Semistructured Interviews for Personality Disorders

For accurate diagnosis of personality disorders, semistructured interviews are the measure of choice in research. Such measures allow assessors to determine the duration, clinical significance, and pervasiveness of particular personality patterns. As noted previously, although semistructured interviews often are not used in clinical practice, they possess many strengths that make them preferable to unstructured interviews. A thorough review of all of the semistructured interviews is provided by Rogers (2001), and readers are referred to Rogers's

(2003) practical suggestions for choosing among the PD interviews for research and clinical practice.

Five semistructured interviews allow for diagnosis of the full set of PD diagnoses found in DSM-IV. All of these interviews may be used to assess PDs in youth; however, assessors need to determine whether aspects of the interviews need to be modified for use with a younger population. For example, it is essential to ensure that the questions apply to the life context of adolescents (e.g., questions about school, friendships, romantic relationships). It is also important to ensure that the language is comprehensible to adolescents. Furthermore, assessors need to determine the expected duration of the behaviors or patterns in question. DSM-IV stipulates that the personality patterns need to have persisted for at least 1 year, but the semistructured interviews vary in terms of the required time frame for the patterns (e.g., 2 years preceding the interview, or since early adulthood). Thus, the expected duration of symptoms for adolescents may differ from that expected for adults.

The five semistructured interviews vary along a number of dimensions that need to be considered when selecting an instrument (Clark & Harrison, 2001; Rogers, 2001). First, the interviews vary according to whether they are organized by diagnosis, with all of the questions for each diagnosis clustered together, or by topic (e.g., interests and activities, work, interpersonal relationships), or whether there are two versions—one by diagnosis and the other by topic. Each organization method has potential strengths and weaknesses (reviewed in Clark & Harrison, 2001; Rogers, 2001). Second, the semistructured interviews vary according to whether they have screeners that help determine which questions and diagnoses to pursue in greater detail with the longer interview. Third, as noted, the interviews vary in the time frame during which the symptoms are expected to have persisted. Fourth, the interviews vary in number of questions and length. Fifth, some of the interviews have been used in research with adolescents, whereas others have received little or no published use in research with this population.

The *Diagnostic Interview for DSM-IV Personality Disorders* (DIPD-IV; Zanarini, Frankenburg, Sickel, & Yong, 1996) is an interview organized by diagnoses and takes ap-

proximately 90 minutes to administer. Symptoms are assessed for their presence over the 2 years preceding the assessment. The measure had received little research attention until recently; thus, there is less empirical research on this interview than on some others. However, the DIPD-IV has been used in the Collaborative Longitudinal Personality Disorders Study of (CLPS; Skodol, Gunderson, et al., 2005), a longitudinal, multisite adult study. In this study, most disorders were found to have fair to good test-retest reliability and median interrater reliability; however, test-retest reliabilities for the dimensional disorder measures were considerably higher (generally $> .75$) (Zanarini et al., 2000). The CLPS has provided a rich set of validity data for the four primary diagnoses assessed: schizotypal PD, borderline PD, avoidant PD, and obsessive-compulsive PD (Skodol, Gunderson, et al., 2005). I found no published clinical studies in which this interview was used with adolescents; however, the measure has been used in PD research with adolescents (M. Zanarini, personal communication, July 5, 2006). The measure may be obtained by contacting the author.

The *International Personality Disorder Examination* (IPDE; Loranger, 1995, 1999) is an interview organized by topics. It is unique in that it has two separate modules, one designed to assess DSM-IV PDs and the other designed to assess the International Classification of Diseases (ICD-10) PDs. The DSM-IV module is highly similar to an earlier, thoroughly researched version designed to assess DSM-III-R PDs. Both modules take up to 3 hours to administer, which is far too long for routine clinical use. However, the DSM-IV module takes only 60–90 minutes, and this module alone should be adequate for most clinical and research purposes. The personality patterns are assessed by determining the age of onset, and at least one trait from each disorder must have been present before the age of 25. Informant reports are optional but recommended. There is a screening measure, but Rogers (2001) raised some possible concerns about its use. Rogers noted the strengths and weaknesses of this interview. As for strengths, the instrument has demonstrated good reliability and validity (with the possible exception of poor validity for cluster A diagnoses). The instrument was also designed with international research in mind and may be especially suitable for cross-cultural settings. As for weaknesses, the instru-

ment may not be as valid with patients with more severe Axis I diagnoses (psychotic disorders, severe depression).

The earlier version of the IPDE, the *Personality Disorder Examination* (PDE; Loranger, Susman, Oldham, & Russakoff, 1988), has been used in a number of studies with adolescents (see citations in Levy et al., 1999), thus providing some evidence for the validity of the measure with youth. The IPDE and PDE specify that the traits need to have been present for at least 3 years in adolescents to qualify for diagnosis; thus, the standards for duration are higher than those in DSM-IV. In at least one sample of adolescents (Becker et al., 1999), the measure demonstrated good interrater reliability, but this study also found evidence for lower internal consistency for the diagnoses and less discriminant validity than is often found in adult assessment. It is possible that these problems were due to the application of adult criteria from DSM-IV to adolescents, not problems with the interview per se. Nonetheless, this interview also has shown some promise for use with adolescents. The measure may be obtained by contacting Psychological Assessment Resources or the World Health Organization.

The *Personality Disorders Interview-IV* (PDI-IV; Widiger, Mangine, Corbitt, Ellis, & Thomas, 1995) can be administered either by diagnosis or by topic. The interview takes 90–120 minutes to administer and requires the trait to have been present at least since age 18 and for much of adulthood. However, the interview may be used with adolescents if modified to fit with the stipulations of DSM-IV. Rogers (2001) noted that some preliminary data demonstrate adequate interrater reliability, but validity data are limited, because of little empirical use of the instrument. Rogers described the instrument's strengths as its extensive and thoughtful manual, and its questions that "closely reflect that diagnostic criteria" (p. 250). Rogers noted that the instrument includes some questions that are relatively complicated and sophisticated in language; this could potentially be a problem for use with adolescents, so some questions may need to be modified. Because the PDI-IV manual provides such helpful information about PDs, the manual may be read in conjunction with other semistructured interviews that lack a detailed manual.

The *Structured Clinical Interview for DSM-IV Axis II Personality Disorders* (SCID-II; First

et al., 1997) is an interview organized by diagnosis. The questions follow the order of the symptoms and diagnoses in DSM-IV. It is the shortest of all the semistructured interviews and can be completed in 30–45 minutes. Traits are assessed to determine whether they have been present for the last 5 years (clearly this time frame would need to be modified with adolescents). A self-administered screener, called the SCID-II-Q, may be used to determine which diagnoses to assess more thoroughly and cut down on administration time for the SCID-II (Piedmont, Sherman, Sherman, & Williams, 2003). There is also a computer-administered version of the SCID-II that still requires the active involvement of the interviewing clinician. The SCID-II has demonstrated good reliability and validity in adult samples (First & Gibbon, 2004; Rogers, 2001). The SCID-II has the advantages of being relatively short, straightforward, and easy to administer; drawbacks are that it may miss some important traits and be less suitable for patients who are uncomfortable acknowledging personality difficulties (Rogers, 2001, 2003).

The SCID-II requires an eighth-grade reading level and may be adapted for use with adolescents. In fact, the SCID-II and its previous DSM-III-R version appear to be the semistructured interviews that have received the most widespread use in studies of personality disorders in adolescents (Asarnow et al., 2001; Brent, Johnson, Perper, & Connolly, 1994; Chanen et al., 2004; Daley et al., 1999; Lavan & Johnson, 2002; Mittal et al., 2006; Neumann & Walker, 2003). The SCID interviews have been used in research on the full spectrum of personality disorders in adolescents. In one study of adolescents that used the SCID-II, PD features had to have persisted for at least 2 years to meet threshold criteria (Chanen et al., 2004). The adolescent PD studies have begun to establish the SCID-II's adequate reliability in adolescents. The SCID can be obtained from the American Psychiatric Press or at www.scid4.org.

The *Structured Interview for DSM-IV Personality* (SIDP-IV; Pfohl, Blum, & Zimmerman, 1997) is the most recent version of the earliest omnibus semistructured interview for Axis II disorders. The SIDP-IV has both diagnostic and topical versions of the interview (the diagnostic format is available only for the DSM-IV version of the SIDP). The interview takes 60–90 minutes to administer, although

the interview may be shortened by omission of DSM appendix diagnoses. The informant interview, which contains some questions not found in the patient interview, may potentially be quite useful in assessing adolescents. As with the SCID-II, traits are assessed to determine whether they have been present for the last 5 years, which necessitates modification of the SIDP-IV for use with adolescents. A brief interview screener is available. The SIDP-IV and its predecessors have demonstrated good inter-rater reliability and validity (Rogers, 2001). Rogers (2001, 2003) has commented on a number of strengths of this interview. The topically organized version includes natural questions that make the interview flow well and that may be especially useful with defensive or guarded patients. The interview may be used with patients with a wide range of Axis I pathology (including psychotic and mood disorders). In addition, relative to other semistructured interviews, the SIDP-IV appears to yield fewer cases of comorbid PDs. The SIDP-IV interviews appear to have been used rarely with adolescents in published studies (Brent et al. [1990] and Mittal et al. [2006] are exceptions), but given the strengths of the instrument, wider use may be warranted.

Recommendations for Selecting a Semistructured Interview

All five semistructured interviews are potentially good means of assessing PDs in adolescents. Three of the interviews or their earlier versions have been used in published research with adolescents: the IPDE, the SCID-II, and the SIDP-IV; thus, these three interviews have already proved useful with this population. Deciding among these three interviews depends on several considerations. If a topical format is preferred (because of a defensive or guarded interviewee, or a need for a more conversational interview structure), then the IPDE and SIDP-IV can be used. If a diagnostic format is preferred (because of a desire to keep the interview short by omitting unlikely diagnoses based on questionnaire information), then the SCID-II or SIDP-IV can be used. Other considerations may include the need for a cross-culturally sensitive interview (the IPDE), a relatively shorter interview (the SCID-II), an interview that may be used with patients with significant Axis I disorders (the SIDP-IV), or an interview with an informant version (the SIDP-IV).

Measures of Single Personality Disorders and Traits

In addition to the omnibus questionnaire instruments and semistructured interviews described previously, a number of instruments have been used to assess single personality disorders or traits in isolation, including borderline PD (or borderline features), narcissistic PD (or narcissism), and psychopathy. The single-trait measures of borderline and narcissistic PD are not recommended generally for clinical use because of the frequent comorbidity of personality disorders. At the very least, if these measures are used in clinical practice, then it is important to screen for possible comorbid personality pathology. However, the measures may be useful in some research contexts or in selected clinical contexts; again, though, even in research, it would be useful in many cases to include an additional omnibus measure of personality pathology.

Borderline Personality Disorder Measures

There are at least three semistructured interviews and two questionnaires for assessing borderline PD or pathology in youth. The *Diagnostic Interview for Borderlines* (DIB; Gunderson, Kolb, & Austin, 1981), a 132-item, semistructured interview, yields scores for five domains of functioning: Social Adaptation, Affect, Cognition, Impulsivity, and Interpersonal Relationships. The interview was later revised, resulting in the *Diagnostic Interview for Borderlines—Revised* (DIB-R; Zanarini, Gunderson, Frankenburg, & Chauncey, 1989), which dropped the Social Adaptation section. Both the DIB and the DIB-R have been used in research with adolescents (e.g., Ludolph, Westen, Misle, & Jackson, 1990; Pinto, Grapentine, Francis, & Picariello, 1996). The interviews are based on Gunderson's conception of borderline PD, which is related to the DSM diagnostic view but does not entirely overlap (Kaye & Shea, 2000). Another variation of the DIB is the *Child Version of the Retrospective Diagnostic Interview for Borderlines* (C-DIB; Greenman, Gunderson, Cane, & Saltzman, 1986), a structured process for chart review. The C-DIB was developed to assess a condition described as "borderline pathology of childhood," which was observed in highly impaired children who exhibited the impulsivity, mood lability, and cognitive symptoms seen

in adults with borderline PD. The C-DIB has been used effectively in a longitudinal study of such pathology (Guzder, Paris, Zelkowitz, & Feldman, 1999; Paris, 2005b). The *Borderline Personality Inventory* (BPI; Leichsenring, 1999), a 53-item self-report instrument developed to assess Kernberg's concept of borderline PD, appears to have good reliability and convergent validity with other borderline PD questionnaire measures. The BPI has received some preliminary research use with adolescents (Chabrol et al., 2004). Finally, the *Borderline Personality Features Scale for Children* (BPFS-C; Crick, Murray-Close, & Woods, 2005), a newly developed self-report measure for children age 9 and older, is based on the BOR (Borderline) scale of the *Personality Assessment Inventory* (PAI; Morey, 1991) for adults and was created by modifying the BOR scale to make it developmentally appropriate for children. It taps affective instability, identity problems, negative relationships, and self-harm. Based on an initial longitudinal study, the measure appears to be reliable, moderately stable over 1 year, and valid in terms of predicting other measures of borderline pathology.

Narcissistic Personality Disorder Measures

At least one semistructured interview and two modified versions of a questionnaire assess narcissistic PD or narcissism in youth. The *Diagnostic Interview for Narcissism* (DIN; Gunderson, Ronningstam, & Bodkin, 1990), a semistructured interview, includes 33 statements and results in five scores: Grandiosity, Interpersonal Relations, Reactiveness, Affects and Mood States, and Social and Moral Judgments. The DIN was developed based on Gunderson's conception of narcissism and appears to measure a broader construct than the DSM disorder. The DIN was modified for a retrospective chart review study of adolescent inpatients (Kernberg, Hajal, & Normandin, 1998). A parent version has also been developed to assess younger children ages 8–13—the *Parent Diagnostic Interview for Narcissism* (P-DIN; Guilé et al., 2004). The primary questionnaire measure of narcissism in adults, the *Narcissistic Personality Inventory* (NPI; Raskin & Terry, 1988), is a 40-item questionnaire. The NPI has been modified in two different versions for youth: the *Narcissistic Personality Inventory—Children* (NPIC; Barry, Frick, & Killian, 2003) and the *Narcissistic Personality*

Inventory—Junior Offender (NPI-JO; Calhoun, Glaser, & Stefurak, 2000). Hilsenroth, Handler, and Blais (1996) reviewed other adult measures of narcissism that potentially could be adapted for use with youth.

Psychopathy Measures

Psychopathy is a construct that has received a great deal of research attention over the last decade as researchers have begun to explore the nature and manifestations of this trait in youth. Psychopathy includes a number of behavioral and personality tendencies: risk-taking and impulsivity, grandiosity, manipulateness, lack of empathy and remorse, and shallow relationships (Lynam & Gudonis, 2005). Aspects of psychopathy are included in DSM-IV diagnostic criteria for antisocial PD. However, antisocial PD cannot be diagnosed in youth under age 18, and the developmental precursor diagnosis is conduct disorder. The DSM-IV diagnosis of conduct disorder does not adequately capture aspects of psychopathy. Thus, there is no real place in DSM-IV for classifying psychopathic tendencies in youth. Yet recent research has revealed that psychopathy can be measured reliably in youth, that it is stable during the adolescent years, and that it predicts a number of important associated features and outcomes, including more severe and stable conduct problems (Kotler & McMahon, 2005; Lynam & Gudonis, 2005; Salekin & Frick, 2005). Childhood psychopathy appears to be at least partially heritable, and these inherited characteristics are likely to result in impaired socialization across development (Blair, Peschardt, Budhani, Mitchell, & Pine, 2006).

Three recent articles provide a thorough and careful review of the measures developed thus far to assess psychopathy in youth (Kotler & McMahon, 2005; Lynam & Gudonis, 2005; Vaughn & Howard, 2005). Consequently, the measures are described only briefly here; readers are referred to those reviews for more details. Presently at least four measures have been used to assess psychopathy in youth; three of these are questionnaires, and one is an interview/chart review checklist. All four measures are based in part on the most prominent adult measure of psychopathy, *Hare's Psychopathy Checklist—Revised* (PCL-R; Hare, 1991, 2003). To use the PCL-R, the clinician conducts a semistructured interview and chart review, then rates the individual on 20 items.

In the modified youth versions, inappropriate PCL-R items have been dropped (e.g., items about unstable marriages), and new, developmentally appropriate items have been added (e.g., teases others, keeps same friends). All four measures have shown good reliability at the total scale level and preliminary evidence of validity (Kotler & McMahon, 2005; Lynam & Gudonis, 2005).

The *Antisocial Process Screening Device* (ASPD; Frick & Hare, 2001) is a 20-item rating scale with self-report, parent, and teacher versions; it can be used with youth ages 6–18. It is modeled closely after the PCL-R and is the measure that has received the greatest research use thus far. The *Child Psychopathy Scale* (CPS; Lynam, 1997; revised version is in Lynam et al., 2005) is likewise based on the PCL-R but consists of 13 miniscales, each comprising two to seven items drawn from the Child Behavior Checklist (CBCL; Achenbach, 1981) and the California Child Q-set (CCQ; Block & Block, 1980). The CPS has parent, teacher, and youth versions. The *Youth Psychopathic Traits Inventory* (YPI; Andershed, Gustafson, Kerr, & Stattin, 2002), a 50-item self-report inventory for adolescents, is designed to minimize reluctance to acknowledge psychopathic traits and focuses on the affective and interpersonal features of psychopathy. The final measure is *Hare's Psychopathy Checklist—Youth Version* (PCL-YV; Forth, Hart, & Hare, 1990; Forth, Kosson, & Hare, 2003), which, like the PCL-R, comprises a 20-item rating scale completed on the basis of a thorough semistructured interview and chart review. The PCL-YV is essentially a version of the PCL-R adapted for youth. Although the questionnaire measures serve as rapid screening devices, the PCL-YV is a more time-consuming diagnostic instrument. Although all four of these psychopathy measures require further validation (including clarification about their factor structures), all show considerable potential for the measurement of this important pathological trait.

Two Personality Disorder Measures That Are Difficult to Classify

The *Children in the Community* (CIC) measures (Cohen & Crawford, 2005; Cohen et al., 2005) were developed for use in what is currently the only longitudinal epidemiological sample study of PDs. At each time point of the

study, the CIC PD measure items were selected and modified from existing PD measures, and new items were added to provide developmentally appropriate coverage of the current DSM system. The CIC measures thus took different forms at different assessment points (e.g., parent and child interviews, self-report questionnaire). Although these measures are not suitable for clinical use, they could potentially be adapted for use in research studies. The authors can be contacted for more information on these measures.

The *Shedler–Westen Assessment Procedure–200 for Adolescents* (SWAP-200-A) is an assessment procedure that helps to structure clinicians' perceptions of adolescents' personality functioning. The SWAP-200-A and its adult counterpart, the *Shedler–Westen Assessment Procedure–200* (SWAP-200; Westen & Shedler, 1999), were designed in part as alternatives to the semistructured interviews and questionnaires that are typical in PD research. Westen and Shedler have argued that semistructured interviews and questionnaires are problematic for PD assessment because of their reliance on direct questioning of the patient about personality patterns. In contrast, in typical practice, clinicians look to patients' narratives about their daily lives and relationships, and to the patients' observed behavior in interaction with the clinician (Westen, 1997), presumably because clinicians implicitly view these methods as more valid.

To use the SWAP-200 or the SWAP-200-A, clinicians must first conduct a thorough systematic clinical interview with an adolescent patient and his or her parents (e.g., see the Clinical Diagnostic Interview; Westen, 2004) or obtain a thorough understanding of an adolescent through repeated clinical contact over time. The SWAP systems may then be used by the clinician to quantify clinical judgments about the patient. The SWAP-200 and SWAP-200-A both comprise 200 statements describing a fairly comprehensive set of behaviors and personality tendencies related to personality pathology, as well as statements about defense mechanisms, coping, relevant Axis I characteristics, and healthy psychological functioning (Westen & Shedler, 1999; Westen et al., 2003). Clinicians use a Q-sort procedure to quantify the appropriateness of the SWAP statements for the patient. In the Q-sort, the informant sorts a set of cards (with one SWAP statement on each) into a forced distribution based on

how well each item describes the adolescent. Thus far, the SWAP-200-A has been used to explore the structure of personality pathology in adolescents (Westen et al., 2003; Westen, Dutra, & Shedler, 2005). In addition, it is possible to calculate dimensional scores for DSM-IV PD diagnoses by comparing patients' scores on the SWAP-200-A with prototype descriptions for the PD diagnoses (Westen et al., 2003). The SWAP-200-A and SWAP-200 have already proved that they can yield useful information in research on personality pathology in adolescents and adults, and the statements included in the measure seem to capture aspects of patient functioning that may be helpful for clinicians as they conceptualize cases, plan treatment, and measure treatment outcomes. Future research will help clarify the role that the SWAP systems may play in clinical practice. The SWAP-200-A is available at www.psychsystems.net/lab.

CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE RESEARCH

This chapter has reviewed evidence demonstrating that it is possible for youth to have PDs, and that it is both important and possible to assess such patterns. Given the relative newness of research in this area, much work remains to better refine assessment procedures for adolescents with PDs. Several directions for future research are suggested. First, many of the available assessment measures for adolescents are the same instruments created for adults, adapted in various ways for use with adolescents. But, it is possible that more thorough modifications are necessary to make some of the measures (e.g., the semistructured interviews) developmentally appropriate. Some of the adult measures (e.g., the screening measures) need to be studied for use in adolescents to clarify whether they function similarly with adolescents and adults. Second, much more work is needed to determine whether the existing instruments are psychometrically sound. Although there is evidence for the reliability of many of the measures and some preliminary evidence of construct validity, many aspects of validity are unexamined. Other important aspects of validity to establish include predictive validity, discriminant validity, diagnostic utility, and treatment utility (Mash & Hunsley, 2005). Third, although it is clear that assess-

ment information must be gathered from more than source, the relative usefulness of information from various informants is unknown. Fourth, the lack of empirically supported treatments for adolescents with PDs is a glaring and serious problem that needs to be addressed. I hope that the recent surge of interest in understanding adolescents with PDs will continue and that it will ultimately point to effective treatments for such youth.

ACKNOWLEDGMENT

Work on this chapter was supported by grants from the Colgate Research Council.

Subject Index

Page numbers followed by *f* indicate figure, *t* indicate table

- AAMR Adaptive Behavior Scale, 578–579
description of, 579*t*
- Aberrant Behavior Checklist, 512, 585
description of, 584*t*
- Abuse Dimensions Inventory, 714–715
- Abuse–neglect dynamics, assessment of, 667, 668*t*–669*t*, 670–677
- Abusive Sexual Exposure Scale, 717
- Academic achievement, assessment of, 568, 569*t*, 570–571
- Academic engaged time, measuring, 153
- Accountability, 5
- Achenbach Scales, 234–235
- Achenbach System of Empirically Based Assessment, 15, 145, 539
description of, 145, 146*t*, 148, 153
- ACU. *See* ADHD Checkup
- Acute Stress Checklist for Children, description and contact information, 481
- Acute stress disorder, 399–400
assessment of, 422–423
defining, 410
DSM-IV-TR criteria for, 409–410, 409*t*
- Adaptive behavior, with intellectual disabilities, 578–580, 579*t*
- Adaptive Behavior Assessment System, 540, 579–580
description of, 579*t*
- Adaptive Behavior Evaluation Scale, 580
description of, 579*t*
- Adaptive functioning, assessing, 4–5
- ADHD, 53–131
adolescent, 63–64
in adolescents, self-reports of, 84–85
adult caregivers and, 99
adults with, 64
age at onset, 62–63
assessment of, 79–92
base-rate considerations in, 68
for caregiver’s abilities, 86
for child’s strengths/weaknesses, 86
comments on, 100–101
goals of, 86
intervention-focused approach to, 54
measurement theory and, 81–85
minimally acceptable, 87–90, 87*t*
multimodal, 85–92
and setting/observer influences on scores, 82–84
and state of ADHD diagnosis, 80–81
teacher ratings in, 90–91, 91*t*
and within-person variability, 81, 82, 84–85
with autism, 492, 509
Barkley’s model of, 77–79
with bipolar disorder, 262
childhood onset, 62–63
cognitive/psychomotor difficulties and, 72
combined type, reward-related deficits in, 59
comorbidity with, 66, 70–72, 86
gender and, 69
outcome and, 76
compendium approach to, 54
- conceptualization of, 77–80
conduct problems associated with, 134
cost to society, 53
cross-setting symptom
pervasiveness in, 64–65
definition and primary symptoms, 57, 59–60
impulsivity, 59–60
inattention, 57, 59
developmentally inappropriate behavior in, 61–62
diagnostic challenges in, 81
documenting, 66–67
DSM-IV approach to, 54
DSM-IV-TR criteria for, 58*t*, 60–67, 81
DSM-IV-TR subtypes of, 61
epidemiology of, 67–68
etiologies of, 72–76
environmental, 75–76
genetic, 74–75, 89
neurologic, 72–74
pregnancy/birth-related, 74
executive functioning in, 56, 59, 72–73, 77–79
gender differences in, 68–69
history of, 55–57
incremental validity and, 54–55
with intellectual disability, 559
interventions for, 101–103
choice of, 104–105
evaluating, 103–105
individual variability and, 104
legal and ethical issues, 105–106
with ODD, 55, 65
overview of, 55–77
peer relationships and, 72
persistent life course, 63–64

- ADHD (*cont.*)
 prevalence of, 53, 67
 responses to interventions, 103–105
 ruling out alternative diagnoses and, 65–66
 screening parents for, 162
 situational and contextual factors, 69–70
 social factors and, 72
 with substance use disorder, 189–190
 treatment options, 101–103
 within-subject variability in, 81–82, 84–85
- ADHD Checkup, 54, 92–100
 adult function/relationships in, 99
 child/adolescent feedback in, 100
 comorbid conditions in, 99
 family assessment task in, 96–98, 97*t*
 feedback in, 98
 history and background, 92–94
 parent–child interactions in, 99–100
 peer relations in, 100
 school adjustment in, 100
 semistructured interview in, 94–96
 symptoms in, 98–99
 telephone contact in, 94
- Adolescent Alcohol and Drug Involvement Scale, 194, 195*t*
