About the Editors

Eric J. Mash, PhD, is Professor of Psychology in the Department of Psychology and Program in Clinical Psychology at the University of Calgary. He is a fellow of the American and Canadian Psychological Associations; has served as an editor, editorial board member, and editorial consultant for many scientific and professional journals; and has written or edited numerous books and journal articles related to children's mental health, child and adolescent psychopathology, child and adolescent psychotherapy, and child and family assessment. Dr. Mash's research has focused on family relationships across a variety of child and family disorders, including attention-deficit/hyperactivity disorder (ADHD), conduct problems, internalizing disorders, and maltreatment. He is a recipient of the Leadership Education in Neurodevelopmental Disabilities Distinguished Alumnus Award from the Oregon Health & Science University.

Russell A. Barkley, PhD, is Research Professor of Psychiatry at the State University of New York Upstate Medical University at Syracuse and Clinical Professor of Psychiatry at the Medical University of South Carolina. He is a Diplomate in three specialties: Clinical Psychology (ABPP), Clinical Child and Adolescent Psychology, and Clinical Neuropsychology (ABCN, ABPP). Dr. Barkley is a clinical scientist, educator, and practitioner who has authored, coauthored, or coedited 20 books and clinical manuals and published more than 200 scientific articles and book chapters related to the nature, assessment, and treatment of ADHD and related disorders. He is the editor of the bimonthly clinical newsletter *The ADHD Report*. Dr. Barkley has presented more than 600 invited addresses internationally and appeared on many nationally televised programs on behalf of children and adults with ADHD. He has received several awards from the American Psychological Association for his contributions to research on ADHD, to clinical practice, and to the dissemination of science.

Preface

Welcome! True to prior editions, this volume focuses on contemporary perspectives on the assessment of childhood psychological disorders. Yet our focus in this edition has also changed somewhat from that of earlier editions. Where previously we sought relatively comprehensive reviews of assessment methods and issues related to various childhood disorders, in this volume we now also focus on “best practices” or state-of-the-art approaches to the evaluation of those disorders. This additional emphasis was necessitated by several developments in the field of assessment, not the least of which is the voluminous extant literature on assessment approaches for each disorder, and for assessment more generally, and the tremendous expansion in the variety of evaluative methods. Our shifting emphasis was also driven by the obvious recognition that evaluators are under increasing pressures to limit the time spent conducting clinical evaluations, requiring that they utilize the best and most cost-effective methods now available while still attending to the clinical issues raised in the evaluation of children generally, and for each disorder more specifically. Yet overall our goal remains the same as in earlier editions: to invite major thought leaders to prepare chapters that reflect the cutting-edge empirically based methods and clinical issues related to evaluating the disorder(s) in which they specialize. We believe that goal has been achieved admirably by the current array of authors participating in this volume. We hope you will agree.

We acknowledge our considerable gratitude to these authors for taking substantial time from their work to update their chapters or prepare entirely new ones. We also wish to thank Seymour Weingarten and Bob Matloff of The Guilford Press for once again permitting us this opportunity to showcase contemporary approaches to assessment. We are further indebted to those working in the production department at Guilford for polishing these chapters to a higher gloss and more consumer-friendly organization and comprehension, particularly Laura Specht Patchkofsky for her matchless production editing skills in shepherding a volume of this complexity to completion and Jacquelyn Coggin for her skillful copy editing. We are also both continually indebted to our wives, Heather Mash and Pat Barkley, for creating a welcoming and supportive home and family life in which our professional activities can flourish. Both have done so for more than three decades—a miraculous feat in contemporary times and with outspoken, overworked, and professionally preoccupied men such as ourselves. There is no way to repay such a debt but we acknowledge it with infinite gratitude here. Finally, to our readers we express our sincerest appreciation for your interest in this volume. We trust you will find it to be a useful and informative guide to the best approaches to the evaluation of children and adolescents with psychological disorders.

PART I

Introduction

Assessment of Child and Family Disturbance

A Developmental–Systems Approach

Eric J. Mash
John Hunsley

From the time of their conception, children in our society are assessed, evaluated, and labeled with respect to their physical status, behavior, language, cognition, learning, social competence, mood, and personality. These assessments are guided by the implicit assumptions about children's development and behavior held by significant others, and rooted in societal and cultural norms. Parents, other family members, teachers, peers, community members, and health care professionals all participate in this ongoing process, as do the children themselves. For most children, these evaluations occur during everyday social transactions and, to a lesser extent, during periodic formal evaluations best characterized as "routine" (e.g., regular medical checkups, school reports). As a result of these assessments, some children are identified as *deviating* from a normal course of development with regard to their behavior, physical condition, mental development, or conformity to social norms and expectations (Kagan, 1983; Mash & Dozois, 2003). When a negative valence is assigned to these deviations, a child is likely to be informally labeled as belonging to a group of children who display similar characteristics (e.g., "diffi-

cult," "shy," "slow," "overactive"). It is these children and their families who may then come to the attention of society's professional assessors, who utilize special strategies to build upon the informal assessments that led to the referral (e.g., Kamphaus & Campbell, 2006; Kamphaus & Frick, 2005; Mash & Terdal, 1997b; Reynolds & Kamphaus, 2003a, 2003b; Sattler, 1998, 2001; Sattler & Hoge, 2006).

About one in five children and adolescents in the United States suffer from some type of mental health problem during the course of a year (U.S. Department of Health and Human Services, 1999), and about 50% of all mental disorders in adults have an onset prior to age 14 (Kessler, Bergland, Demler, Jin, & Walters, 2005). Although there is much agreement concerning the need for systematic assessments of children and adolescents who display or are at risk for later problems, there has been and continues to be considerable disagreement and debate regarding how childhood disorders should be defined; what child characteristics, adaptations, and contexts should be assessed; by whom and in what situations children should be assessed; what methods should be used;

and how assessment information should be integrated, interpreted, and utilized (Jensen, Hoagwood, & Zitner, 2006; Mash & Hunsley, 2005a). Despite these disagreements, there is a general consensus regarding the need for the development of assessment strategies not as an endpoint, but as a prerequisite for planning, implementing, and evaluating effective and efficient services for children (Achenbach & Rescorla, 2006a; Mash & Hunsley, 2005a). Clearly, the value of any clinical assessment procedure ultimately depends on whether it helps the children and families who are being assessed. Such an evidence-based utilitarian approach to the assessment of children and families is a major theme underlying this volume, one that transcends many of the conceptual and methodological differences and preferences that emerge in the current discussion.

This volume examines current approaches to the *developmental-systems assessment* (DSA) of child and adolescent disorders. As described in this chapter, DSA has evolved from the concepts and methods of developmental psychopathology (Cicchetti, 2006), child and family behavioral assessment (Mash & Hunsley, 2004; Mash & Terdal, 1997a; Ollendick & Hersen, 1993), and evidence-based assessment (Hunsley & Mash, 2007; Mash & Hunsley, 2005b), and continues to embrace many of the following fundamental ideas and methods associated with each of these approaches: the use of developmentally sensitive assessments; a focus on the interplay of the child's physical status, affect, behavior, and cognition; the important role of context in assessment, including the child's family (i.e., parent-child interactions, sibling interactions) and larger social systems (i.e., peer relations, influence of teachers, cultural factors); the view of assessment as an ongoing process used to inform decision making; the use of empirically justifiable and feasible assessment methods, multimethod assessment strategies, and multiple informants; an emphasis on assessment information that leads to the design of effective interventions; and the ongoing evaluation of treatment progress and outcomes as an integral part of the assessment process. Our overall purpose in this introductory chapter is to elaborate on these themes, to highlight current principles and practices of DSA with disturbed children and families, and to discuss a number of key issues and concerns surrounding their development and use.

RECENT DEVELOPMENTS

As stated in the introductory chapter to the first edition of this book: "Recognizing the likelihood of ongoing and future changes in assessment strategies related to new empirical findings, emergent ideas, practical concerns, and shifts in the broader sociocultural milieu in which assessments are carried out, this chapter—indeed, this book—should be viewed as a working framework for understanding current approaches to the assessment of children" (Mash & Terdal, 1981, p. 4). This statement is as true today as it was then. As reflected throughout this volume, while retaining certain core elements, DSA has shown dramatic advances since the first edition of this book.

Some of the more notable developments are as follows:

1. An increased emphasis on incorporating developmental considerations into the design, conduct, and interpretation of assessments (Achenbach & Rescorla, 2006a; Peterson, Burbach, & Chaney, 1989; Yule, 1993); the implementation of treatments (Holmbeck, Greenley, & Franks, 2003; Kendall, Lerner, & Craighead, 1984; Luby, 2006); and the conceptualization of child and family psychopathology (e.g., Cicchetti & Cohen, 2006a, 2006b, 2006c; Mash & Barkley, 2003).

2. A heightened interest in issues related to diagnosis and classification. This interest has been accompanied by efforts to integrate DSA and current diagnostic practices in ways that are both sensitive to categorical and dimensional approaches to classification and informed by the limitations associated with current classification systems (Jensen, Hoagwood, et al., 2006; Mash & Terdal, 1997b; Pickles & Angold, 2003).

3. A heightened awareness of the need to assess multiple disorders or symptoms from different disorders in light of the high rates of co-occurrence (comorbidity) for most childhood problems (Kazdin, 2005).

4. A growing recognition of the importance of assessing adaptive functioning, impairment, and, more generally, how children and families are functioning in their daily lives as distinct from symptoms and disorders (Jensen, Hoagwood, et al., 2006; Kazdin, 2005). Such recognition has also led to attention regarding

the extent to which current assessment methods adequately capture important aspects of everyday functioning and quality of life (Bastiaansen, Koot, & Ferdinand, 2005; Kazdin, 2006).

5. A view of DSA as an ongoing decision-making process (Adelman & Taylor, 1988; Carter, Marakovitz, & Sparrow, 2006; Evans & Meyer, 1985) generating interest in the judgmental heuristics that influence this complex information-processing task (Evans, 1985; Kanfer, 1985; Tabachnik & Alloy, 1988), and efforts to develop both clinically and empirically derived decision-making guidelines for specific clinical problems and populations (Frazier & Youngstrom, 2006; Nezu & Nezu, 1993; Sanders & Lawton, 1993).

6. Growing attention to prevention-oriented and socially relevant assessments for high-risk populations (Ialongo et al., 2006; Tuma, Loeber, & Lochman, 2006). Attention emanating from current social concerns has focused on a wide range of groups and issues, including single-parent and stepfamilies, unemployment, children in day care, immigrant families, poverty, accidental injuries, child abductions, sexual abuse, family violence, delinquency, teen violence, adolescent substance abuse, adolescent suicide, and exposure to extreme stressors such as war, torture, and terrorist attacks.

7. An increasing emphasis on understanding the interrelated influences of child and family genetics (Rende & Waldman, 2006), neurobiology (Gunnar & Vazquez, 2006), cognition (Dodge & Pettit, 2003), affect (Dix, 1991; Gottman & Levenson, 1986), and behavior, as assessed within the context of ongoing social interactions (e.g., Bradbury & Fincham, 1987; Gottman, Katz, & Hooven, 1996; Lorber & Slep, 2005).

8. The extension and assimilation of DSA concepts and practices into child health care settings within the general frameworks of developmental pediatrics (Parker, Zucker, & Augustyn, 2005), behavioral pediatrics (Gross & Drabman, 1990), and pediatric psychology (Roberts, 2005).

9. A growing recognition of the need for empirically driven theoretical models as the basis for organizing and implementing assessment strategies with children and families (Mash & Barkley, 2003; McFall, 1986).

10. Increasing technological advances, particularly use of the Internet and computers

during both the data-gathering and decision-making phases of assessment (Ancill, Carr, & Rogers, 1985; Whalen et al., 2006). Suggested Internet/computer applications have included gathering interview, self-monitoring, test, and observational data; organizing, synthesizing, and analyzing assessment data, and supporting decision making; monitoring treatment progress and outcomes; and using daily diaries. Technological advances have led to a heightened interest in the utility and feasibility of using actuarial models in clinical decision making (Achenbach, 1985; Frazier & Youngstrom, 2006; Mash, 1985).

11. Conceptual and methodological convergence on an ecologically oriented systems model (Bronfenbrenner, 1986; Hartup, 1986) as the appropriate framework for organizing and understanding assessment information derived from disturbed children and families (Evans, 1985; Wasik, 1984). This has led to a heightened interest in the assessment of whole-family variables (Forman & Hagan, 1984; Mash & Johnston, 1996b; Rodick, Henggeler, & Hanson, 1986) and the relationships among family systems, and between family systems and the broader sociocultural milieu (Cowan & Cowan, 2006; Dunst & Trivette, 1985, 1986; Parke, MacDonald, Beital, & Bhavnagri, 1988).

12. Increased recognition of the growing cultural diversity in North American society (Quintana et al., 2006; Serafica & Vargas, 2006) and the need to consider such diversity, broadly defined, in the assessment and treatment of disturbed children and families (Achenbach & Rescorla, 2006b; Forehand & Kotchick, 1996; Tharp, 1991).

13. Further attention to accountability in assessment and to the development of brief, feasible, and cost-effective assessment strategies (Hayes, 1996; Hayes, Follette, Dawes, & Grady, 1995). Such attention has been fueled by the growing concern for reducing costs within a rapidly changing health care delivery system (Mash & Hunsley, 1993; Strosahl, 1994).

14. Increased emphasis on the treatment evaluation functions of DSA in light of the current emphasis on evidence-based treatment practices (Barrett & Ollendick, 2004; Biglan, Mrazek, Carnine, & Flay, 2003; Buysse & Wesley, 2006; Hibbs & Jensen, 2005; Kazdin & Weisz, 2003; Mash & Barkley, 2006;

Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). This emphasis has led to heightened attention to the development of meaningful and practical measures for monitoring progress and assessing outcomes in clinical practice (Burlingame, Wells, Lambert, & Cox, 2004; Lambert et al., 2003; Nelson-Gray, 1996; Ogles, Lambert, & Masters, 1996).

It is apparent from this brief overview of developments over the past quarter of a century that current DSA approaches to child and family assessment are complex and varied. These approaches are best conceptualized within an assessment framework that examines the child's development and functioning in the context of the maturational stage of the biological and especially neurological systems, social systems, decisional processes, and practical considerations in which clinical assessments of disturbed children and families are typically conducted.

DEFINING DSA

We use the term "developmental-systems assessment" to describe a range of deliberate assessment strategies for understanding both disturbed and nondisturbed children and their social systems, including families and peer groups. These strategies employ a flexible and ongoing process of hypothesis testing regarding the nature of the problem, its causes, and likely outcome in the absence of intervention, and the anticipated effects of various treatments. It is our view that the generation of better hypotheses to test at the idiographic level can best proceed from an understanding of the general theories and principles of psychological assessment (e.g., Cronbach, 1990; Nunnally & Bernstein, 1994; Urbina, 2004); information concerning normal and abnormal child, and family development (e.g., Cicchetti & Cohen, 2006a, 2006b, 2006c; Mussen, 1983); and knowledge about groups of children and families with similar types of problems, including knowledge about prevalence, core symptoms, developmental features and course, associated characteristics, etiologies, and system parameters (Cicchetti & Cohen, 2006c; Mash & Barkley, 2003). This general view of DSA is reflected throughout the chapters in this volume.

DSA OF CHILD AND FAMILY DISTURBANCE: A PROTOTYPE-BASED VIEW

Rather than attempting to define DSA in terms of its necessary or essential features, we believe that a prototype-based view (e.g., Cantor, Smith, French, & Mezzich, 1980) best depicts the current state of the field. Within such a framework, the general category DSA is based on sets of imperfectly correlated features referred to as "prototypes" (Rosch, 1978). Assessment cases having the largest number of general category features are considered to be the most typical examples of DSA. The prototypical view also recognizes that within the more general category of DSA, there can exist a hierarchically but imperfectly nested set of sub-categories, such as "DSA with young children" or "DSA with adolescents." DSA may take many different forms depending on the specific parameters associated with different child and family problems. For example, the prototype for DSA with a 4-year-old child with an oppositional disorder is quite different than that for an adolescent with depression. This view is consistent with the relativistic, contextually based, and idiographic nature of DSA strategies, and with the organization of this volume around categories of commonly occurring childhood disorders.

In the points that follow, we use the prototype-based view to present some of the more commonly occurring conceptual, strategic, and procedural characteristics of DSA (Mash & Terdal, 1997a):

1. DSA is based on conceptualizations of personality and abnormal behavior that emphasize the child's thoughts, feelings, and behaviors as they occur in specific situations, as well as the child's more general personality traits and dispositions (e.g., temperament, psychopathy) (Mischel, 2004; Mischel, Shoda, & Mendoza-Denton, 2002).
2. DSA is predominantly idiographic and individualized. Although comparison to norms is important, a greater relative emphasis is given to understanding the individual child and family than to nomothetic comparisons that describe individual children primarily in relation to group norms.
3. DSA emphasizes the important role of situational influences on behavior. It is recognized that the patterning and organization of an individual's behavior across situations is highly

idiographic (Mischel, 1973); therefore, it is important to describe the child's behaviors, cognitions, and affects as they occur in specific situations. The pragmatic outcomes of an emphasis on situational specificity in DSA have been a greater sensitivity to the measurement of situational dimensions and a corresponding increase in the range of environments sampled; for example, information about home, school, and neighborhood environments has been added to samples of the child's and parent's behavior obtained under highly controlled and standardized testing conditions in the clinic.

4. DSA emphasizes both the consistency and variability of child and family behaviors, cognitions, and affects over time. Because situationally related changes appear to be the norm rather than the exception throughout childhood and adolescence, the predominant DSA view has emphasized the need to consider change, not just stability, particularly during transitional periods of development. That being said, it is important to recognize that consistency can be assessed in relation to many levels of behavior and, depending on the specificity of the behavior under consideration, different results may obtain. If a child's behavior is described in terms of a highly idiographic response topography (e.g., whining), then we may find little consistency over time. In contrast, definitions based on broader response classes that encompass a wide range and pattern of behaviors (e.g., aggression) both within and across age levels may evidence more temporal consistency. Furthermore, if we look at response functions rather than at specific topographies, we may find that phenotypically different responses reflect a dynamic stability in which certain patterns of adjustment are repeated over time. As stated by Garber (1984), "Although there is little evidence of homotypic continuity—symptomatic isomorphism from early childhood—there is some evidence that children may show consistency in their general adaptive or maladaptive pattern of organizing their experiences and interacting with their environment" (p. 34). This organizational-developmental viewpoint has been supported by findings from longitudinal studies of development, which have suggested that patterns expressed in early relationships often repeat themselves over time (Kaye, 1984; Sroufe & Fleeson, 1986). The type of child and family characteristic being assessed also has implications for the question of temporal stability. For

example, some characteristics may show stability over time (e.g., achievement motivation, dependence and passivity in females, serious aggressive behavior, and intellectual mastery), whereas others may not (Garber, 1984).

5. DSA is systems-oriented. It is directed at describing and understanding characteristics of the child and family, the contexts in which such characteristics are expressed, and the structural organizations and functional relationships that exist among situations, behaviors, thoughts, and emotions.

6. DSA emphasizes contemporaneous controlling variables relative to historical ones. However, when information about more temporally remote events (e.g., age of onset) facilitates an understanding of current influences, such information is sought and used in assessment. For example, knowing that a mother was physically or sexually abused as a child may help us understand her current attitudes and behavior toward her own child (Crooks & Wolfe, Chapter 14, and Wolfe, Chapter 15, this volume). Similarly, knowledge of early attachment patterns may assist us in understanding a child's current pattern of relational disturbance (Kobak, Cassidy, Lyons-Ruth, & Ziv, 2006).

7. DSA is more often concerned with behaviors, cognitions, and affects as direct samples of the domains of interest rather than as signs of some underlying or remote causes. For example, assessments focusing on a child's cognitive deficiencies, distortions, or misattributions target these characteristics as functional components of the problem to be modified rather than as symptoms of some other problem.

8. DSA focuses on obtaining assessment information that is directly relevant to treatment. Relevance for treatment usually refers to the usefulness of information in identifying treatment goals, selecting targets for intervention, designing and implementing interventions, and evaluating the outcomes of therapy (Carr, 1994; Mace, 1994).

9. DSA recognizes the importance of using multiple informants, including the child, parents, teachers, and peers, as a way to obtain information from different perspectives and settings. Because the data obtained from one source rarely correlate highly with those obtained from other sources, the assessor must be cautious to avoid considering any single source of information as the "gold standard," unless such a position is warranted based on research evidence.

10. DSA relies on a multimethod assessment strategy to capture the diverse aspects of most clinical problems. This approach emphasizes the importance of using a variety of assessment methods, including interviews, questionnaires, and observations (Kamphaus, Petoskey, & Rowe, 2000). However, the inherent value of one method over another is not assumed, but should be based on the purposes and needs associated with specific assessments (McFall, 1986), available resources, the utility of the information obtained, and what method is deemed most useful in a specific setting (Silverman & Ollendick, 2005).

11. DSA is an ongoing self-evaluative process. Instead of conducting assessments on one or two occasions prior to treatment, the need for further assessment is dictated by the effectiveness of the methods in facilitating desired treatment outcomes and the extent to which treatment goals are being met.

12. DSA is empirically anchored. The assessment strategies—in particular, the decision regarding which variables to assess—should be guided by knowledge concerning the characteristics of the child and family being assessed, and the research literature on specific childhood disorders. In the case of assessments that are theoretically driven, theories should be closely tied to empirical evidence. Similarly, decisions regarding the methods used in assessment are also based on their empirically established psychometric properties and their feasibility in relation to specific assessment purposes (Hunsley & Mash, in press).

COMMON ASSESSMENT PURPOSES

Inherent in the view of DSA as an ongoing problem-solving strategy is the recognition that assessments of children and families are always carried out in relation to one or more purposes. Along with the assessor's working assumptions and conceptualizations about normal and abnormal child and family behavior, these purposes determine which individuals, behaviors, and settings are evaluated; the choice of assessment methods; the way findings are interpreted; the specification of assessment and treatment goals; and how the attainment of these goals is evaluated. Questions surrounding the assessment of child and family disturbances can be considered only within the context of the intended assessment purpose(s). Therefore,

decisions regarding the appropriateness or usefulness of particular assessment methods and procedures are always made in relation to the needs of the situation. For example, discussions concerning the relative merits of information obtained via self-report versus direct observation have little meaning outside of a specific set of assessment contexts and purposes.

Many writers have outlined common purposes for which child and family assessments are conducted (e.g., Achenbach & Rescorla, 2006a; Mash & Terdal, 1997a). Broadly conceived, these include (1) diagnosis, or assessment activities focusing on formulating a diagnosis and identifying the nature of the problem; (2) prognosis, or generating predictions concerning future behavior under specified conditions; (3) case conceptualization and treatment planning, or the gathering of information that augments diagnostic information to yield a full clinical case conceptualization to assist in the development and implementation of effective interventions; (4) treatment monitoring and treatment outcome evaluation, or assessments that monitor progress during the course of treatment and evaluate the overall effect of treatment on symptoms, diagnosis, and general functioning, and the treatment's efficiency, acceptability, and satisfaction to consumers. Because these purposes are addressed in relation to each of the specific disorders in the chapters that follow, we comment on them only briefly here.

Diagnosis

The four purposes of assessment we mentioned earlier often occur in phases for individual cases. Initial diagnostic assessments are concerned with questions relating to general screening and administrative decision making (e.g., Can the child be appropriately served by a particular agency or educational program?); whether or not there is a problem (e.g., Does the child's behavior deviate from an appropriate behavioral or social norm?), and the nature and extent of the problem (e.g., What is the child doing or not doing that results in a distressed family or school situation, or impairment in the child's functioning?); and whether the presentation of the problem conforms to one or more categories of a diagnostic classification.

The term "diagnosis" has acquired several meanings (Achenbach, 1985). One of these,

taxonomic diagnosis, views diagnosis and classification as equivalent, and focuses on the formal assignment of cases to specific categories drawn from either a system of disorder classification such as the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; American Psychiatric Association [APA], 2000) or empirically derived taxometric categories, prototypes, or typologies (Achenbach, 1993). A second and much broader meaning of the term “diagnosis,” *problem-solving analysis* or *diagnostic formulation*, considers diagnosis to be an analytic information-gathering process directed at an understanding of the nature of a problem, its possible causes, treatment options, and outcomes. This broader meaning of “diagnosis” is the definition that is most consistent with the concepts and practices of DSA, although DSA also recognizes the utility of taxonomic diagnosis as an organizational framework for applying existing knowledge about a class of cases to a diagnostic formulation for a new case (Achenbach & Rescorla, 2006a; Kazdin, 1983; Mash & Terdal, 1997a; Powers, 1984).

The diagnostic phase within DSA is conducted with the expectation that, with further case formulation, assessment will lead directly to recommendations for subsequent clinical services. Questions often asked during the diagnostic phase of DSA include (1) What is the child doing, thinking, or feeling that causes distress, brings them into conflict with the environment, or impairs functioning? and (2) What are the potential controlling variables for these problems? DSA diagnoses are often highly individualized and based on direct empirical support. The methods employed during the early diagnostic phases of DSA tend to be global and extensive—they have been described as having broad bandwidth but low fidelity—and the use of interviews, global self-report instruments, observational narratives, and simple behavioral code systems is common.

Prognosis

Every child and family assessment carries with it some projection regarding short- and long-term outcomes for the child under varying conditions. Knowledge concerning risk and protective factors, and the likely outcomes for certain behaviors during later periods of development, is required for making judgments about deviance. Because many childhood problems are

not intrinsically pathological and are exhibited to some extent by most children, decisions regarding whether or not to treat the problem often depend on prognostic implications. Implicit in any decision about whether to initiate intervention is a projection that things will remain the same, improve, or deteriorate in the absence of treatment, or that outcomes will vary as a function of differing treatments. With children, treatments are often directed at enhancing developmental processes, not just removing symptoms or restoring a previous level of functioning. Information concerning developmental processes (e.g., emotion regulation) may also provide the basis for anticipatory interventions in high-risk situations in which the prognosis is known to be poor. A host of decisions is related to children’s mental health and the legal system for which information concerning prognosis is required, for example, assessments of suicide risk (Goldston & Compton, Chapter 7, this volume) or a parent’s ability to provide an adequate caregiving environment for their child (Crooks & Wolfe, Chapter 14, this volume).

Questions concerning prognosis are often considered in relation to longitudinal information, as derived, for example, from studies of risk or resilience in high-risk children (Luthar, 2006). For example, children with greater resources (e.g., intellectual ability, stable and supportive families) are generally more competent and show more adaptive patterns of dealing with stress (Masten, Burt, & Coatsworth, 2006). Although such findings can provide a basis for general predictions, their direct applicability to decision making for individual children and their families is not always clear. Studies of individual at-risk children who do well may provide suggestions as to the types of interventions that might be appropriate in high-risk situations.

Longitudinal studies of long-term outcomes for children with different types of disorders also provide information concerning prognosis. For example, the most persistent and pernicious types of conduct disorder are associated with a family history of antisocial behavior, early neuropsychological deficits, comorbid attention-deficit/hyperactivity disorder (ADHD), early onset and variety of antisocial and aggressive symptoms, callous-unemotional traits (deficient guilt, remorse, empathy, etc.), and poor family functioning (Dishion & Patterson, 2006; Moffitt, 2006).

Questions concerning prognosis are frequently raised early in the assessment process. However, such questions are also important following treatment to assess the likelihood that treatment gains will be maintained, especially when long-term maintenance for certain problems is known to be poor (e.g., aggression). The systematic assessment of maintenance of treatment effects in the child and family areas has received limited attention to date.

For many children, early problems that can have a severe and lasting negative impact need to be taken very seriously (e.g., Kendall, Hudson, Choudhury, Webb, & Pimentel, 2005). However, the identification of early problems also needs to be viewed with some caution, because the malleability of child behavior also means that for some children these problems may be reduced or even eliminated with treatment or other changes in children's environment.

Case Conceptualization and Treatment Planning

The case conceptualization and treatment planning phase of DSA focuses on obtaining information that is directly relevant to devising effective treatment strategies (Eells, 2007). This gathering of information builds on the previously obtained diagnostic information, and includes further specification and assessment of potential controlling variables (e.g., cognitive distortions or misattributions, patterns of social rewards and punishments), determination of the child's and family's resources for change (e.g., strengths, self-regulatory skills), assessment of potential social and physical resources that can be used in carrying out treatment, assessment of motivation for treatment and readiness for change in both the child and significant others, indication of potential reinforcers, specification of realistic treatment objectives, and recommendations for types of treatments that are likely to be most acceptable and, based on the evidence, most effective for treating specific types of childhood problems. Since parental adherence to treatment recommendations following assessments may be low, it is also important to assess factors that contribute to nonadherence, for example, discontinuity in care, long wait times, or a lack of readiness for change (Geffken, Keeley, Kellison, Storch, & Rodrigue, 2006).

The assessment procedures that characterize this phase are more problem-focused than

those in the diagnostic phase, and specific types of problem checklists (e.g., fear survey schedules, measures of hyperactivity-impulsivity, depression inventories, impairment surveys), observational assessments (e.g., command-compliance analogues), and specific behavior codes (e.g., on-task behavior, self-stimulation, aggression) are more likely to be used in this phase than in earlier stages of assessment.

Treatment Monitoring and Treatment Outcome Evaluation

The treatment monitoring and treatment outcome evaluation phase of DSA involves the use of procedures designed to determine whether treatment objectives are being met, whether changes that have occurred can be attributed to specific interventions, whether the changes are long-lasting and generalizable across behaviors and situations, whether the treatment is economically viable, and whether treatments and treatment outcomes are acceptable to the clients.

Assessments for determining whether treatment goals are being met require the measurement of targeted objectives over time. Such measurement indicates the presence or absence of change, which in many cases may be sufficient. However, to determine whether changes are a function of the treatments introduced for individual children and families, it is necessary to observe in a controlled fashion, for example, by using a single-case research design (Freeman & Mash, in press). Although such designs can be extremely useful from a research standpoint, a key question concerns their feasibility in clinical practice and their adequacy in representing the often complex system parameters and relationships that characterize treatment goals in current, evidence-based treatment practices with children and families (Mash & Barkley, 2006).

Evaluations relative to the acceptability of treatments and relevance of treatment changes have been discussed under the rubrics of social validity (Foster & Mash, 1999; Kazdin, 1977; Wolf, 1978), treatment acceptability (Kazdin, 1981, 1984), consumer satisfaction (Kiesler, 1983; LeBow, 1982; McMahon & Forehand, 1983), and clinical significance (Atkins, Bedics, McGlinchey, & Beauchaine, 2005; Kendall, 1999). Such issues are especially pertinent to interventions for children, which must be gauged against ongoing or projected develop-

mental changes. Measurement issues surrounding long-term follow-up are also highly relevant to DSA (Mash & Terdal, 1980). The methods used during the evaluation phase of assessment tend to be highly focused, brief, and specific in comparison to those in earlier assessment phases. The need for reliable, valid, and cost-efficient measures of treatment outcome is becoming increasingly important in the current health care context in which services for children and families are being provided (Daleiden, Chorpita, Donkervoet, Arensdorf, & Brogan, 2006).

The purposes described thus far relate to clinical decision making for individual children, which is characteristically the focus of DSA. There is also a need to recognize that broader societal and institutional purposes often underlie assessment practices with children and families, including classification for administrative record keeping, program development and evaluation, policy planning, quality assurance, and the advancement of scientific knowledge. The types of assessments required to meet these purposes may differ substantially from those required for the clinical assessment of individual children and families.

CHILDREN'S FUNCTIONING AND ITS DETERMINANTS

Childhood Disorders versus Individual Symptoms or Behaviors

The chapters in this volume are organized around the assessment of specific childhood disorders. This organization reflects our view that children and families present themselves for assessment showing characteristic patterns, clusters, or constellations of problems rather than individual symptoms or behaviors (Mash & Dozois, 2003). Both clinical and empirical evidence indicate that broad patterns of child disturbance labeled *externalizing* (e.g., aggression, rule-breaking behavior) and *internalizing* (e.g., anxious-depressed, withdrawn-depressed, somatic complaints) are relatively stable over time and across raters (Achenbach & Rescorla, 2001). For this reason, we believe that assessment best follows an empirically based understanding of characteristic *patterns* of behavior, adjustment, and maladjustment (Kazdin & Kagan, 1994). As a first step in the assessment process, all clinicians engage for-

mally or informally in the identification of behaviors, cognitions, and emotions that cluster together (Barlow, 1986).

We concur with Kanfer's (1979) view that "different problem areas require development of separate methods and conceptualizations that take into account the particular parameters of that area" (p. 39), and that assessment of certain domains may be impeded until conceptual models or data are available to identify the symptoms and associated features that need to be assessed. Empirically derived conceptual models to guide assessments of child and family disorders in both clinical and research contexts are emerging at a rapid rate (see Mash & Barkley, 2003; Mash & Hunsley, 2005a). One of the best-articulated, theory-driven, empirically based models for assessment is represented by Patterson's (1982) work with children and families exhibiting antisocial problems. Through the use of multiple methodologies and statistical methods such as structural equation modeling, a number of important constructs and their relationships have been implicated in the development of children's antisocial behavior (Dishion & Patterson, 2006; Patterson, 1986; Patterson & Bank, 1986). This work suggests the importance of assessing several molar and micro-variables when working with antisocial children and their families (e.g., whether the child is rejected or perceived as antisocial by others; the likelihood of the child's unprovoked negative behavior toward parents and siblings, and its duration; the extent to which parents monitor their children and spend time with them; the parents' inept discipline, as reflected in their use of explosive forms of punishment, negative actions and reactions, and inconsistent/erratic behavior; and deviant peer influences). Building on this database, recent models of antisocial behavior have incorporated additional variables (e.g., social-cognitive and emotional processes) that serve to guide assessments of children and adolescents with conduct problems (Dodge & Pettit, 2003). Each chapter in this volume provides one or more conceptual models and an empirical base for the specific disorder under discussion, and the assessment strategies that are presented follow from this framework.

In specifying constellations of problems or "syndromes" as a basis for one's assessment strategies, it is important to recognize that syndromes can be viewed in a number of differ-

ent ways (Achenbach & Edelbrock, 1978, p. 1294):

1. The syndrome may be viewed as representing a personality or character type that endures beyond the immediate precipitating events requiring professional attention.
2. The syndrome may be viewed as reflecting dimensions or traits, so that children are best described individually in terms of their scores on all syndromes rather than by categorization according to their resemblance to a particular syndrome.
3. The syndrome may be viewed as a reaction type, whose form is as much a function of specific precipitating stresses as of individual characteristics.
4. The syndrome may be viewed as a collection of behaviors that happen to be statistically associated because the environmental contingencies supporting them are statistically associated.

These different views are all consistent with the assumptions underlying DSA, and they are not necessarily independent of one another. It may be that reaction types that become well established early in development eventually emerge as enduring, but not necessarily irreversible, character types. For example, research has suggested that preferential orientations toward others, self, and the object world when confronted with interactive stress may be exhibited by infants as young as 6 months of age (Tronick & Gianino, 1986).

The concept of syndromes in DSA with children and families is also represented by the concepts of *response class* and *response covariation* (e.g., Kazdin, 1982, 1983; Voeltz & Evans, 1982; Wahler, 1975). These notions imply that certain behaviors tend to co-occur, or to be correlated with one another, and/or that certain behaviors tend to covary, such that changes in one are associated with changes in the other. Research into response covariation has suggested indirect paths of clinical intervention—for example, when decreases in a child's noncompliant behavior lead to a reduction in bedwetting (Nordquist, 1971) or stuttering (Wahler, Sperling, Thomas, Teeter, & Luper, 1970). The existence of such response classes has important implications, in that assessment of these relationships may suggest maximally effective courses of intervention.

Although an extensive discussion of the many issues surrounding the concepts of response class and response covariation is beyond the scope of this chapter, several important questions need to be addressed before these concepts can have widespread applicability in the DSA of children and families.

1. First, there is currently little information as to how to identify response classes. Potential response classes have been derived via serendipitous discovery, from clinically described syndromes, from conceptual models or theories about child and family disorders, from statistical methods for grouping data, and through systematic functional analysis. In light of the potentially enormous number of topographically dissimilar responses that could be related, guidelines are needed for limiting the number and range of responses to be assessed.

2. Response class representations are miniature systems, and guidelines are needed for mapping out the structural organizations and functional relationships that describe a particular response class, as well as its relationships to other systems. In this context, discussions and findings relative to the comorbidity of childhood disorders (i.e., the tendency for children to meet diagnostic criteria for multiple disorders) are relevant to understanding relationships among different response classes (e.g., Caron & Rutter, 1991; Youngstrom, Findling, & Calabrese, 2003).

3. Although the focus in DSA has been on "response" classes, we are more often talking about constellations of responses, cognitions, emotions, and physiological reactions. The more varied and complex response classes become, the more they seem to approximate descriptions of clinical disorders as presented in current diagnostic systems.

4. Are response classes to be defined idiosyncratically for each child who is assessed, or can we expect them to have some generality across children?

5. The relationship between response classes and situations has received little attention (Wahler & Graves, 1983). Can we expect response classes to be situation-specific, as some research has suggested (Patterson & Bechtel, 1977), or will some response clusters show generality across situations?

6. Most discussions of response classes have focused on the individual. However, it would be equally feasible to identify response clusters

for more complex social units—for example, parent–child dyads, siblings, couples, or the family.

Although these issues are in need of further investigation, research on response covariation has sensitized assessors to the fact that consideration of only a narrow range of symptoms and behaviors fails to represent adequately the more general network of behaviors, of which this behavior may be a part, or the fact that this network of behaviors may be functionally embedded in larger social systems.

As presented in this volume, the DSA view of child and family disorders focuses on common patterns of behavior and behavior–context disturbances. Rather than emphasizing the use of assessment methods per se, these methods are considered primarily in relation to the specific problems and contexts in which they are to be used. For example, although there are general principles associated with the development and use of particular assessment methods, the nature of an interview with the parent of a depressed child should be different than an interview with the parent of a child with autism. It is believed that an understanding of the specific parameters associated with childhood depression (Rudolph & Lambert, Chapter 5, this volume) or with an autistic disorder (Ozonoff, Goodlin-Jones, & Solomon, Chapter 10, this volume), in concert with knowledge about the general principles of interviewing (e.g., Sattler, 1998), will serve to generate more specialized and ultimately more useful assessments for children experiencing these types of problems.

Impairment in Functioning versus Symptoms and Disorders

In addition to assessing the characteristic patterns of behavior associated with specific childhood disorders, it has become increasingly apparent that assessment of the degree of impairment in children's functioning is essential to defining and understanding their problematic behavior (Jensen, Hoagwood, et al., 2006; Kazdin, 2005). Symptoms and specific impairments are not necessarily highly correlated. Many children who show considerable impairment may not meet the symptom criteria for having a problem and, as a result, may not receive the intervention they clearly need (Angold, Costello, Farmer, Burns, & Erkanli, 1999; Gordon et al., 2006). Similarly, symptom

reduction during treatment does not necessarily correlate with overall improvement in functioning. Thus, the assessment of functional impairment, in addition to symptoms and disorders, is important in determining the impact of the disorder, identifying treatment goals and service needs, and monitoring outcomes. A number of scales designed to assess a child's impairment in functioning may be used for these purposes (Winters, Collett, & Myers, 2005).

Classification and Diagnosis

One of the more controversial areas in the assessment and treatment of disturbed children and families has been the use of diagnostic labels based on global classification systems. Although diagnostic criteria for children have become increasingly differentiated and specific, many concerns remain regarding classification and diagnosis. Over the decades, the same labels have been used to describe different sets of clinical phenomena (Zachary, Levin, Hargreaves, & Greene, 1981), and different labels have been used to describe the same clinical disorder (e.g., hyperactivity, hyperkinesis, attention deficit disorder, ADHD) (Barkley, 2006). Systems for the classification of childhood disorders have received extensive discussion that has increased since the appearance of DSM-III, which included an increased number of child categories (APA, 1980).

There is some agreement regarding the general neglect of meaningful taxonomic frameworks for describing children and families, and the need for classification systems to guide theory, research, and practice. For example, Achenbach and Edelbrock (1978) stated that “the study of psychopathology in children has long lacked a coherent taxonomic framework within which training, treatment, epidemiology, and research could be integrated” (p. 1275). Despite their increased use, all classification systems that have emerged thus far have met with criticism. For example, as Nathan (1986) stated, “For the most part, when more effective treatments have been developed or more light has been shed on etiology, it has not been by virtue of one or another classification scheme that this has come about” (p. 201).

Although DSA acknowledges the need for a classification system of child and family disorders, including widely accepted systems such as DSM-IV-TR (APA, 2000), there continues to be dissatisfaction with the currently available ap-

proaches (Doucette, 2002; Kupfer, First, & Regier, 2002; Watson & Clark, 2006). These dissatisfactions with existing classification systems have centered around their lack of fit with many real-world patients, who often present with clusters of symptoms that cross multiple diagnostic categories; empirical inadequacies; their primarily descriptive and relatively atheoretical nature; the complexity of using the system in clinical practice; the subjective–impressionistic criteria used to derive individual categories; the failure to provide empirically derived operational criteria for assignment to categories; the heterogeneity that exists within diagnostic categories; the static nature of the categories when applied to the developing child; the use of diagnostic criteria that are not adjusted for the child’s age or sex; the lack of demonstrated relevance for treatment; the potentially undesirable consequences of labeling; a lack of sensitivity to contextual influences, including the role of ethnicity and culture; and a general insensitivity of diagnostic criteria to the relational difficulties that characterize children and families (Beach, Wamboldt, Kaslow, Heyman, & Reiss, 2006; LeBow & Gordon, 2006).

An alternative to current classification schemes has yet to emerge despite these criticisms and the long-standing recognition of the need for alternatives (Adams, Doster, & Calhoun, 1977; Adelman, 1995; Hayes & Follette, 1992; Jensen, Knapp, & Mrazek, 2006). The seeming lack of progress in this area likely reflects the many challenges in developing a viable alternative that would address the aforementioned dissatisfactions, as well as the increasing priority given to the development of evidence-based treatment practices. It is not clear that the development of global classification systems for childhood disorders will do much to facilitate effective intervention at the level of the individual child (cf. Pelham, Fabiano, & Massetti, 2005), although such systems might potentially improve communication, combine data from diverse sources, epidemiological studies, and comparison treatments, and increase understanding of causes (Kessler, 1971).

Efforts to classify childhood disorders have followed several traditions. The first involved the development of clinically derived classification categories based mostly on subjective consensus, as characterized by the systems developed by the Group for the Advancement of

Psychiatry (1974), the World Health Organization (1992), the Zero to Three/National Center for Clinical Infant Programs (1994) and Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood (DC:0–3R) Revision Task Force (2005), and the American Psychiatric Association (1980, 1987, 1994, 2000). Although it is beyond the scope of this chapter to review these systems in detail (see Achenbach, 1985; DelCarmen-Wiggins & Carter, 2004), commonly occurring categories are exemplified by those provided in DSM-IV-TR (APA, 2000). These disorders of infancy, childhood, and adolescence include ADHD; disruptive behavior disorders such as oppositional defiant disorder and conduct disorder; feeding and eating disorders such as pica, rumination disorder, and feeding disorders of infancy and childhood; tic disorders such as Tourette’s disorder and chronic motor or vocal tic disorder; elimination disorders such as enuresis and encopresis; separation anxiety disorder; selective mutism; reactive attachment disorder, and stereotyped movement disorder. Also included in DSM-IV-TR are developmental and learning disorders such as mental retardation; learning disorders in reading, mathematics, and written expression; developmental coordination disorder; communication disorders such as expressive language disorders, mixed receptive–expressive disorders, language disorder, phonological disorder, and stuttering; and pervasive developmental disorders, including autistic disorder, Rett’s disorder, childhood disintegrative disorder, and Asperger’s disorder. In addition, many other diagnostic categories for anxiety, mood, and substance use disorders, and relational disturbances used for adult diagnoses are also used for children, with minor modifications in symptom criteria or duration. DSM-IV-TR criteria for assignment to specific categories are presented throughout the chapters of this volume. Generally these criteria include the presence of a specified number of symptoms; a minimum time period during which the specified symptoms must be present; developmental inappropriateness of those symptoms; age or age-of-onset criteria; exclusionary criteria, if the problem is secondary to other disorders; and impairment in functioning.

In recognizing that a simple enumeration of symptoms may not be sufficient for treatment planning or predicting individual outcomes, DSM-IV-TR also provides a multiaxial classifi-

cation scheme that includes clinical disorders and other conditions that may be a focus of clinical attention (Axis I); personality disorders and mental retardation (Axis II); general medical conditions (Axis III); psychosocial and environmental problems (Axis IV); and global assessment of functioning (Axis V). However, only the first three axes constitute an official diagnostic evaluation, and the amount of differentiation for Axes I and II is disproportionately large when compared with that for Axes IV and V. In addition, although clearly important, Axes IV and V presently have limited or undetermined reliability or validity (Goldman & Skodol, 1992; Van Goor-Lambo, 1987).

Efforts to increase the accuracy and reliability of psychiatric diagnoses have resulted in the development of a number of semistructured and structured interview protocols for obtaining information to assist in making a diagnosis. Many of these are described in the chapters that follow. There has been an increase in the use of these procedures for the identification of groups of children in assessment and treatment outcome studies, and to a lesser extent clinically. In this context, accurate DSM-IV-TR diagnoses offer some direction regarding the range of behaviors/symptoms, settings, and associated features that might then be assessed clinically in a more intensive idiographic fashion (Powers, 1984). It is likely that until assessors are willing, able, and provided with the incentives to invest the time and resources needed to develop and promote a more empirically based classification alternative to DSM-IV-TR and its successor DSM-V (anticipated to appear in 2011) (Kupfer et al., 2002), administrative requirements, the need to communicate with other professionals, and the need for a taxonomy to direct and organize research and clinical activities will all contribute to the use of DSM diagnoses as an important component of DSA with children and families. At present, there is simply no readily available alternative (First, 2005).

A second major approach to the classification of childhood disorders is an empirical one, involving the use of multivariate statistical methods such as factor and cluster analyses (Achenbach, 1993; Achenbach & Rescorla, 2001; McDermott & Weiss, 1995; Reynolds & Kamphaus, 2004). This approach assumes that there are a number of independent dimensions of behavior (i.e., traits), and that all children possess these sets of behavior to varying

degrees. In contrast to classification approaches that use clinically derived categories of childhood disorder, the dimensional approach focuses on empirically derived categories of behavioral covariation. Although empirically derived classifications are more objective and potentially more reliable, they also possess associated problems. No classification system can be better than the items that comprise it, and, as noted by Achenbach (1985), "subjective judgment is involved in selecting the samples and attributes to be analyzed, the analytic methods, and the mathematical criteria" (p. 90). Other concerns that need to be addressed include (1) possible interactions between the methods of data collection (e.g., ratings, direct observations, questionnaires), the informants (e.g., parents vs. teachers), or characteristics of the sample (e.g., ethnicity), and the dimensions that emerge, and (2) the lack of sensitivity of global trait dimensions to situational influences (e.g., duration of the disorder, setting in which behavior is rated, when the ratings are made).

Multivariate studies are consistent in identifying two broad dimensions of child behavior labeled "externalizing" and "internalizing." More specific syndromes that have been verified via confirmatory factor analysis include aggressive behavior and rule-breaking behavior (externalizing dimension), anxious-depressed, withdrawn-depressed, somatic complaints (internalizing dimension), and attention problems, thought problems, and social problems (Achenbach & Rescorla, 2001).

Much of the recent impetus for the development of multivariate classification approaches in child and family assessment comes from the extensive work of Achenbach and his colleagues with the Child Behavior Checklist and profile (Achenbach, 1991) and the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2000, 2001). It is not possible here to do justice to the scope and magnitude of this work and the research it has generated (for a detailed discussion of this approach, see Achenbach, 1985, 1993; Achenbach & Rescorla, 2001). Briefly, Achenbach describes a number of advantages associated with utilizing a taxometric integration of prototypical syndromes, in which an individual child may be classified on the basis of the similarity of his or her profile of syndrome scores with the centroid of each previously derived profile type. Beginning with the rationale that

child syndromes consist of imperfectly correlated features, the argument is made that a prototype-based view of classification is preferable to one that employs the assignment of individuals to categories based on the presence of a small number of essential or cardinal features. Although it has been recognized that the conceptual derivation of prototypes for syndromes is possible (e.g., Horowitz, Post, French, Wallis, & Siegelman, 1981; Horowitz, Wright, Lowenstein, & Parad, 1981), operational definitions of prototypical syndromes are ideally generated via multivariate statistical analyses. It is argued that the use of quantitative indices, standardized assessment data, and computerized data processing permit the integration of large and complex datasets, reduce the likelihood that information-processing biases influence clinical judgments, and enable the clinician to focus on other, not easily standardized aspects of assessment and treatment.

As reflected throughout this volume, the use of multivariate assessment procedures in the DSA of children and families has increased considerably (e.g., Reynolds & Kamphaus, 2002, 2004) and is a reflection of the increasing availability and relative ease of use of these procedures, the accumulation of evidence for their validity in relation to a variety of assessment purposes, and a growing interest in child and parent perceptions as mediators of behavior and behavior change. Many of the criticisms of the multivariate approach from a DSA perspective have been based on dissatisfaction with the often global and ambiguous content being assessed, the fact that information is heavily based on subjective reports, and the general lack of sensitivity to situational influences. However, these criticisms are not inherent to the approach per se, because it is quite possible to derive “syndromes” that are based on other theories, have different contents, employ other methods, and sample a broader range of settings than is currently the case. Conceivably, syndromes of reaction types specific to particular situations (e.g., profiles of reaction types to stressful family events, social confrontation, medical procedures, or academic tasks) may also be derived.

More serious criticisms of the multivariate strategy within a DSA framework is its nomothetic emphasis on comparisons between an individual child and some group norm, and the limited relevance of this approach in the design of treatment strategies for individual children

(Peterson, 1968). Despite these criticisms, current DSA has integrated standardized multivariate assessments into clinical practice in formulating treatment goals—for example, in cases where the parent’s perceptions indicate that the child is deviant, but observations of the child’s behavior suggest otherwise (e.g., Mash, Johnston, & Kovitz, 1983)—and as one outcome measure for assessing the impact of treatment on parent and teacher perceptions of the child’s behavior.

A third approach to classification follows from a developmental perspective on child psychopathology. Although this perspective is often adopted in clinical practice, it has not had a significant impact on formalized diagnostic practices with children. For example, many of the DSM-IV-TR categories for children are simple extensions of those used to categorize adults, with minor changes to adjust for developmental level, and the focus of the multivariate approaches has been on the categorization of individual behaviors and traits rather than on the patterns of adaptation that characterize different periods of development. The classification system for children from birth to 3 years has a strong developmental emphasis but has not, as yet, been systematically evaluated in research or clinical practice (DC:0–3R Revision Task Force, 2005; Lieberman, Barnard, & Wieder, 2004).

In an insightful developmental perspective on classification, Garber (1984) outlined many of the complexities and challenges that underlie this approach. Central to this view is the need to assess children’s levels of functioning within different developmental domains (e.g., emotional, cognitive, social, physical) and their patterns of coping in relation to major developmental tasks (e.g., regulation of biological functions, attachment, dependence, autonomy, self-control, conformity to rules). Children are diagnosed in relation to their successes or failures in negotiating normative developmental expectations and demands, and it is believed that diagnostic models should emphasize adaptations and organizations of behavior at various developmental levels, rather than static traits, signs, or symptoms.

A developmental perspective is quite consistent with the emphasis in DSA on describing children’s reactions in relation to situational demands, but it presents some formidable challenges in practice, not the least of which are mapping out and defining “normative” devel-

omental sequences and creating a relevant taxonomy of developmental tasks. Longitudinal studies in child development and developmental psychopathology provide a rich database from which to assess and classify developmental adaptations during the first few years of life, and more recently, during middle childhood and adolescence. This database increases the promise of a developmentally anchored classification system, although this promise is still a long way from being realized. Nevertheless, a developmental perspective on classification, and developmental models more generally, are an integral part of DSA with children and families.

The classification systems we have discussed thus far, especially DSM-IV-TR and the multivariate approaches, have tended to focus exclusively on the child. They are derived from models that generally view disorders as residing in the child rather than in the ongoing and reciprocal interactions between the child and her or his larger social system. However, individual symptomatic and diagnostic variables are limited in characterizing children's mental health outcomes in the absence of information about the child's larger social context, including peer and family relationships; home, school, and neighborhood environments; and cultural and societal factors (Achenbach & Rescorla, 2006; Hoagwood, Jensen, Petti, & Burns, 1996). Classification models for describing larger social systems, such as the parent-child dyad (Egeland & Sroufe, 1981), sibling relationships (Ellis & DeKeseredy, 1994), the marital relationship (Weiss & Margolin, 1986), and the family (Mash & Johnston, 1996a; Mink, Meyers, & Nihara, 1984; Mink, Nihara, & Meyers, 1983), are available but rarely used in clinical settings. It is believed that these types of classification approaches have the potential to incorporate DSA emphasis on contextual influences into our diagnostic practices. Similarly, there continues to be an enormous need in assessments with children and families for the development of taxonomies that describe situations (Mischel, 1977; Schlundt & McFall, 1987). Most assessment procedures continue to focus on individuals, and the degree of measurement sophistication achieved in describing the situations in which children and families function is still quite primitive, often reflecting global topographical features of the setting, such as home versus school. Elaborated classification schemes that reflect the differentiation

that occurs within settings are needed, and previous work on the ecological assessment of environments should provide some direction in this regard (e.g., Vincent & Trickett, 1983). For example, the Classroom Environment Scale (Moos & Trickett, 2002) examines classroom environments in terms of relationship (e.g., involvement, affiliation, teacher support), personal growth (e.g., task orientation, competition), and system maintenance and change (e.g., order and organization, rule clarity, teacher control, innovation).

On a final note, some efforts have been made to integrate categorical and dimensional approaches in DSA through the development of DSM-oriented scales based on items from multivariate scales judged by expert mental health professionals to be consistent with DSM-IV-TR diagnostic categories (Achenbach & Rescorla, 2001). In addition, there have been discussions regarding possible ways to incorporate multivariate approaches into future revisions of the DSM (First, 2006). The view at this time seems to be that this may likely occur with respect to Axis II personality disorder categories (see Shiner, Chapter 17, this volume), but not Axis I clinical disorder categories (Watson & Clark, 2006). Finally, another alternative may be to give up the notion of one all-encompassing diagnostic system in favor of the idea that different systems of classification may be needed for different purposes, for example, in relation to meeting clinical versus research needs, or for different clinical assessment purposes (e.g., diagnosis vs. case formulation).

Outcomes of Labeling Children

Much has been written about both positive and negative aspects of assigning diagnostic labels to children. On the positive side, it is argued that labels help to summarize and order observations; facilitate communication among professionals with different backgrounds; guide treatment strategies in a global fashion; put clinicians in touch with a preexisting, relevant body of more detailed research and clinical data; and facilitate etiological, epidemiological, and treatment outcome studies (Rains, Kitsuse, Duster, & Friedson, 1975). On the negative side are criticisms regarding how effective current diagnostic labels are in achieving any of the aforementioned purposes, and concerns about the negative effects of assigning

labels to children (Hinshaw, 2006). Possible negative effects include how others perceive and react to the children (Bromfield, Weisz, & Messer, 1986), and how the labels influence children's perceptions of themselves and their behavior (Guskin, Bartel, & MacMillan, 1975).

The most important outcomes associated with the labeling of disturbed children may not be the ones associated with labeling or diagnosis by professionals. Rather, the informal labeling processes surrounding child and family behavior, and the interpretations of formal labels by parents, teachers, peers, and children themselves are likely to have the greatest impact (e.g., Coie & Pennington, 1976; Compas, Friedland-Bandes, Bastien, & Adelman, 1981; Dollinger, Thelan, & Walsh, 1980). Further study and assessment of the general beliefs and everyday cognitions of parents and teachers, how parents and teachers use labels to organize their experiences with both normal and disturbed children, and how such labeling influences their responses to and feelings about children are likely to increase our understanding of child and family disturbances (Sigel, McGillicuddy-DeLisi, & Goodnow, 1992). Several lines of research that appear promising in this regard include studies that have examined labeling and attribution processes in parents of disturbed and nondisturbed children (Bugental & Johnston, 2000), and those that have looked at "parents as problem solvers" in common, but demanding, childrearing situations (e.g., crying, noncompliance, refusal, trips to the supermarket) (Holden, 1985a, 1985b). Labeling is a prepotent human response, and there is a need to find methods to assess the usual ways in which those interacting with the children organize child behaviors. In identifying the types of labels used, the conditions under which they are used, and the effects associated with their use, it is likely that we will need to consider the unique characteristics of the interactants, as well as those universal processes that characterize humans as information processors (Kanfer, 1985).

Etiological Assumptions Regarding Childhood Disorders

Several important points concern the relationship between DSA and etiological assumptions about childhood disorders:

1. The first point concerns multiple causality. Given that the child is embedded in a complex and changing system, it is likely that many potentially relevant controlling variables contribute to the problem and need to be assessed, including physical and social-environmental events, and intraorganismic variables of both a neurobiological and a cognitive nature.

2. No a priori assumptions are made regarding the primacy of controlling variables that contribute to child and family disorders. This view rejects particular sets of controlling variables as being more important than others (e.g., physical vs. social causes) either contemporaneously or historically, and is intended to counteract the popular belief in many child assessment and treatment settings that the identification of malfunctioning physical systems through medical examination, neuropsychological testing, or historical information somehow provides a more fundamental explanation for the child's problems. Such an analysis is both incomplete and inaccurate, because it gives greater weight to physical causes in explaining child behavior and ignores potential psychosocial and environmental influences of equal or greater importance.

3. Although no assumptions are made in DSA regarding the primacy of etiological influences, primacy may be given to certain variables when they are suggested by data, or because of their methodological or practical feasibility. Variables that are observable, easily measured, and readily modified may become the focus for assessment when such an approach facilitates remediation of the problem.

4. It is assumed that there is an ongoing and reciprocal interaction among relevant controlling variables, so that attempts to identify *original* causes in assessment are not likely to be fruitful. Putative causes that occur earlier in development (e.g., birth injury or social deprivation) are important, but they are not assumed to be more significant contributors to the child and family's difficulties than contemporaneous physical and social processes.

5. The processes by which relevant controlling variables for most deviant child and family behaviors exert their influence are assumed to be similar and often continuous with those for nondeviant behavior. Principles related to basic biological and social processes are equally applicable in understanding both deviant and nondeviant behavior.

6. Although controlling variables that are contemporaneous and situationally present are frequently emphasized as important influences in DSA, there is also the need to consider both extrasituational and temporally more remote events. For example, stressors such as marital discord have a direct impact on a mother's immediate reaction to her child's behavior (Davies & Cummings, 2006). Passman and Mulhern (1977) have shown that a mother's punitiveness toward her child increases with the amount of external stress to which she is exposed, and Wahler (1980) has reported an inverse relationship between contacts with people outside the family and child behavior problems. Children's behaviors *in situ* represent only one contributor to parental reactions (e.g., Mash & Johnston, 1983), which may be influenced by not only external factors of the types just mentioned (Dunst & Trivette, 1986) but also the general rules, strategies, and propositions that parents apply in interacting with their children (Dix & Ruble, 1989; Geller & Johnston, 1995; Lytton, 1979). These influences may explain why treatment-related changes in children's behavior do not necessarily lead to changes in parental perceptions or reactions to their children.

DIMENSIONS OF DSA

One of the most salient characteristics of developing children is the active interplay that takes place between each child and her or his biological makeup, physical and social environments, and the cultural milieu into which the child is born. Guided by genetic endowment and maturation, relentlessly striving to understand the surrounding physical realities and social expectations, the child is nurtured, shaped, and socialized. No passive partners in this dialogue, children in turn shape their social world, and set their own expectations and demands (Bell & Harper, 1977; Emery, Binkoff, Houts, & Carr, 1983). This developmental engagement is characterized by conflict and equilibrium in the physical, cognitive, emotional, and social domains, and almost always by quantitative and qualitative movement and change. Any assessment of children and families must begin with recognition of the ebb and flow of this developmental dialogue, because it has critical implications for the manner in which child behaviors

are conceptualized, measured, classified, diagnosed, modified, and evaluated. The recognition that child and family behaviors are embedded within normative developmental sequences guided by organizational principles, and that they occur within a nested hierarchical context of interacting micro- and macrosocial influences (Bronfenbrenner, 1986; Cicchetti, 2006), necessitates a view of DSA that reflects both the uniqueness and the multidimensionality of children. This view leads to a number of important generalizations regarding assessment:

1. Developing children represent a unique population that requires special assessment considerations of a conceptual, methodological, and practical nature.

2. The assessment of childhood disorders necessarily involves normative judgments as to what constitutes (a) developmental deviation, (b) performance variation in relation to an appropriate reference group, (c) developmentally appropriate adaptation to a range of situational demands, and (d) unexpected deviation from a projected course of individual development. Of necessity, judgments usually include comparisons of a child with both group and self-referent norms.

3. Assessment of children and their families invariably involves multiple targets, including somatic and physiological states, behaviors, cognitions, and affects.

4. Given the large number and variety of factors at the individual and systems levels implicated for most child and family disorders, decision rules are needed for the selection of meaningful targets for assessment and intervention (Evans, 1985; Mash, 1985). When one considers the potentially infinite number of variables and their interactions that *could* be assessed in disturbed family systems, it is clear that evidence-based decision rules are needed to determine what factors *should* and *should not* be assessed, and by what methods.

5. The situations in which children function are varied and include family, day care, school, formal and informal peer groups, and other neighborhood and community settings. Embedded within each of these global settings are numerous subsettings. In light of this, multi-situational analysis is the rule in DSA, and one of the tasks of assessment is to determine which aspects of the child's functioning are unique to

specific contexts, and which occur across situations.

6. The pervasiveness of developmental change and situational variation in children suggests the need to assess patterns of behavior over time, as well as more global situational consistencies, in the family, neighborhood, community, and culture.

Special Considerations in Assessing Children

Although the assessment of children has much in common with the assessment of adults, numerous conditions and constraints are associated with assessing children are not ordinarily encountered when assessing adults, including many unique ethical and legal concerns (e.g., Koocher & Rey-Casserly, 2003; McGivern & Marquart, 2000; Melton, Ehrenreich, & Lyons, 2001; Rae, Brunnquell, & Sullivan, 2003). The uniqueness of child assessment follows from generalizations about children as a group, characteristics of children and their contexts during different periods of development that may interact with the types of assessments being conducted, and common features of situations in which children ordinarily function and in which they are assessed.

Rapid and Uneven Developmental Change

With respect to generalizations about children as a group, a noteworthy characteristic is their rapid and uneven developmental change (Evans & Nelson, 1977). Such change has implications for judgments concerning child deviance and the selection of appropriate methods of assessment. Studies have described both the age trends for many child behaviors and ways in which the social significance and meaning of a problem may vary with the age of the child (e.g., Achenbach & Edelbrock, 1981; Achenbach, Howell, Quay, & Conners, 1991). Many behaviors that are common at an earlier age are considered inappropriate in an older child (e.g., noncompliance, tantrums). Some childhood problems, for example, some types of antisocial behavior, suggest a pattern of “arrested socialization” (Patterson, 1982).

Developmental deviation has been defined empirically in relation to a variation from observed behavioral norms for children of a similar age and gender (Achenbach & Edelbrock, 1981); theoretically, either in terms of a deviation from some expected behavioral pattern

characteristic of particular stages of cognitive or psychosexual development (Santostefano, 1978); or in terms of the child’s failure to reorganize his or her behavior over time in relation to age-appropriate developmental adaptations (Greenspan & Porges, 1984).

Cross-sectional and longitudinal data describing age trends for a range of normal and problem child behaviors are beginning to accumulate (Bongers, Koot, van der Ende, & Verhulst, 2003). Prior data based exclusively on global parent reports are being buttressed by direct observations of ongoing social interactions. Information concerning proportions of children at different ages exhibiting various problems is also being reinforced with more specific information about children’s success or failure in making age-related adaptations, such as the formation of a secure attachment, the development of purposeful communication, and the regulation of emotions. Much of this research conducted in the area of developmental psychopathology is just beginning to find its way into clinical assessments with children and families (Cicchetti & Cohen, 2006c). Making normative judgments in the context of adaptations over time is quite compatible with the assumptions of DSA, because an organizational approach requires careful specification of situational demands (e.g., developmental tasks).

Normative information describing *qualitative* changes across age is needed. Although qualitative change is difficult to assess, it would appear that many childhood problems, such as fears (Southam-Gerow & Chorpita, Chapter 8, this volume), ADHD (Smith, Barkley, & Shapiro, Chapter 2, this volume), and conduct disorder (McMahon & Frick, Chapter 3, this volume), change both qualitatively and quantitatively with age. Judgments regarding deviance and normality need to be made in relation to both types of change.

Rapid and uneven developmental change also carries implications for the stability or instability of assessment information over time. Behavior at one age may not be predictive of behavior at a later time; this is especially true for assessments with very young children. For example, in examining aggressive behavior in males, Olweus (1979) reported that the degree of stability tended to decrease linearly as the interval between the two times of measurement increased, and that stability in aggressive behavior could be broadly described as a positive linear function of the interval covered and

the subject's age at the time of the initial measurement.

Plasticity and Modifiability

A second characteristic of children as a group that has implications for assessment and treatment relates to the plasticity and modifiability of infants and young children in relation to environmental influences. Experience can shape both behavior and neural structure and function (Cicchetti & Curtis, 2006). Because children's behavior is under the strong and immediate social control of parents, teachers, and other children, the need for assessment of these environmental influences is usually greater than that in assessments with adults. Yet this process is also reciprocal, in that genetically guided and managed neural structures and functions can influence what is experienced and even determine the very process of learning itself. For instance, the extent to which young children perceive particular stimuli or events as threatening, thus warranting fear or even a flight response, can vary in part due to genetic variation of this trait within the population. However, the extent to which the child has been previously exposed to highly fearful and traumatic events may also sensitize the child to fear reactions in similar future exposures, beyond what his or her genetic endowment may have affected. Hence, modifiability is an interactive and potentially reciprocal process.

Age and Gender

A third characteristic of developing children is their diversity, both within and across ages. There is a need to integrate developmental principles into assessment and treatment (Edelbrock, 1984; Yule, 1993). Developmental characteristics such as a child's age and gender have implications for not only judgments about deviance but also choice of the most appropriate assessment methods. One obvious developmental consideration relates to the constraints placed on the use of child self-report measures as a function of age-related language and cognitive abilities. The nature of children's reaction to being observed and their understanding of assessment purposes also vary with age. Assessments of young children may be affected by the children's wariness of strangers, whereas adolescents may also be wary of assessment by adults, but for quite different reasons.

A child's gender also plays an important role in judgments of deviance, with concomitant implications for the interpretations of assessment information. Norms used to make judgments about child behavior and the overt behavioral reactions of parents and teachers vary as a function of whether a child is male or female. Studies have also revealed differences in the rates and expression of childhood disorders for boys and girls (see Bell, Foster, & Mash, 2005). The dimensions that emerge from multivariate studies of child behavior problems differ for boys and girls after the age of 3 (Achenbach, 1993), and recent work suggests that the same disorder (e.g., depression, conduct disorder) may manifest itself in different ways depending on the sex of the child (Bell et al., 2005).

Common Features of Assessment Situations

Several common features in the types of situations in which children are typically evaluated have implications for assessment (Evans & Nelson, 1977; Mash & Terdal, 1997b). Childhood distress is typically framed in terms of its impact on others. Children are referred by adults, which means that children who are not experiencing subjective distress may not understand the reasons they are being assessed (Reid, Patterson, Baldwin, & Dishion, 1988; Yeh & Weisz, 2001). Adult referral suggests the need to consider factors that have been shown to influence the referral process, including the type and severity of problem, parent and teacher characteristics, social class, and culture.

There is a strong relationship between learning difficulties and behavior problems in childhood, and child assessments are often carried out in the context of cognitive/intellectual evaluations (Reynolds & Kamphaus, 2003a; Sattler & Hoge, 2006) or response to intervention procedures (Speece & Hines, Chapter 13, this volume). The co-occurrence of learning and behavior problems in children reflects the more general observation that problem child behaviors rarely occur in isolation. This means that child assessment is typically multidisciplinary, involving a range of professionals, including educators, psychologists, speech pathologists, and a variety of health personnel.

It is common for children referred for assessment to undergo repeated evaluations. This is especially the case for children with chronic disabilities or conditions, for whom repeated

evaluation and planning are often mandated by legislative requirements. Children who display less severe or acute problems also undergo repeated evaluations, reflecting both the fragmentation that is characteristic of mental health delivery systems for children and families, and, more positively, the need to re-evaluate children following behavioral or educational treatment programs. Repeated evaluations necessitate that assessment methods for children be robust across ages and relatively insensitive to the effects of practice.

Normative Comparisons

We have commented a number of times on both the benefits and limitations of normative comparisons. Normative information provides a way to establish an individual child's position on some dimension relative to the performance of other members of a suitable reference group. To make valid normative comparisons, valid norms are needed that reflect the distribution of scores in the populations of interest (Achenbach, 2001). Once this condition is met, it is important to examine issues related to the utility of normative comparisons generally and to the kinds of normative information that are likely to be most useful. Hartmann, Roper, and Bradford (1979) outlined a number of potential uses for normative comparisons in assessment:

1. Normative comparisons are frequently useful in identifying deficient or excessive performance, as would be the case when a child engages in excessively high rates of aggressive behavior. Normative information about rates of aggression in comparable situations by comparable children, depending on social judgments and reactions to the behavior, may serve to identify the child as having a problem.

2. When complaints about children reflect parental expectations that differ markedly from existing norms, as is the case in some abusive family situations (Mash et al., 1983), the focus and type of intervention may differ markedly from that used in the absence of such normative information.

3. When norms suggest that childhood problems are common or transient at particular ages (e.g., early reactions to separation, certain fears, bedwetting), such information may be used to guide decisions regarding the need for intervention. This is not to argue that nor-

mal difficulties are not a real concern for the child and family, or that educative or coping strategies would not be helpful in dealing with these problems. Normative disruptive behavior should not be considered "normal" without careful consideration of the context in which it occurs and its relationship to other responses and other individuals. Most normative behaviors, especially those derived from multivariate studies, are typically presented in terms of their frequency of occurrence for the general population. For example, Edelbrock (1984) noted that "arguing" was reported as a problem by more than half of the parents of nonreferred children, and "the fact that it is such a common complaint about normal children suggests that it should not receive high priority as a target for clinical treatment" (p. 29). However, it is possible that the "functions" of arguing in a group of children referred for treatment are qualitatively different than those in a non-referred population, so that in one group arguing functions as a cue for further escalation of coercive behavior, whereas in another group it may not (Patterson, 1982). Under these circumstances, frequent reports of arguing in non-clinic samples would not provide a sound basis for giving this response a low priority in treatment for clinic-referred children. Nevertheless, in many instances, knowledge that a problem is common and transient suggests that extensive clinical intervention is not required (Achenbach, 2001).

4. When there are norms for skilled versus inept performances, such information may be used to establish both intermediate treatment targets and long-term treatment goals, and to assess whether or not these goals have been met.

5. Norms may be useful for grouping children into relatively homogeneous treatment groups that subsequently could produce greater precision with respect to the most effective types of treatment for children with particular difficulties.

6. Normative information for specific assessment measures may enhance the comparability of findings obtained through different data sources. For example, parent report and direct observation measures may yield equivalent information when the scores on each reflect a similar degree of deviation, as in the case of a child rated one standard deviation above the mean on two different methods used to assess children's aggressive behavior.

7. Normative information may be useful in evaluating the clinical significance or social validity of treatment outcome, for example, to determine whether the treated child's behavior is comparable to that of nonproblem children following treatment. Researchers have noted improvement in the behavior of children with ADHD and conduct disorder with treatment, but a significant number of these children continue to function outside the normative range (Barkley & Guevremont, 1992; Kazdin & Esveldt-Dawson, 1987).

Although these described uses of norms refer primarily to behavior, normative information regarding situational factors may also help to identify some high-risk situations for the development of particular problems. For example, normative information regarding the quality of the child's school environment (e.g., high expectations, good group management, effective feedback and praise, setting of good models of behavior by teachers, pleasant working conditions, and giving students positions of trust and responsibility) may serve as a basis for the detection of early problems when such conditions are deficient, with a subsequent focus on prevention (Rutter, 1979). Similarly, norms regarding the presence or absence of certain family background variables for particular childhood disorders—for example, those related to parental antisocial personality disorder (Frick et al., 1992) or child abuse (Crooks & Wolfe, Chapter 14, this volume)—may also serve to identify high-risk situations. In general, norms for contextual factors have received far less attention than those for individual child behaviors.

Selection of Treatment Goals

The identification of behaviors that are targeted for change has been a hallmark of DSA with children and families. However, many reports begin with a designation of the problem to be treated, with little information about the decisional processes utilized in this selection. A number of important points concerning the selection of target behaviors for treatment as one outcome of the assessment process have been made (Mash & Terdal, 1997a):

1. Models of therapy and assessment that focus on a single target behavior as being synonymous with the goals of treatment provide

incomplete representations of both the assessment and change process.

2. An appropriate representation of the problem space for DSA is provided by a systems framework that encompasses a wide range of potentially important responses, individuals, and contexts that might be contributing to the problem.

3. Such systems representations of the child's and family's problems require decision rules for determining how best to conceptualize the system of interest and what aspects of the system should be modified to bring about the most widespread, meaningful, and lasting changes.

4. In practice, decision rules that are often employed in assessment reflect the theoretical preferences and subjective judgments of practicing clinicians (e.g., Nurcombe, Drell, Leonard, & McDermott, 2002). Such clinical decision making is subject to a variety of information-processing errors, many of which stem from the basic limitations (e.g., limited attention and memory) of human information processors to deal with complex datasets under conditions that often involve time pressures and high levels of uncertainty (Achenbach, 1985; Cantor, 1982).

5. An actuarial approach to the selection of treatment goals, and the ways these goals might be most effectively achieved, offers promise as an adjunct to clinical decision making (Achenbach, 1985; Cattell, 1983). The ready availability of computers may facilitate such an approach (Farrell, 1991).

6. If treatment goals are conceptualized in a systems framework, then the derivation of empirically based decision rules for intervention requires that structural and functional interrelationships between different aspects of the system be documented and described. The identification of constellations of target behaviors and response covariations becomes important (Kazdin, 1982, 1985; Voeltz & Evans, 1982).

7. Target behavior selection is conceptualized as a dynamic and ongoing process in which information derived from assessment and the impact of various interventions may be utilized in reformulating treatment goals. Such an approach is consistent with the DSA emphasis on the important relationship between assessment and treatment. Not only does assessment information lead to treatment recommendations but also treatment outcomes are used to determine the need for additional as-

assessment and reformulation of the problem as necessary (Weisz, Chu, & Polo, 2004).

These points emphasize that specification of target behaviors for the individual child, *by itself*, is not likely to provide a complete representation of the family's difficulties or the range of desired treatment goals. Nevertheless, information concerning the types of child behaviors that are often the focus of intervention can be useful within the context of a broader decision-making framework (Mash & Terdal, 1997a). Such information reflects both conceptual and empirical guidelines that commonly underlie target behavior selection.

Some of the more commonly mentioned *conceptual* guidelines for selecting and prioritizing behaviors for treatment include the following:

1. The behavior is considered to be physically dangerous to the child and/or to others in the child's environment.
2. The behavior should provide an entry point into the natural reinforcement community of the child.
3. The behaviors selected should be positive, to avoid a problem focus in treatment.
4. Behaviors viewed as essentials for development should be given high priority. For example, language, cognitive development and school performance, motor skills, rule-governed behavior, problem-solving skills, and peer relationships are common treatment targets. Implicit in this emphasis is the notion that many of these behaviors are embedded in normal developmental sequences, such that the failure to take corrective action early results in cumulative deficits, with the child falling even further behind.
5. Behaviors viewed as essential early elements for more complex response chains have also received priority. Classes of general imitative behavior, compliance, and cognitive styles have been viewed as requisite behaviors that enable a range of other responses.
6. Behaviors that maximize the flexibility of the child in adapting to new, changing environments are viewed as important treatment targets. The emphasis on teaching children general coping skills and self-regulatory strategies is consistent with this notion.
7. Behaviors that dramatically change the existing contingency system for the child (e.g., parent management training), such that

maladaptive environmental reactions to the child are altered, are viewed as likely to contribute to long-term benefit.

Some of the more commonly cited *empirical* criteria for selecting particular child behaviors for treatment include the following:

1. The behaviors are consistent with some developmental or local norms for performance.
2. The behaviors have been shown, as a result of careful task analysis, to be critical components for successful performance; teaching classroom survival skills such as on-task behavior, attending, or peer discussion about class work is an example of this approach.
3. The behaviors are subjectively rated as positive by recognized community standards.
4. The behaviors effectively discriminate between "skilled" and "nonskilled" performers.
5. The behavior's natural history is known to have a poor long-term prognosis.

Multisituational Analysis

Information about the context in which the child's behavior, cognitions, and affects occur is an essential ingredient for any DSA concerned with the assessment of relevant controlling variables to be utilized in the design of effective treatments. Contextual information is crucial, because children function in many different settings. The criterion for what constitutes "competent" performance is likely to vary with the parameters of the situation, suggesting the need for situation-specific measures of behavior (e.g., Dodge, McClaskey, & Feldman, 1985) and ecological assessments (Willems, 1973, 1974). Despite the acknowledged importance of assessing situations in DSA with children and families, it continues to be an area of relative neglect. Greater within-situation differentiation, which recognizes both differences and potential functional similarities in dissimilar environments, will be needed if the potential of situational analysis for the development of effective interventions is to be realized.

One type of molecular situational analysis has examined children's differential responses to varying social stimuli, for example, parents' use of different types of commands or language constructions to direct their chil-

dren's behavior (Forehand, 1977). Other studies have attempted to identify different types of home, classroom, or institutional situations or task structures that predict particular child responses. For example, home situations in which the mother is occupied; time constraints, such as dinnertime, bedtime, getting dressed, going to school; or situations involving social evaluation, such as visits to others' homes, going to the store, or visits to restaurants increase the likelihood of problem behavior in both normal and disturbed children (DuPaul & Barkley, 1992).

Other studies have examined classroom activity structures that predict different types of child social and academic behavior; examples include instructional arrangements (Greenwood, Delquadri, Stanley, Terry, & Hall, 1985), group versus individual activities (Patterson & Bechtel, 1977), quiet versus noisy conditions (Whalen, Henker, Collins, Finck, & Dotemoto, 1979), self-paced versus other-paced activities (Whalen et al., 1979), room size, seating arrangements, groupings of children based on different levels of ability, and formal versus informal task requirements (Jacob, O'Leary, & Rosenblad, 1978). Similar variables have been examined in institutional and day care environments. In addition, general environmental conditions related to space, noise, and temperature are variables of potential importance. For example, systematic variations in the rates of desirable and undesirable child behavior in the home associated with temporal and climatic variables, such as time of day, day of the week, precipitation, and temperature, have been reported (Russell & Bernal, 1977).

It is likely that situational variation will moderate not only behaviors but also cognitions and affects in family members. For example, in examining cognitions relating to perceptions of equity within the marital relationship, such perceptions may differ depending on the context that is being assessed (sex, finances, etc.). As mentioned previously, there is a need to develop a taxonomy of situations to guide both research and applied work in child and family DSA. In attempting to build such situational taxonomies, the following remarks by Mischel (1977) are of importance:

Depending on one's purpose many different classifications are possible and useful. To seek any single "basic" taxonomy of situations may be as fu-

tile as searching for a final or ultimate taxonomy of traits; we can label situations in as many different ways as we can label people. It is important to avoid emerging simply with a trait psychology of situations, in which events and settings, rather than people, are merely given different labels. The task of naming situations cannot substitute for the job of analyzing how conditions and environments interact with people in them. (pp. 337–338)

Expanded Temporal and Contextual Base

DSA assessment focuses on both contemporaneous behavior and controlling, as well as more distal, conditions. Current influences include those that are proximal to the behavior in time and to the situation in which the child's behavior is assessed. For example, an assessment of parent-child interaction may examine controlling variables in terms of the parents' responses to the child in that situation (e.g., cues and consequences). In such an assessment, developmental-historical information may not be given a particularly important role, and the parents' response could be viewed as a direct reaction to the child's immediate behavior in the situation rather than the result of the cumulative effects of many prior experiences with the child, or the parents' belief systems. However, numerous findings indicate that parents' responses are based on more than the immediate behaviors of their children. For example, parents of aggressive children may respond harshly, even when their children are behaving appropriately (Patterson, Reid, & Dishion, 1992). Thus, assessing developmental and historical factors, in addition to parent and child behaviors in the immediate situation, is important to understanding the parent-child interaction.

Similarly, broader contextual factors, such as parental personality, family climate, peer relations, marital relationships, family support, and community conditions, have been shown to be potent sources of influence for child behavior—indeed, as or more important than the reactions of significant others to the child's behavior at the time of its occurrence (Mash & Dozois, 2003). Given the multitude of situationally and temporally remote distal events that have been shown to be important determinants of child and family behavior and of treatment outcomes, a relative emphasis on the assessment of proximal information within a broader developmental, temporal, and social context is essential.

METHODS OF ASSESSMENT

DSA methods are much the same as those used in assessments with children and families more generally. They include unstructured and structured interviews, checklists and questionnaires, self-monitoring procedures, analogue assessments, psychophysiological recordings, and direct observation. The uniqueness of the methods used in DSA is based on the assumptions underlying the approach as we have described them, how the methods are used, and how the results are interpreted and integrated into treatment.

The chapters in this volume provide comprehensive reviews of the methods used to assess a wide spectrum of childhood disorders and problems. In the discussion that follows, we highlight prevalent concerns and issues associated with the use of particular methods. We emphasize again that the major underlying theme of this volume is that methods are best used in relation to specific purposes for children displaying specific types of problems. Nevertheless, because part of the assessment task initially is to identify the problem category that best describes the individual child and his or her family, some methods (e.g., screening instruments, diagnostic interviews, general behavioral checklists) are not problem-specific. In addition, a number of assessment methods have applicability across different problems, which is important because so many children referred for assessment are known to display multiple problems and disorders.

Selection of Methods

When we consider the literature on clinical assessment of children and families, along with writings in child development, abnormal child psychology, developmental psychopathology, education, and child psychotherapy, there is clearly no shortage of available instruments with which to assess children and families (Kazdin, 2005). Numerous checklists and coding systems have been developed to assess child behavior, parent-child interaction, and family interaction. In other areas, such as social support or family stress, the number of available measures is also large. What is lacking at this time seems to be an agreed-upon set of decisional criteria and rules concerning which of the available measures are best suited for particular purposes, and when and how these mea-

asures are to be used (Hunsley & Mash, 2007; Mash & Terdal, 1997a).

In practice, the most frequently used decision criteria often equate the quantity and quality of assessment information. This rather crude heuristic assumes that the best assessments sample as many domains as possible, using the widest variety of methods. Traditional test batteries, in which children receive a standardized evaluation that includes an interview with the parent and/or child, an IQ test, a projective personality test, and a test for organicity or perceptual dysfunction, illustrate this approach. Long-standing criticisms of these procedures as being insufficient for diagnosis and treatment have come from clinicians across a range of theoretical orientations (e.g., Santostefano, 1978).

Although there is much empirical support for the notion that different methods of assessment may, and often do, yield different kinds of information, the view that use of multiple methods result in a truer or more useful description of the child and family has not been adequately tested. In some instances, the accumulation of greater amounts of information in the clinical context may actually serve to reduce accuracy, while increasing judgmental confidence (Nisbett, Zukier, & Lemley, 1981). With large amounts of information, the influence of relevant diagnostic data may be diluted by the presence of an increased number of nondiagnostic features. It is important that attention be given to the incremental validity associated with use of multiple methods to avoid redundancy and the perpetuation of potentially unnecessary and costly procedures. "Incremental validity" refers to the extent to which additional information contributes to the prediction of a variable beyond what is possible with other sources of data (Hunsley & Mash, 2007). For example, does obtaining additional assessment information improve the efficiency and outcome of treatment (Hayes & Nelson, 1987, 1989; Hunsley & Meyer, 2003; Johnston & Murray, 2003)?

The many purposes for which assessments with children and families are carried out indicate that referred children need not be assessed in all possible ways (Mash & Hunsley, 2005b). What factors contribute to decision making regarding the selection of methods? Although it is not possible to discuss all factors in detail, the choice of assessment methods for a particular case is based on considerations such as the purpose(s) of the assessment (e.g., screening vs.

treatment evaluation), the nature of the problem (e.g., overt vs. covert, chronic vs. acute), the characteristics of the child (e.g., age, sex, cognitive and language skills) and of the family (e.g., social class, education, single parent vs. intact marriage), the assessment setting (e.g., clinic, home, classroom), characteristics of the assessor (e.g., conceptual preferences, level of training, available time and resources), and characteristics of the method (e.g., standardization, reliability, validity, clinical utility, complexity, sensitivity to treatment change, amount of technical resources or training required for use, feasibility in clinical practice). These and other considerations in selecting particular methods to assess specific childhood disorders are discussed in each of the chapters of this volume.

Interviews with Parents and Others

Regardless of therapeutic orientation, and despite numerous criticisms concerning reliability and validity, the clinical interview continues to be the most universal assessment procedure (Sattler, 1998). However, the interviewer's behaviors and expectations, the kinds of information obtained in the interview, the meaning given to that information, and the degree of standardization vary across therapeutic orientations and purposes (Sattler & Mash, 1998). As an information-gathering procedure, clinical interviews are used flexibly on repeated occasions and are frequently integrated with other types of assessment information, such as observations of family interaction to assess, for example, family problem-solving skills, readiness for change, adherence to treatment, and nonverbal patterns of communication.

Given that a DSA conceptualization of child and family disorders requires an understanding of reciprocal social relationships, and that children are usually referred by adults, it is almost always necessary to obtain descriptions from adults about the nature of the children's difficulties, social circumstances, physical status, and general development. Most typically a child's parent(s), usually the mother and to a lesser extent the father, are the primary informants. However, although less frequently called upon, other adults (e.g., teachers, other family members, friends) and other children (e.g., siblings and peers) may also provide useful and potentially important assessment information (Bierman & McCauley, 1987).

Interviews with parent(s) provide information about the child, the parent, the parent-

child relationship, and family relationships and characteristics more generally. The relative focus in each of these areas varies with the nature of the presenting problem and the purpose(s) for which the interview is conducted. Research has identified relationships between parental characteristics and children's functioning in both family and school settings (e.g., Forehand, Long, Brody, & Fauber, 1986), and between parental affects, such as depression, and child behavior, suggesting that information gathering in the interview needs to include a focus on the child, the parent(s), sibling relationships, and the marriage or couple relationship, as well as relationships between these various family subsystems.

Common purposes of interviews with parents include the following (Haynes & Jensen, 1979): (1) gathering information about parental concerns, expectations, and goals; (2) assessing parental perceptions and feelings about the child's problems, concerns, and goals; (3) identifying possible factors that may elicit or maintain problem behaviors; (4) obtaining historical information about the child's development, problem and nonproblem behaviors, and prior treatment efforts; (5) identifying potentially reinforcing events for both child and parent; (6) educating the parent with respect to the nature of the childhood problem (e.g., ADHD, autism), its prevalence, its prognosis, and its possible etiologies; (7) providing the parent with an adequate rationale for assessment and proposed interventions; (8) assessing the parent's affective state, motivation for changing the situation, readiness for change, and resources for taking an active role in helping to mediate behavior change; (9) obtaining informed consent; (10) providing data for the assessment of treatment outcomes, and (11) communicating with the parent about procedures and setting realistic goals for assessment and intervention.

The many interview purposes described mean that the degree of structure, content, and style of parental interviews will vary greatly for children with different problems and needs, and a lack of uniformity may be the rule rather than the exception. Several general points related to interviews with parents require discussion.

Generality and Flexibility

The first point involves the level of generality and flexibility of the interview. Typically, inter-

views with parents have been used to determine treatment eligibility (e.g., screening) or as methods of gaining information that facilitate the design of effective treatments (e.g., case formulation). These purposes necessarily define the interview as being general in nature and require the interviewer to adapt to the various concerns raised by parents. The degree of structure and standardization in these types of interviews with parents is usually low, but it can be increased for other interview purposes—for example, when interview information is to be used as an outcome measure, or when the interview is used to make a formal diagnosis. Alternatively, if pretreatment questionnaires include life-history information or ratings of behavior, then initial interviews can be structured around the information obtained from these questionnaires.

A number of guidelines and standardized formats have long been available for interviews with parents (e.g., Kanfer & Grimm, 1977; Wahler & Cormier, 1970). These formats are useful, although many are also quite general and make no a priori assumptions regarding the specific interview content that is likely to be most meaningful. Consistent with the theme of this book, we believe that problem-specific interview formats are needed. For instance, interviews with parents of children with anxiety should focus on anxiety-related symptoms (e.g., Silverman & Ollendick, 2005), and those with parents of children with autism should systematically obtain information about commonly identified problems, situations, and controlling variables associated with autism (Ozonoff, Goodlin-Jones, & Solomon, 2005). Rather than assuming that interviewers have the specific information needed to guide interview content and process, we believe that interview schedules that include disorder- and context-specific information lead to more systematic, standardized, efficient, and useful interviews possessing greater reliability and validity. Such problem-specific interview schedules are described in the chapters of this volume, and others are presented in the comprehensive volume on interviewing by Sattler (1998).

Reliability and Validity

It should be emphasized that questions concerning reliability and validity are meaningful only in relation to the interview purpose. For

example, if the purpose of the interview is to gain information about a mother's perception of her child as a possible controlling variable for her reactions to her child, then a lack of correspondence between maternal report and that of other informants is of less concern than it would be if the mother's report is used to assess rates of child behavior over time to assess the impact of treatment.

With respect to reliability, primary concerns relate to issues such as (1) whether information obtained on one occasion is comparable to information obtained on other occasions from the same parent (e.g., stability); (2) whether information obtained from the parent is comparable to information obtained from another informant—for example, mother versus father (i.e., interobserver agreement; Edelbrock, Costello, Dulcan, Conover, & Kalas, 1986); (3) whether the information reported by the parent is consistent with other parental information in the same interview (i.e., internal consistency); and (4) whether the information obtained by one interviewer is comparable to that obtained by another with the same parent, or with data from a self-report measure completed by the parent (i.e., method error).

The first reliability concern is especially relevant in interviews that require parents to report retrospectively on their children's developmental-social history, one of the more common elements of most child assessments (Yarrow, Campbell, & Burton, 1970). It is well established that retrospective reports are likely to be unreliable and frequently distorted in the direction of socially desirable responses and dominant cultural themes (Evans & Nelson, 1977). It has also long been known that the degree of reliability is related to the nature of the events that parents are reporting (e.g., pleasant vs. unpleasant) and the level of specificity of behavior described (Lapouse & Monk, 1958).

Although parental reports may conform to the demand characteristics of the interview situation, such characteristics might not always predict socially desirable responses. For example, there may be a parental bias toward reporting more negative child behaviors and greater parental distress during an initial interview, when eligibility for treatment is being assessed, whereas posttreatment interviews may be associated with an implicit demand to report improvements in child behavior and reductions in parental distress. This latter point is especially important when interview informa-

tion is to be used as a measure of treatment outcome. Parents of problem children may also be realistic about their children's behavior, in contrast to parents of nonproblem children, who may describe their children in an overly positive fashion. Interinformant agreement between parents or between teachers and parents is difficult to evaluate, because disagreement may reflect true differences in the situation in which each informant observes the child. In general, mothers have been found to be more reliable informants than fathers and usually provide descriptions of their children's behavior that are much more differentiated and situation-specific (McGillicuddy-DeLisi, 1985).

Interviews with other significant adults or with the child's friends, peers, or siblings may be potentially useful but have received little attention in assessment, in part because of ethical concerns associated with obtaining such information. For example, interviews with peers may further stigmatize the child as having a problem, with subsequent changes in how others interact with the child (Martin, 2006). At the same time, data suggest that peer evaluations may be particularly sensitive in identifying children with problems (Bierman & Welsh, 1997; Cowen, Pederson, Babigian, Izzo, & Trost, 1973), although it is not known whether peer judgments regarding the precise nature of these problems are likely to be accurate. Information obtained from siblings may also be important, in that many problem families are characterized by high rates of sibling conflict (Dunn & Munn, 1986). Studies with nonproblem families have suggested that children's views of their siblings are represented by patterns of positive and negative behaviors mixed with positive and negative feelings (Pepler, Corter, & Abramovitch, 1982). However, it may be that both perceptions and behaviors of siblings in problem families are more negatively toned (Patterson, 1982).

Structured Parental Reports about Child Behavior

In addition to unstructured interviews with parents, reports on child behavior and adjustment have also been obtained with more structured methods (Barkley, 1988; Kamphaus et al., 2000; McMahan, 1984). The most widely used methods have been global behavior rating scales requiring either binary judgments concerning the presence or absence of particular

child behaviors or ratings concerning the degree to which the behavior is present or perceived as a problem. These rating scales cover a wide range of presenting complaints and, to a somewhat lesser extent, child competencies, offer a degree of standardization that is uncharacteristic of clinical interviews, permit normative comparisons between children, are economical to administer and score, may be readily used as treatment outcome measures, and provide a rich source of information about parents' perceptions of their children's behavior, including discrepancies in parent perceptions in the same family, and the discrepancies between parent perceptions and data derived through other sources, such as reports by teachers (e.g., McDermott, 1993). On a cautionary note, data suggest that reading levels required for parents to read and understand several of the more commonly used behavior rating scales accurately often exceed parents' reading ability, a factor that has not been routinely considered in the use of rating scales with parents (Jensen, Fabiano, Lopez-Williams, & Chacko, 2006).

In the clinical context, behavior rating scales may serve as comprehensive but general screening instruments, most typically during the early phases of assessment. They provide a reasonable estimate of parental perceptions of a child's overall behavior and adjustment, as aggregated across a wide variety of situations. However, they fail to provide situation-specific information about behavior, or information that can be used to develop a program of intervention. Nevertheless, they may assist in identifying a specific problem, which, in combination with other diagnostic information, may suggest a specific form of evidence-based treatment. Most ratings scales have been used with parents of school-age children, but several checklists and rating scales have now been developed for use with toddlers and younger children (see, e.g., Brassard & Boehm, 2007; DelCarmen-Wiggins & Carter, 2004). For children younger than age 2, the most commonly used parent report measures have been subsumed under the general characteristic of infant temperament (e.g., Rothbart & Goldsmith, 1985; Slabach, Morrow, & Wachs, 1991; Stifter & Wiggins, 2004).

As we have noted, extensive multivariate analyses of parent-completed behavior rating scales have yielded consistent factors, although the factors that emerge vary with the age and

sex of the child, the setting, and a variety of informant characteristics, including ethnicity, race, or income level (e.g., Gdowski, Lachar, & Kline, 1985; Gross et al., 2006). Within a DSA framework, such variations are consistent with the view that behaviors vary in degree and type across situations, and that different informants structure their views of the child in different ways. Although there is a need for more measures with situational norms, the likelihood that the most frequently used checklists will be modified in this direction seems quite low, in light of the large-scale empirical efforts that often go into establishing a sound normative database and psychometric characteristics for behavior rating scales.

One concern surrounding the use of parent behavior rating scales has been the degree of correspondence (or lack thereof) between reports by different informants, most commonly between mothers and fathers, parents and teachers, and, to a lesser extent, children and parents or teachers (e.g., Achenbach, Krukowski, Dumenci, & Ivanova, 2005; Achenbach, McConaughy, & Howell, 1987; De Los Reyes & Kazdin, 2004, 2005). Some researchers have reported high agreement (correlation of .69) between parents on global checklists for both narrow- and broad-band syndromes (Achenbach, 1985, p. 104). However, the degree of agreement or disagreement between parents likely depends on the types of measures being compared (e.g., narrow-band syndromes vs. profiles) and the type of agreement index that is used. Reports by mothers, compared to those by fathers, can lead to different profile interpretations and judgments of clinical significance (Hulbert, Gdowski, & Lachar, 1986). Furthermore, when different raters seeing children in different contexts are compared, interrater agreement tends to be quite low (Achenbach et al., 1987).

In addition to global rating scales and structured interviews, many parent-completed measures that focus on specific content areas or problems have also been developed. These include, for example, parental ratings of a child's overall development, ADHD, autism, self-control, psychopathy, or oppositional defiant disorder (e.g., Hommersen, Murray, Ohan, & Johnston, 2006).

Another type of parent report, used during initial assessments and to monitor changes during treatment, involves parent recording of targeted child behaviors. Typically, parents collect

baseline data on one or two general (e.g., compliance) or specific (e.g., swearing) behaviors that may subsequently be targeted for modification. Less frequently, parents also collect systematic data about antecedent and consequent events to identify potentially important controlling variables to be utilized in treatment. Many different forms have been developed to assist parents in recording their children's behavior. Such forms are common fare in almost all manuals used in parent management training programs. Records kept by parents have the advantage of providing ongoing information in relevant settings, information about behaviors of interest that might not otherwise be accessible to observation in other contexts, and also secondary benefits not directly related to assessment. These include teaching parents better observation, tracking, and monitoring skills; assessing parental motivation; and providing parents with more realistic estimates of their children's rate of responding and feedback on the effects of treatment. On the negative side, there are many practical problems in getting parents to keep accurate records, and parental recordings of behavior may be reactive in the home situation, producing unrepresentative data. In addition, although parent recordings have been used extensively, there is little information available concerning their reliability or validity.

In most cases, parents are the primary informants in assessments of their children, because parental perceptions often determine what, if anything, will be done about their children's problems. Furthermore, professionals' judgments regarding childhood disorders may be influenced more by what parents say about their children than by observed child behavior. Because parent-completed checklists and rating scales provide more information more quickly than could otherwise be obtained through interviews, and are also much more economical with respect to cost, effort, and therapists' time, they are likely to continue to be widely used (Kamphaus et al., 2000).

Parent Self-Ratings

Recent approaches to DSA have increasingly emphasized the importance of assessing parents' self-reported perceptions, cognitions, and feelings (Mash & Terdal, 1997a). Earlier work tended to utilize parents' reports about themselves primarily in areas directly related to the

children's problems (e.g., "How does it make you feel when he does not listen to you?"). Parents' feelings, attitudes, and cognitions were considered important variables, but usually in relation to their influences on how parents reacted to their children or as predictors of the likelihood that parents would involve themselves in treatment. Although these considerations continue, assessment of parents' reports about themselves has increasingly been viewed as important in understanding the nature of the families' problems and in determining potential targets for intervention. Although self-report information from both parents should be obtained, in practice, mothers more frequently provide information than do fathers.

Parent self-ratings have included a variety of procedures designed to assess parental behavior and disciplinary practices, parental cognitions, and parental affects. One type of self-rating concerns reported parenting practices, as assessed with questionnaires about parents' use of discipline (Arnold & O'Leary, 1993) or parents' brief written reports of what they would do in audiotaped or videotaped scenarios of child behavior or situations. Such analogue assessments are a reflection of how parents think they would respond, and the degree of correspondence between expressed intent and actual parent behavior in these situations has received little empirical investigation. Although potentially useful, these analogue self-reports have not been used routinely in clinical practice.

The increasing focus on cognitive variables in DSA, in cognitive-behavioral treatment, and in the study of parent-child relationships more generally, has led to the development of a host of self-report measures that describe different types of parental cognitions. Such measures have been used to assess constructs such as general attitudes about children and child rearing (e.g., Schaefer & Bell, 1958); implicit theories about discipline (e.g., Dix & Ruble, 1989); satisfaction in areas concerned with spouse support, the child-parent relationship, parent performance, family discipline, and control (e.g., Guidubaldi & Cleminshaw, 1985); parental self-esteem, as reflected in degree of comfort in the parenting role and perceived effectiveness as a parent (e.g., Johnston & Mash, 1989); expectations for development and developmentally appropriate behavior (e.g., Azar, Robinson, Hekemian, & Twentyman, 1984); parent attributional processes (Bugental, Johnston,

New, & Silvester, 1998), including those related to the causes of child behavior (e.g., Miller, 1995), childrearing outcomes (Bugental, 1993), or specific problems, such as enuresis (Butler, Brewin, & Forsythe, 1986) or ADHD (Johnston & Ohan, 2005); problem-solving skills in regard to commonly occurring child behaviors and childrearing situations (e.g., Holden, 1985a); empathy in general (e.g., Chlopan, McBain, Carbonell, & Hagen, 1985) and in the parenting domain (e.g., Newberger, 1978); and emotion recognition (e.g., Kropp & Haynes, 1987).

Studies of the cognitive and affective processes of parents have provided information about relationships between parental cognitions and behavior; possible differences in the cognitions of parents in disturbed versus nondisturbed families; and the ways in which parents process information about demanding childrearing situations, including their use of anticipatory or proactive strategies (Holden, 1985b), how anger influences thinking (Dix & Reinhold, 1990), and the effects of maternal mood on child evaluation and parent-child interaction (Jouriles, Murphy, & O'Leary, 1989; Jouriles & Thompson, 1993). Information concerning parents' decisional processes seems especially relevant to formulating treatment goals, because parents' problem solving styles may be directly targeted for treatment (e.g., Blechman, 1985). Many of the measures described have been used in a research context, and their potential utility in clinical assessment needs to be evaluated. Furthermore, a number of different cognitive dimensions have been assessed, and more work is needed to determine whether these are in fact independent dimensions.

An interest in how parents of problem and nonproblem children cope with the stresses surrounding child rearing has led to the development of measures designed to assess the stresses associated with being a parent (e.g., Abidin, 1995), the degree to which specific types of child behavior may be perceived as disturbing (e.g., Mooney & Algozzine, 1978), and the impact on parents of specific handicapping child conditions, such as hearing loss or intellectual disability. Similarly, growing interest in the social networks surrounding disturbed families has led to the development of measures of perceived social support and/or social isolation (e.g., Bristol, 1983; Dunst, Jenkins, & Trivette, 1984; Dunst & Trivette, 1985;

Salzinger, Kaplan, & Artemyeff, 1983; Wahler, Leske, & Rogers, 1979).

Much work has also been directed at parents' reports of their own mood states, particularly maternal anxiety and depression (e.g., Billings & Moos, 1986). A rapidly growing literature documents the profound impact of maternal depression on child functioning and family relationships, beginning in early infancy (Goodman & Gotlib, 2002). Although the prevalence of self-reported depression in mothers of problem children is high, the causal status surrounding this mood state as a determinant or outcome of disturbed family interactions is still under investigation. Likewise, research continues on whether feelings of depression may negatively color parent's views of their children (Richters, 1992).

In summary, parent self-ratings have been used to assess a variety of important characteristics that may contribute to how parents react to, and are affected by, their disturbed children. In addition, assessments of many of the cognitions and affects are likely to suggest important areas for needed interventions, such as when a parent is depressed. In consideration of the future use and development of such self-ratings, a number of evaluative criteria for selecting a self-report measure have been suggested, including whether it can be administered repeatedly as an outcome measure; whether it provides sufficient specificity; whether it is sensitive to treatment changes; whether it guards against common self-report biases, such as social desirability, acquiescence, demand characteristics, faking, or lying; and whether it possesses adequate reliability, validity, and norms (Hartmann, 1984). Many of the parent self-ratings used thus far in child and family DSA do not yet meet these criteria.

Child Self-Report

Concerns regarding the reliability, validity, and practical difficulties associated with obtaining self-report information from children, especially young children, resulted in a minimal reliance on such measures in early work in child and family DSA. Although interviews and checklists of the types administered to adults may not be very informative with preschool- or grade-school-age children, flexible interview formats that are consistent with a child's developmental level can provide important information about the child's behavior, thought

processes, affect, self-perceptions, and views of the environment (Greenspan & Greenspan, 2003; McConaughy, 2005).

The increased use of interviews and child-completed checklists and questionnaires, particularly with older children and adolescents (Bierman, 1983; Bierman & Schwartz, 1986; Reynolds, 1993), is related to a number of factors: (1) the growing recognition of children's unique position as observers of themselves and their social environment; (2) the accumulation of data in support of the notion that children's cognitions and emotions directly influence their behavior and often mediate the effects of intervention; (3) the increased emphasis on children's thoughts and feelings as potential targets for treatment, and the concomitant increase in the use of cognitively based therapy procedures (Kendall, 2006); (4) the growing concern for childhood internalizing disorders, such as depression (Rudolph & Lambert, Chapter 5, this volume) and anxiety (Southam-Gerow & Chorpita, Chapter 8, this volume), which require assessment of children's self-reported feelings; and (5) the development and widespread availability of a number of well-standardized, psychometrically sound structured and semistructured interview and questionnaire procedures.

Unstructured Interviews

The format and content of assessment interviews with children should vary in relation to the child's developmental status, the nature of the child's problem, and the interview purpose. Purposes vary but typically include attempts to elicit information regarding children's perceptions of themselves and their problems, and to obtain samples of how children handle themselves in social situations with adults or other children (Sattler, 1998). Children's views of the circumstances that have brought them to the clinic, expectations for improvement, and comprehension of the assessment situation are all important to assess, as is the manner in which the children interpret significant events in their lives, such as divorce (Kurdek, 1986) or sexual abuse (Wolfe, Chapter 15, this volume). In addition, children's perceptions of their parents, siblings, teachers, and peers likely influence their reactions to them, and are therefore especially important for understanding children's problems, designing interventions, and assessing the suitability of involving such individuals

in intervention. Interviews may also focus on obtaining more specific types of information that children are in a unique position to report, such as their preferred activities and rewards.

Semistructured and Structured Interviews

Unstructured clinical interviews for the purpose of making a formal diagnosis can be extremely unreliable. There are several sources of unreliability, including a lack of clarity concerning decision rules, and the operation of confirmatory biases and other types of judgmental errors (Achenbach, 1985). As a result, structured interviews have been used extensively in research studies with a primary focus on identifying homogeneous populations of children conforming to particular diagnostic criteria. However, their use in clinical practice has been less common, mostly due to training requirements, time, and other resource demands.

A number of structured and semistructured diagnostic interviews for children and adolescents were developed in the late 1970s and early 1980s, for example, the Diagnostic Interview Schedule for Children and Adolescents (Costello, Edelbrock, & Costello, 1985; Costello, Edelbrock, Kalas, Kessler, & Klaric, 1982), the Child Assessment Schedule (Hodges, 1985), the Schedule for Affective Disorders and Schizophrenia for School-Age Children (Chambers et al., 1985; Puig-Antich & Chambers, 1978), and the Diagnostic Interview for Children and Adolescents (Herjanic & Reich, 1982). These interview schedules have undergone changes to accommodate subsequent revisions in DSM criteria, and the reader is referred to various chapters in this volume for discussions of the applicability of these interviews to specific childhood disorders.

Numerous empirical investigations with these interviews have produced interesting findings that have implications for the assessment of children more generally. For example, the reliability of the interview may interact with the particular dimension (e.g., affective, cognitive, behavioral) being evaluated. Edelbrock, Costello, Dulcan, Kalas, and Conover (1985) found that for descriptions of internal states, the reliability of the interview was related to the child's age; children under age 10 showed little consistency in their interview reports, even over periods as brief as 1 or 2 weeks. Young children showed a particular

tendency to change their responses from affirmative during an initial interview to negative in a second interview several days later.

The potential utility of structured psychiatric interviews in clinical practice is not clear at this time. Certainly, the increased standardization and gains in reliability associated with use of these procedures provide some advantages. However, most of the structured interview formats tend to produce global indices concerning the presence or absence of a disorder rather than the more specific information needed to formulate a picture of a particular child, family, and peer group for the purposes of intervention. It is possible that more cost-effective methods (e.g., checklists and rating scales) can provide the necessary information concerning the presence of a disorder in a way that frees up time and resources to generate more useful information for treatment (cf. Pelham et al., 2005).

Few structured child interviews have been developed for purposes other than obtaining a formal diagnosis. Bierman (1983) presented some extremely useful guidelines as to how such interviews might be developed, illustrating how empirical information about developmental processes (e.g., person perception as related to age) may be used to determine the types of questions asked in an interview. The few structured formats for interviews with children have been developed primarily as research instruments. However, growing interest in children's perceptions and feelings in DSA suggests that greater standardization may be warranted in interview procedures with children for purposes other than formal diagnosis, particularly in interview procedures that are feasible in clinical practice. Presumably, such standardized instruments would examine children's reports in relation to a variety of commonly occurring situations in the home and classroom that are relevant for children with specific types of disorders.

Child-Completed Checklists and Questionnaires

The number and use of child-completed checklists and questionnaires in DSA have also increased (Reynolds, 1993). Although the content and response format for child-completed measures have varied with children's developmental status, these measures have for the most part been used with older children, and often as a measure of treatment outcome. A wide vari-

ety of self-report instruments have been developed for describing the cognitive, affective, and behavioral domains (Myers & Winters, 2002; Winters, Myers, & Proud, 2002). Although many of the early self-report measures were downward extensions of instruments initially developed for adults, current measures are based more directly on work with children. Some of the areas that have been assessed with child-completed checklists and questionnaires include general personality dimensions, such as introversion–extroversion; anxiety and depression; perceived locus of control; social competence; self-esteem and self-concept in general, and academic or social domains specifically; anxiety and depression; cognitive distortions; perceptions of family members and peers; and perceived behavior problems and competencies. A discussion of relevant child-completed checklists and questionnaires as used in the context of specific disorders is provided in each of the chapters that follow.

Self-Monitoring Procedures

A number of discussions of self-monitoring procedures in assessments with children, as well as related methodological issues, are available (e.g., Bornstein, Hamilton, & Bornstein, 1986; Shapiro & Cole, 1984). There is a long tradition of having children use self-monitoring procedures for behaviors such as attention in the classroom (Brodin, Hall, & Mitts, 1971), academic responses (Lovitt, 1973), class attendance (McKenzie & Rushall, 1974), talking out in class (Brodin et al., 1971), and aggression (Lovitt, 1973). In most instances, self-monitoring procedures with children have been undertaken as part of a larger set of self-assessment procedures (e.g., recording, evaluation) intended to modify the behavior being monitored. There are few descriptions of children self-monitoring their own behavior and life situations to provide diagnostic information for developing treatments or measuring treatment outcomes. Consequently, the assessment functions of self-monitoring procedures with children have not received much elaboration. In recent work, electronic diaries hold promise in providing the type of ongoing information about behavior in contexts that could be useful for developing a treatment plan and monitoring treatment progress and outcomes (Whalen et al., 2006).

Direct Observations of Behavior

Mash and Terdal (1976) have described a direct observational procedure as a method for obtaining samples of clinically important behaviors and settings (in relation to diagnosis, treatment design, prognosis, and evaluation), in a naturalistic or an analogue situation structured to provide information about behaviors and settings comparable to what would have been obtained *in situ*. Direct observational methods usually involve recording behavior when it occurs; using trained and impartial observers who follow clearly specified rules and procedures regarding the timing of observations and their context; using previously designated categories that require a minimal degree of inference; and using some procedure to assess reliability (Barrios, 1993; Cone & Foster, 1982; Hartmann, 1982; Reid et al., 1988).

It has been argued that direct observation is less subject to bias and distortion than are verbal reports from either children or parents and teachers. However, this question cannot really be addressed without considering the informant, the child or family behavior being described, and the context and purposes for assessment. Furthermore, support for this argument comes as much from studies demonstrating poor reliability and validity associated with verbal report as from studies directly demonstrating observational data to be accurate and unbiased. In fact, many studies have shown that observed behavior may be readily distorted by biases on the part of both observers and those being observed. For example, Johnson and Lobitz (1974) demonstrated that parents of nonproblem children can make their children look either good or bad when instructed to do so. However, it is possible that some types of problem families may find it difficult to make themselves “look good” to outside observers. For example, it has been reported that abusive mothers continue to behave in ways considered to be socially undesirable, even when they are being observed (Mash et al., 1983; Reid, Taplin, & Lorber, 1981). Nevertheless, in light of the demand characteristics of most observation situations (e.g., relating to diagnosis of the problem, eligibility for treatment, educational placement, legal adjudication, and evaluation of treatment change), it seems likely that observation likely influences the behavior of those being observed.

In discussing observational procedures, it should be noted that given the findings related to possible biases and reactivity in direct observation, the potential unrepresentativeness of observational data, the current conceptual emphasis on cognitive and affective variables in DSA, and particularly the many practical concerns and demands associated with observational procedures in clinical practice, the utility of direct observation as a clinical assessment procedure has yet to be established (Mash & Foster, 2001).

Observational Procedures with Children and Families

A wide range of observational procedures have been used to assess children and families, ranging from simple single-behavior or single-purpose recording schemes that can be conducted with a minimal amount of observer training to complex and exhaustive multi-behavior, multicontext interaction code systems (Reid et al., 1988). The numerous factors involved in selecting an appropriate observational procedure include the stage and purpose of the assessment, the behaviors of interest, the situation in which observation is to occur, observer characteristics, and technical resources (Mash & Terdal, 1981).

There are detailed discussions in the literature on direct observational assessment procedures, and the methodological and practical issues surrounding their use (e.g., Barrios, 1993; Foster & Cone, 1986; Hartmann, 1982). These issues are concerned with factors influencing the objectivity and reliability of observations, such as code system characteristics (e.g., number, complexity, and molecularity of categories); characteristics of the behaviors being observed (rate and complexity); methods of assessing reliability (e.g., awareness of reliability checks); observer characteristics (e.g., age, sex); methods of calculating reliability; sources of observer and observee bias under a range of conditions; reactivity to being observed; and ways in which observational data should be summarized and interpreted. An extensive discussion of these issues is beyond the scope of this chapter, but sensitivity to these methodological concerns is a necessary part of any observational assessment of children and families, because they have a direct bearing on the validity of the findings. A minimally acceptable set

of criteria for any observational code would be that it is objective (e.g., two observers classify behavior in the same way), that it has mutually exclusive subcategories, and that it provides data that are amenable to objective analysis. Given these minimal requirements, further validation as to a wide range of goals and purposes is possible.

Selecting Code Categories

The use of observational codes requires decisions relating to both the content (e.g., what categories to include) and the structure (e.g., number of categories, temporal base, mechanics for observing and recording) of the code system (Hawkins, 1982). For the most part, content, code selection, and observational system construction have been carried out on a rational basis. Consistent with the view of maintaining low levels of inference, the family behaviors observed are often those directly reported as problematic by parents and teachers, or those that fit with the theories or experiences of the assessor. We believe that category and code system selection can be improved, with greater attention to the parameters associated with the specific populations of families being observed and the settings in which they function. Specialized observational assessment coding systems for specific childhood disorders are provided in some of the chapters of this volume. These systems reflect behaviors and setting variables shown to have empirical relevance for the disorders being assessed.

Recently, more attention has been given to observations that focus on not only molecular responses but also larger, more global units for describing family interaction. Implicit in this trend are the notions (1) that larger response chains have qualitative features of their own, and although molecular codes may not reveal these dimensions, subjective impressions by trained or "culturally sensitive" human observers may; and (2) that global ratings can provide a more efficiently obtained and equivalent integrative summary of the molecular responses. When Weiss and Chaffin (1986) compared two marital code systems based on either global ratings of communication or on many specific categories, they found that the degree of overlap was moderate and pointed out that the two systems might be useful for different purposes, and that in light of the high costs of using com-

plex category systems, the use of more global ratings might be explored. Several researchers supplemented molecular observations with more global judgments and found that experienced raters whose global judgments are averaged and composited can often provide reliable and valid indices of psychologically complex behaviors (Moskowitz & Schwarz, 1982; Weinrott, Reid, Bauske, & Brummett, 1981). It would appear that there are assets and liabilities associated with the use of molar and molecular ratings, and that some combination of the two may be useful (Cairns & Green, 1979). If future empirical work can establish the utility, reliability, and validity of more global ratings for specific purposes, then the next step would be to promote the use of these procedures in the clinical context.

There has also been an increased interest in coding the affective qualities of interactions, in part as a result of the many studies that have found relationships between depression and behavior problems in families. Some code systems have superimposed a more subjectively based valence code over the behavioral dimension. It is possible, for example, to code compliant behavior that has either positive or negative accompanying affect (Dishion et al., 1984). Other observational systems code specific affects, such as anger, contempt, whining, sadness, or fear directly (Gottmann & Levenson, 1986), or code *categories* of affect, such as aversion, dysphoria, happiness, or caring (Hops & Davis, 1995). The work on affective coding in child and family behavioral assessment is relatively recent, and the empirical findings are sparse. In addition, most of this work has been conducted in a research context, and its direct applicability to clinical assessment and intervention is just now being explored. Nevertheless, it would appear that this promising trend in the observational assessment of children and families will likely continue.

Settings for Observation

Following from a situation-specific view of behavior, observational assessments with children have been carried out in a wide range of settings, the most common of which are the clinic, the home, and the classroom (Harris & Reid, 1981; Zangwill & Kniskern, 1982). Other examples of observational settings have included institutional environments, such as

group homes for delinquent adolescents, living environments for intellectually disabled or autistic children, playgrounds, supermarkets, and children's groups. More specific situations within each of these global settings have also provided structure for observation—for example, free play versus command-compliance instructions in the clinic, or observation at mealtime versus bedtime in the home.

A major concern associated with the choice of observational settings has been the degree of control imposed on the situation by the assessor. Assessors have previously emphasized the importance of observation in the child and family's natural environment, imposing the least amount of structure as possible, to see things "as they typically occur." This emphasis has reflected a reaction against the nonrepresentative and exclusive clinic observations characteristic of many clinical child assessments. Although *in situ* assessment is still recognized as an important part of DSA with children, there is also an increased recognition that unstructured observations—in the home or preschool, for example—may not always be the most efficient or practical method for obtaining samples of the behaviors of interest.

Observation in natural environments may be especially unrevealing with behaviors that occur at a low rate or that are especially reactive to observation. Many nonstructured family and peer interactions consist of no interactions or low-rate "chatty" exchanges (Mash & Barkley, 1986). For example, in one study of nonproblem families, over one-third of the observations were characterized by mutual noninvolvement of family members (Baskett, 1985). In another study, in which dominance and dependent behaviors were observed in the preschool, almost 8 weeks of observation were required to obtain generalizable data (Moskowitz & Schwarz, 1982). Such findings suggest that, in some circumstances, the use of "evocative" situations to highlight infrequently occurring response systems may prove to be a more efficient and reliable assessment strategy than the use of unstructured naturalistic observations.

In further contrasting naturalistic and structured observations, the assumption that home observations are "natural" and that observations in the clinic or laboratory are "artificial" is an oversimplification. Home observations may at times provide us with artificial reactions to natural conditions, whereas clinic observa-

tions may provide us with natural reactions to artificial conditions. Which information is more meaningful depends a great deal on the purpose of the assessment. When cross-setting comparisons of behavior (e.g., home vs. clinic) do not agree, this cannot be assumed to be a function of the unrepresentativeness of behavior in the clinic, unless there is some independent verification of the representativeness of the home observation. In most instances there is no such verification; therefore, it is inaccurate to equate representativeness with the naturalness of the physical setting, as is often done.

When home or classroom observations have been neither feasible nor appropriate, a variety of structured laboratory or clinic observation settings for sampling the behaviors of interest may be utilized (Hughes & Haynes, 1978). Such analogue situations have provided a wide range of structures for assessing parent-child behaviors, including free-play interactions between parent and child; a variety of command-compliance situations, such as the parent having the child clean up or put away play materials, or occupy him- or herself while the parent is busy reading or talking on the telephone; academic task situations; problem-solving situations, such as figuring out how to play a game together; and highly structured observations of the social reinforcement properties or punishment styles of parents. The range of potentially relevant analogue situations to be used in assessment is restricted only by the ingenuity and physical resources of the assessor. The challenge, however, is for systematic assessments of reliability and validity that permit the use of more standardized, psychometrically well-developed, and practical analogues than have been the case to date (Mash & Foster, 2001).

Using and Interpreting Observational Data

Direct observational data are utilized for a number of assessment purposes: They can serve as a basis for making recommendations for treatment and be used to monitor treatment progress and outcomes. Perhaps the most frequent but least understood use is with respect to treatment, because the processes by which direct observations have been translated into clinical recommendations are often poorly defined, unspecified, or oversimplified. However, in practice, these types of observation-based treatment recommendations represent informal hypothesis testing rather than systematically or

empirically derived outcomes. It is also not clear whether such recommendations represent the fitting of observations to preferred and/or common hypotheses, or the derivation of hypotheses that are genuinely based on what has been observed.

Interpretations of observational data have typically followed from summarizations of child behavior-adult response sequences over relatively brief time intervals. It is often the pattern of behavior based on interactional responses in immediately adjacent time intervals about which interpretations are made, with the assumption that immediate cues and reactions serve as major controlling events. For example, a mother's reaction to her child's behavior is assumed to follow from the child's response that preceded it. However, the causes for both child and adult behavior may emanate from more remote points in observational sequences than those immediately adjacent in time; there is a need for empirical and conceptual criteria that can be utilized to formulate interpretations of observational data based on stylistic patterns of responding, and in relation to more distal controlling events.

Perhaps the most recurrent issue in the use of observational assessment procedures has been their feasibility of use in clinical practice, including concerns related to cost. The latter has been noted as one factor in the lack of observational procedures use by clinicians. Interestingly, the cost (including dry runs, observer time, travel costs, and data summarization) of a comprehensive observational assessment can amount to less than the cost of a comprehensive personality assessment (Reid et al., 1988).

Family Assessment Methods

Consistent with the conceptualization and treatment of childhood disorders in the context of the family (Alexander & Parsons, 1982; Sroufe & Fleeson, 1986), many measures designed to tap family functioning have been developed. Many of these "family measures" are being incorporated into the DSA of children and families (e.g., Foster & Robin, 1997). Myriad tools have been created for assessing relational problems in the family (Mash & Johnston, 1996b). For example, in the *Handbook of Family Measurement Techniques* (Touliatos, Perlmutter, Straus, & Holden, 2001), well over 1,000 instruments are reviewed. For more specific information related

to family assessment methods, the reader is referred to the comprehensive volumes on family assessment by Touliatos and colleagues (2001), Grotevant and Carlson (1989), Jacob and Tennenbaum (1988), and McCubbin and Thompson (1987).

Formal Testing with Children

The use of developmental scales, intelligence and achievement tests (Kamphaus, 2005), perceptual-motor tests, neuropsychological assessments (D'Amato, Fletcher-Janzen, & Reynolds, 2005; Yeates, Ris, & Taylor, 2000), personality tests, and many other instruments is common practice among clinicians who assess children and families (Kamphaus et al., 2000). The reader is referred to individual chapters in this volume for discussions of the utility of specific tests in DSA with specific populations of children, and to general resources describing the use of these other tests (e.g., Reynolds & Kamphaus, 2003a, 2003b; Sattler, 2001; Sattler & Hoge, 2006).

SUMMARY

In describing some of the more general issues characterizing the DSA of children and families in this introductory chapter, we have tried to set the stage for detailed discussions of the assessment of specific types of childhood disturbances in the chapters that follow. We have presented the view that DSA with children and families is best depicted as a problem-solving strategy for the clinical evaluation of disturbed children and families. This highly empirical approach to clinical child assessment uses theory and research to guide the selection of constructs to be assessed for a specific assessment purpose; the methods, informants, and measures to be used in the assessment; and the manner in which the assessment process unfolds. It involves the recognition that even with data from psychometrically strong measures, the assessment process is inherently a decision-making task in which the clinician must iteratively formulate and test hypotheses by integrating data that are often incomplete or inconsistent. Therefore, it is important to evaluate the accuracy and usefulness of this complex decision-making task in light of potential errors in data synthesis and interpretation, the costs associated with the assessment process

and, ultimately, the impact the assessment has on clinical outcomes for the children and families being assessed (Hunsley & Mash, 2007). Recent work in DSA has become increasingly systems oriented and sensitive to developmental parameters. A general theme we have emphasized in this introduction is that DSA of children and families is most meaningful when strategies are based on empirically established measurement principles and derived in relation to specific childhood disorders. This is the theme that underlies the chapters that follow.

PART II

Behavior Disorders

Attention-Deficit/Hyperactivity Disorder

Bradley H. Smith
Russell A. Barkley
Cheri J. Shapiro

Individuals with attention-deficit/hyperactivity disorder (ADHD), by definition, display difficulties with attention and/or impulse control and hyperactive behavior relative to most individuals of the same age and sex (American Psychiatric Association [APA], 2000). This is a prevalent disorder, with modern estimates indicating that at least 3.0 to 7.8% of the general population meet criteria for ADHD in studies in the United States and around the world (Biederman, 2005). Although ADHD is usually first diagnosed in childhood, it need not be so, with some cases not coming to clinical attention until adolescence or adulthood, if at all. Up to 67% of all cases arise in childhood, before 7 years of age (Applegate et al., 1997), with 98% or more developing by age 16 years (Barkley, Murphy, & Fischer, in press). ADHD typically persists into adulthood and is seen in 66% or more of cases diagnosed in childhood (Barkley, 2005).

ADHD causes significant impairment in the vast majority of major life domains, such as educational, family, and peer functioning, and may contribute to problems such as impaired personal safety, criminal behavior, and substance abuse (Barkley, Fischer, Smallish, & Fletcher, 2004, 2006; Molina & Pelham, 2003). The annual costs to society due to

ADHD are estimated to be in the billions of dollars (Jensen et al., 2005). Thus, it is an important disorder to identify properly and treat effectively. Unfortunately, ADHD presents as a heterogeneous disorder, and response to treatment may be somewhat idiosyncratic. Fortunately, there are good methods for diagnosing and treating ADHD (Smith, Barkley, & Shapiro, 2006). The key elements of state-of-the-art procedures for diagnosis and monitoring treatment response are presented in this chapter, including, but not limited to, heavy reliance on collateral information, ability to account for variations in task and situation, and frequently repeated data collection.

This chapter focuses primarily on evaluation of children and adolescents with ADHD. We start with a brief discussion of background and theory related to ADHD, including a detailed critique of the current diagnostic criteria for ADHD. We then describe three levels of assessment for ADHD: (1) the minimally sufficient assessment; (2) the ADHD checkup, which combines assessment and intervention; and (3) the assessment of response to intervention. A more detailed presentation on assessing and treating ADHD, including information on evaluating adults with ADHD, is found in Barkley (2005).

This chapter extends its predecessor in the third edition in two important directions. First, by incorporating motivational interviewing into the assessment, it is reconceptualized as an intervention in part designed to motivate parents and individuals with ADHD to better adopt and comply with intervention recommendations. We call this the “ADHD checkup,” or ACU, which is based on the “Family Checkup” (Dishion & Kavanagh, 2003) and the “drinker’s checkup” (Miller & Rollnick, 2002).

The second new direction emphasizes assessment as an ongoing process. It is critically important to evaluate response to treatment repeatedly and on a case-by-case basis. This is necessary because response to treatment, although commonplace at the group level (e.g., 65–85% of cases respond to medications for ADHD), is hard to predict at the individual level of analysis; therefore, treatment is never guaranteed to work. Whether it does so should be specifically evaluated (Barkley, 2005). Thus, every case of ADHD should be approached as an individualized case study, yet be feasible for most families and clinicians.

This chapter makes an additional departure from previous editions by eschewing a compendium approach, in which all available measures receive notice and comment in favor of a focus on a reduced set of procedures that are feasible and clinically meaningful. It provides a new, dynamic, intervention-focused approach to evaluation of ADHD. For instance, even though the criteria for ADHD specified by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; APA, 1994) have merit, they also suffer from some significant limitations. A DSM-IV diagnosis of ADHD alone provides only the most basic information to guide selection and evaluation of treatment. It must be supplemented by a person \times environment interaction, in which the symptoms of the disorder are conceded to have strong neurological and genetic underpinnings, whereas the extent of impairments in major life activities that arise from symptoms depend in large part on context and comorbidity. Therefore, we recommend that the scope of evaluation be expanded to include collecting data from multiple informants (e.g., parent and teacher knowledge of ADHD), assessing the extent of comorbid disorders and developmental/learning disabilities, comparing multiple environments associated with high and low func-

tioning, getting information on systemic factors that might influence diagnosis and treatment (e.g., marital discord, poor home-school communication, pertinent community resources), and assessing motivation or readiness to change. This is done with the ACU. Assessment should resemble not just a snapshot, but a dynamic video that informs treatment decisions by evaluating ongoing responses to intervention. Done efficiently, it can be acceptable, feasible, economical, and sustainable in settings in which the procedures are most needed, yet time and cost are crucial factors.

INCREMENTAL VALIDITY

A guiding principle in this chapter is the concept of incremental validity (Sechrest, 1963)—that purely redundant measures should be eliminated. This is especially true when the choice is between relatively inexpensive measures (e.g., standardized rating scales) and relatively expensive measures (e.g., structured interviews). The notion that “less is more” applied to redundant measures has both practical and scientific advantages (Cohen, 2003). Efficient nonredundant assessments place less of a burden on families, teachers, and practitioners, yet they achieve greater clarity and validity.

Unfortunately, many professionals use excessively lengthy, redundant assessment batteries or otherwise inefficient methods to seek unnecessary comprehensiveness (Pelham, Fabiano, & Massetti, 2005). This undermines the goal of making assessment feasible in most clinical settings. Practitioners should naturally make informed choices about assessment methods based on available evidence, allowing room for clinical judgment when such data are not available. We recommend that clinicians, and even researchers, should not waste their time routinely conducting structured diagnostic interviews for every child (e.g., Diagnostic Interview Schedule for Children [DISC]; Shaffer et al., 1996) because they add very little to clinical prediction or diagnostic accuracy beyond what is achieved with the far more efficient and cost-effective parent and teacher ratings scales (Pelham et al., 2005). Instead, we recommend a stepwise protocol in which symptom information is initially gained via rating scales, and screen-positive cases are further evaluated with semistructured interviews. Those interviews place emphasis on motivational interviewing

techniques to enhance treatment adoption and adherence.

We appreciate that our recommendation is probably more rigorous than what is normally done in contemporary clinical practice. For instance, primary care clinicians often make diagnostic and treatment decisions based primarily on parent reports (Wolraich, 2002). Although sometimes “less is more,” a multitude of biases exists in any single measure or source, giving a misleading view of the child. Instead, a multitrait-multimethod (MTMM; Campbell & Fiske, 1959) approach is indicated, but not slavishly so. It is surely expedient to rely on a simple, easy to collect measure, such as a parent rating scale, but it may be problematic for various reasons (i.e., parental bias due to maternal depression or anti-ADHD stories in the media). To paraphrase H. L. Menken, “For every complex problem, there is a simple solution—and it is wrong.”

CHAPTER OVERVIEW

We begin with a brief overview of ADHD, covering the history, definition and primary problems, diagnostic criteria, onset and life course, prevalence, gender differences, etiologies, and predictors of outcomes. We then briefly review Barkley’s theory of ADHD, because it can guide assessment and conceptualization of this disorder. We then describe the ACU. This approach includes “guided participation” or “motivational interviewing” that has a solid theoretical and empirical basis in other clinical populations (Dishion & Kavanagh, 2003; Miller & Rollnick, 2003; Sanders & Lawton, 1993). Thereafter, we make some recommendations for assessing adults with ADHD. The strong genetic basis to ADHD means that parents are likely to have the same disorder, so assessing adults may be a supplemental activity to the evaluation of the child. Also, because ADHD tends to be a chronic disorder, it seems important to take a lifespan perspective on its assessment. Finally, we provide some information on assessing response to treatment. For the specific details of treatment, we direct the interested reader to other volumes (e.g., Smith et al., 2006) and manuals or training materials (e.g., Barkley, 1997d) that have a strong evidence base (see Pelham, Wheeler, & Chronis, 1998).

The process of assessment typically changes the attributes being measured—what metho-

dologists often call “reactivity,” which is typically viewed as a negative confound in the evaluation process (Webb, Campbell, Schwartz, & Sechrest, 1966). Yet through the guided participation process, reactivity can be harnessed as a positive force in the therapeutic process. Thus, assessment should be regarded as the initial phase of intervention. Furthermore, good intervention includes continued assessment in an interactive or dialectical process.

OVERVIEW OF ADHD

Over the prior 25 years (Barkley, 1981) there has been tremendous change in the conceptualization of and criteria for diagnosing ADHD, with growing consensus that “ADHD” is heterogeneous, comprising a set of disorders or subtypes. Diagnosis involves looking at two sets of core symptoms (i.e., inattention and hyperactivity/impulsivity) and determining whether the disorder is predominately related to either set or to their combination. Yet future diagnostic criteria might need to consider a third set of core symptoms of ADHD, such as sluggish cognitive tempo, that may define a qualitatively different subset of children (Milich, Balentine, & Lynam, 2001; Todd, Rasmussen, Wood, Levy, & Hay, 2004).

History

A more extensive history can be found in the text by Barkley (2005). The first clinical description of children with symptoms of ADHD was published over 100 years ago. In a series of three lectures to the Royal College of Physicians in England, George Still described children in his clinical practice who were quite aggressive, defiant, resistant to discipline, highly emotional, poorly inhibited, and otherwise lacking in self-control (Still, 1902). Most were also excessively active and distractible, with poorly sustained attention to tasks. Such children would probably now be viewed as having not only ADHD but also oppositional defiant disorder (ODD) or even conduct disorder (CD) (APA, 2000).

During the next 35 years, few papers appeared on this subject in children, presumably as a consequence of two world wars. Papers that were published in relation to the disorder or its symptoms focused on either (1) the en-

cephalitis epidemic of the early part of that century as causing such symptoms or (2) the motor restlessness that characterized these children (Childers, 1935; Levin, 1938). Scant attention was given to disturbances in self-regulation and social conduct.

More widespread interest in these children did not emerge until after World War II. At that time, the highly influential writings of Strauss and Lehtinen (1947) and their colleagues advocated that restless and inattentive behavior was de facto evidence of brain damage in children. The term “minimal brain damage” was coined to refer to these children, and strict guidelines were advocated for their education.

Conclusions concerning brain damage as a cause of hyperactivity became less frequent over time, though brain dysfunction was believed somehow to be related to the disorder. This resulted in a softening of the terminology for the disorder from “minimal brain damage” to “minimal brain dysfunction” (Wender, 1971). Eventually, the link with neurological damage was dropped from the diagnostic terminology. Nevertheless, the association of ADHD with abnormal brain functioning remained strong until the 1970s, when a series of publications disputed the relationship to brain damage (Rutter, 1977).

Increasing emphasis on excessive motor activity as the central symptom of the disorder arose from the 1950s through the 1970s. Some authors (Laufer, Denhoff, & Solomons, 1957) posited a possible defect in the filtering of stimuli in the central nervous system as the cause, allowing excessive stimulation to reach the cortex. Later, others viewed the disorder as simply a daily rate of motor activity significantly deviant from that of normal children (Chess, 1960; Werry & Sprague, 1970), without reference to its origins. The disorder began to be known by its behavioral symptoms instead, such as “hyperactive child syndrome” (Chess, 1960) or “hyperkinetic reaction of childhood” (APA, 1968).

By the mid-1970s, evidence suggested that hyperactive children also had major deficits with sustained attention and impulse control. Douglas and Peters (1979) argued that the disorder comprised impairments in (1) investment, organization, and maintenance of attention; (2) inhibition of impulsive responding; (3) modulation of arousal levels to meet situational demands; and (4) a strong tendency to seek immediate reinforcement. Excessive mo-

tor activity was viewed as being problematic, but the core deficit of the disorder was proposed to involve attention and inhibitory problems.

The APA (1980) eventually relabeled the disorder as “attention deficit disorder ([ADD] with or without hyperactivity)” in DSM-III, in part as a result of Douglas’s (1983) influential reviews on the field. The change essentially demoted hyperactivity to an unnecessary or simply a related characteristic, yet one that could be used to create subtypes of the disorder based on its presence or absence (APA, 1980).

Later in the 1980s, the disorder was relabeled yet again as “attention-deficit/hyperactivity disorder” in DSM-III-R (APA, 1987), suggesting a reemergence of the importance of hyperactivity as one of the central features of the disorder, equal in import to the other features (i.e., inattention and impulsiveness). The subtyping scheme of “without hyperactivity” was demoted in this revision, not because children who are primarily inattentive do not exist, but because it was unclear at the time whether they represented a true subtype of this disorder or a separate diagnostic entity altogether (Barkley, 1990; Carlson, 1986). Clinicians could label such children as having “undifferentiated attention deficit disorder” but were provided no criteria for diagnosis, nor was the relationship of this disorder to ADHD clarified. More research was recommended before the answers to these issues could guide such a taxonomic enterprise.

Across the 1980s, many scientists came to posit that the central deficiency in ADD/ADHD children was poor executive functioning or poor self-regulation of behavior (Barkley, 1981, 1990; Douglas, 1983; Kendall & Braswell, 1985). This trend continues to the present (see below; Barkley & Murphy, 2006). It resembles in some respects a return to Still’s (1902) earlier notions that deficits in volitional inhibition and moral regulation of behavior explain the disorder, if the moral regulation is taken to mean the selection of actions as a function of their future consequences for oneself and for others, as Still intended.

In 1994, when the DSM was once again revised (DSM-IV), several important changes were added to the diagnostic criteria. These are discussed in detail later in the chapter. Suffice it to say here that the option of diagnosing children with a subtype of the disorder characterized by primary attention problems without

hyperactivity or impulsiveness has been restored to this taxonomy, despite continuing scientific uncertainty over whether children who are primarily inattentive actually represent a subtype of ADHD or an entirely separate disorder (Barkley, 2005; Barkley, Grodzinsky, & DuPaul, 1992; Lahey & Carlson, 1992; Milich et al., 2001).

In DSM-III-R (APA, 1987), an attempt was made to draw upon the results of factor-analytic studies of child behavior rating scales to aid expert opinion in the selection of symptoms (Spitzer, Davies, & Barkley, 1990). A small-scale field trial employing 500 children from multiple clinical sites was conducted to narrow down the potential list of symptoms and to specify a cutoff score on this list that best differentiated between children with ADHD and other diagnostic groups. In the most recent revision (APA, 2000), DSM-IV-TR criteria are based on a better field trial and more thorough analysis of its results (Applegate et al., 1997; Lahey et al., 1994). These DSM-IV-TR criteria appear in Table 2.1 and are discussed in detail in a separate section.

Definition and Primary Symptoms

The term “symptom” as used here refers to a behavior (e.g., skips from one uncompleted activity to another) or group of behaviors that covary (e.g., inattention) and are believed to represent a dimension of a mental disorder. We want to distinguish between the terms “symptom” and “impairment,” because the two are often confused in clinical discussions of disorders. Impairments are consequences or outcomes of symptoms or symptom classes, such as retention in a grade; failure to graduate from high school; and proneness to vehicular crashes or license suspensions, teen pregnancy, or criminal arrests. In this section we describe the major symptom dimensions of ADHD. Related impairments are described elsewhere in the chapter.

There is strong consensus that ADHD is defined by two clusters of symptoms: inattention and hyperactivity–impulsivity (Barkley, 2005). These core symptoms of ADHD are correlated with each other, but growing information indicates that they are partially distinct, such that individuals having largely one set of symptoms (inattention, mainly) and not the other (hyperactive–impulsive behavior) may describe a qualitatively different group, and possibly a

different disorder (Diamond, 2005; Milich et al., 2001; Nigg et al., 2005). Thus, a person diagnosed with ADHD may have problems related to inattention or hyperactivity–impulsivity, or typically both. Available evidence indicates that by adulthood, this two-dimensional structure could evolve into a three-dimensional one, in that symptoms of largely verbal impulsiveness come to form a dimension separate from that of hyperactivity (Barkley et al., in press). Some have argued that other dimensions of ADHD may also exist (e.g., slowed cognitive tempo, discussed in more detail later). These dimensions have not yet been incorporated into the definition of ADHD. Therefore, this section focuses on the well-established core symptoms of inattention and hyperactivity–impulsivity.

Inattention

The construct of attention as studied in neuropsychology is multidimensional and may refer to alertness, arousal, selectivity, focus, encoding, sustained attention, distractibility, or span of apprehension, among others (Barkley, 1988; Hale & Lewis, 1979; Mirsky, 1996; Strauss, Thompson, Adams, Redline, & Burant, 2000). However, the number of distinct components identified in neuropsychological batteries remains unclear (Strauss et al., 2000). Research shows that those with ADHD do not have significant difficulties with automatically orienting to visual information, which may be mediated by posterior brain attention circuits (Nigg, 2006). Instead, they have their greatest difficulties with aspects of attention related to persistence of effort, or sustaining attention to tasks, sometimes called vigilance (Douglas, 1983; Newcorn et al., 2001; Swaab-Barneveld et al., 2000). These deficits are believed to be mediated through largely frontal brain attention circuits (Nigg, 2006).

Difficulties with persistence are sometimes apparent in free-play settings, as evidenced by shorter durations of play with each toy and frequent shifts in play across various toys (Barkley & Ullman, 1975; Routh & Schroeder, 1976; Zentall, 1985). However, inattention is most dramatically apparent in situations requiring the child to sustain attention to dull, boring, repetitive tasks (Barkley, DuPaul, & McMurray, 1990; Fischer, Barkley, Smallish, & Fletcher, 2005; Newcorn et al., 2001; Zentall, 1985). Examples of such tasks include independent

TABLE 2.1. DSM-IV-TR Criteria for ADHD

A. Either (1) or (2):

- (1) six (or more) of the following symptoms of **inattention** have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

Inattention

- (a) often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
- (b) often has difficulty sustaining attention in tasks or play activities
- (c) often does not seem to listen when spoken to directly
- (d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
- (e) often has difficulty organizing tasks and activities
- (f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as school work or homework)
- (g) often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools)
- (h) is often easily distracted by extraneous stimuli
- (i) is often forgetful in daily activities

- (2) six (or more) of the following symptoms of **hyperactivity–impulsivity** have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

Hyperactivity

- (a) often fidgets with hands or feet or squirms in seat
- (b) often leaves seat in classroom or in other situations in which remaining seated is expected
- (c) often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
- (d) often has difficulty playing or engaging in leisure activities quietly
- (e) is often “on the go” or often acts as if “driven by a motor”
- (f) often talks excessively

Impulsivity

- (g) often blurts out answers before the questions have been completed
- (h) often has difficulty awaiting turn
- (i) often interrupts or intrudes on others (e.g., butts into conversations or games)

B. Some hyperactive–impulsive or inattentive symptoms that caused impairment were present before age 7 years.

C. Some impairment from the symptoms is present in two or more settings (e.g., at school [or work] and at home).

D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of a Pervasive Developmental Disorder, Schizophrenia, or other Psychotic Disorder, and are not better accounted for by another mental disorder (e.g., Mood Disorder, Anxiety Disorder, Dissociative Disorder, or a Personality Disorder).

Code based on type:

314.01 Attention-Deficit/Hyperactivity Disorder, Combined Type: if both Criteria A1 and A2 are met for the past 6 months.

314.00 Attention-Deficit/Hyperactivity Disorder, Predominantly Inattentive Type: if Criterion A1 is met but Criterion A2 is not met for the past 6 months

314.01 Attention-Deficit/Hyperactivity Disorder, Predominantly Hyperactive–Impulsive Type: if Criterion A2 is met but Criterion A1 is not met for the past 6 months.

Coding note: For individuals (especially adolescents and adults) who currently have symptoms that no longer meet full criteria, “In Partial Remission” should be specified.

Note. Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*. Copyright 2000. American Psychiatric Association.

schoolwork (Hoza, Pelham, Waschbusch, Kipp, & Owens, 2001), homework or chore performance (Danforth, Barkley, & Stokes, 1991), and certain experimental lab tasks (Newcorn et al., 2001; Swaab-Barneveld et al., 2000).

Another problem is distractibility, or the likelihood that a child responds to the occurrence of extraneous events unrelated to the task. Parents and teachers often rate this symptom as significantly elevated among children with ADHD. The findings for such distracting irrelevant stimulation, however, appear to be a function of whether the distractors are contained within the task or outside of the task materials. Some researchers find that stimulation embedded in the task materials worsens the performance of children with ADHD (Barkley, Koplowitz, Anderson, & McMurray, 1997; Brodeur & Pond, 2001; Marzocchi, Lucangeli, De Meo, Fini, & Cornoldi, 2002; Rosenthal & Allen, 1980). This appears to be the case even with video games (Lawrence et al., 2002). Others find no such effect when studying teens with ADHD (Fischer, Barkley, Fletcher, & Smallish, 1993), suggesting a possible age-related improvement in this specific problem (Brodeur & Pond, 2001). One study found an enhancing effect on attention from intratask stimulation (Zentall, Falkenberg, & Smith, 1985). Thus, within-task cues appear to be key to engaging attention of children with ADHD.

Research supports the notion that impaired attention processes in individuals with ADHD are part of a larger domain of cognitive activities known as executive functioning (EF), and especially working memory (i.e., holding information in mind that one is using to guide performance toward a goal, or remembering to do so (Barkley, 1997b, 1997c; see Martinussen, Hayden, Hogg-Johnson, & Tannock, 2006, for a meta-analysis). Specifically, evidence from the development of rating scales indicates that the DSM items used to define the attention deficits in ADHD load on a larger dimension containing items reflecting EF and, specifically, working memory (Conners, Sitarenios, Parker, & Epstein, 1998; Gioia, Isquith, Guy, Kenworthy, & Baron, 2000). Such attention ratings also correlate significantly with neuropsychological tests of working memory and EF in contrast to those of hyperactive or impulsive behavior (Martinussen & Tannock, 2006). Thus, assess-

ment of ADHD might be improved by adding measures of EF (Jarratt, Riccio, & Siekierski, 2005), but the value of adding such measures has not been thoroughly evaluated.

Impulsivity

A second dimension of ADHD is a deficiency in inhibiting behavior. Usually it is strongly associated with hyperactivity and may be the source of it. Like attention, impulsivity is also multidimensional in nature (Nigg, 2006). Recent theories of impulsivity have focused on the capacity to inhibit or delay prepotent responses, particularly in settings in which those responses compete with rules (Barkley, 1997b). A prepotent response is one that gains the immediate reinforcement (i.e., reward or escape) available in a given context, or that has a strong history of such reinforcement in the past. Though symptoms of impulsivity intercorrelate with those of hyperactivity in childhood strongly enough to form a single dimension, by adulthood, symptoms related to verbal behavior become partially distinct from hyperactivity and motor impulsivity (Barkley et al., in press).

The combined type of ADHD may have several reward-related deficits (Luman, Oosterlaan, & Sergeant, 2005), including difficulties with sustained inhibition of such dominant responses over time (Nigg, 2006), poor delay of gratification (Rappoport, Tucker, DuPaul, Merlo, & Stoner, 1986), a steeper discounting of the value of delayed over immediate rewards (Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001), and impaired adherence to commands to inhibit behavior in social contexts (Danforth et al., 1991). This inhibitory deficit may also include difficulty interrupting an already ongoing response pattern (Schachar, Mota, Logan, Tannock, & Klim, 2000), particularly when given feedback about performance and errors. In the latter case, perseverative responding may be evident despite negative feedback concerning such responding, perhaps reflecting an insensitivity to errors (Wiersema, van der Meere, & Roeyers, 2005).

Children with ADHD tend to be more active, restless, and fidgety than their non-ADHD peers (Porrino et al., 1983; Teicher, Ito, Glod, & Barber, 1996). As with the other symptoms, there are significant situational

fluctuations in this symptom class (Luk, 1985; Porrino et al., 1983). Level of activity does not always distinguish between ADHD and other clinic-referred groups of children (Werry, Reeves, & Elkind, 1987), though its pervasiveness across settings may do so (Taylor, 1986). Such hyperactivity declines significantly across the elementary school years, whereas problems with attention persist at relatively stable levels during this same period of development (Barkley, Fischer, Edelbrock, & Smallish, 1990; Hart, Lahey, Loeber, Applegate, & Frick, 1995; Wolraich et al., 2005). This implies that hyperactivity reflects an early developmental manifestation of a more central deficit in behavioral inhibition that may arise ahead of problems with attention, while declining more steeply with age. Studies that factor-analyze behavior ratings consistently show that hyperactivity and poor impulse control form a single dimension of behavior (DuPaul, 1991; Hinshaw, 1987; Molina, Smith, & Pelham, 2001), at least in children. As noted earlier, by adulthood, verbal impulsiveness may become partially decoupled from the former dimension (Barkley et al., in press). Accordingly, impulsivity and hyperactivity are currently collapsed into a single dimension in ADHD assessment with DSM-IV criteria. This deficit in inhibition, of which early hyperactivity is a part, may become increasingly reflected in poor self-regulation over various developmental stages, even though the difficulties with excessive activity level may wane with maturation (Barkley, 1997a; Barkley et al., in press).

Difficulties with adherence to rules and instructions are also evident in children with ADHD (APA, 2000; Barkley, 1997b). They typically have significant problems with compliance with parental and teacher commands (Danforth et al., 1991) and often do not follow experimental instructions in the absence of the experimenter (Draeger, Prior, & Sanson, 1986) or adhere to directives to defer gratification or resist temptations (Rapport et al., 1986). Like the other symptoms, rule-governed behavior is a multidimensional construct (Hayes, 1989). It remains to be shown which aspects of this construct are specifically impaired in ADHD and to what extent impairments in rule-governed behavior are secondary to the primary symptoms of ADHD (i.e., inattention and impulsivity).

Assessment Implications

The preceding brief review should make it clear that ADHD does not present as a unitary phenomenon. Assessors need to be prepared to deal with variability within and across persons. Yet it may be possible for a person with ADHD to appear focused, persistent, and well controlled in novel, stimulating, or highly rewarding activities or situations. Thus, being attentive and apparently self-disciplined on some occasions does not rule out a diagnosis of ADHD. Indeed, a comprehensive assessment of ADHD will identify situations in which there are few, if any, problems. These situations can be used to highlight positive influences on the behavior of the person with ADHD.

Diagnostic Criteria

DSM-IV criteria (see Table 2.1) are the most widely recognized and accepted criteria for diagnosing ADHD (Kupfer et al., 2000). Generally speaking, there is good support for most of these criteria, especially when they are applied to children (Barkley, 2005). But some significant problems that do exist argue for some latitude in adherence to DSM-IV criteria and anticipation of future refinements based on empirical evidence.

The key elements of the DSM-IV criteria for ADHD may be summarized by the following seven concepts.

1. Individuals with ADHD may have problems related to inattention, hyperactivity/impulsivity, or both.
2. These deficits are significantly inappropriate for the person's age.
3. The disorder should have an onset in childhood.
4. The condition is generally chronic or persistent over time.
5. The core symptoms are significantly pervasive or cross-situational in nature.
6. The deficits are not the direct result of severe language delay, deafness, blindness, or another psychiatric condition, such as autism, depression, or psychosis, that may better explain the symptoms.
7. The core symptoms of ADHD must be causally associated with significant impairment in major life activities, such as educational, familial, social, vocational, adaptive

(self-sufficiency), or other significant areas of life functioning.

DSM-IV Subtypes

The three subtypes set forth in DSM-IV are somewhat self-explanatory and comprise the predominately inattentive subtype (ADHD-I), the predominantly hyperactive-impulsive subtype (ADHD-HI), and the combined subtype (ADHD-C). These subtypes are formed on the basis of the two symptom lists or dimensions presented in the criteria (Burns, Boe, Walsh, Sommers-Flanagan, & Teegarden, 2001; DuPaul et al., 1998; Gioia et al., 2000; Lahey et al., 1994). These dimensions have been replicated across various countries and ethnic groups, including Puerto Rico (Bauermeister et al., 1995); Native Americans (Beiser, Dion, & Gotowiec, 2000); U.S. ethnic groups (DuPaul et al., 1998); Australia (Gomez, Harvey, Quick, Scharer, & Harris, 1999); Brazil (Rasmussen et al., 2002); and, Spain, Germany, and the United States (Wolraich et al., 2003).

Some researchers now find another construct or dimension of inattention symptoms that is not represented in the DSM-IV-TR inattention list. Indeed, the symptoms were eliminated as a result of a field trial that showed them to have low or weak association with the other inattention symptoms (see Lahey et al., 1994). Yet this subset of symptoms is becoming useful in identifying another subtype of inattentive children, and possibly adults. This dimension represents a sluggish cognitive tempo, or SCT, and its typical symptoms include children being more sluggish, passive, hypoactive, daydreamy, slow-moving, prone to stare, confused, and “in a fog” than are normal children or those with ADHD-C (McBurnett, Pfiffner, & Frick, 2001; Milich et al., 2001; Todd et al., 2004). Indeed, some of these symptoms are the very antithesis of ADHD (e.g., hypoactivity).

Given that SCT may be a valid and distinct dimension of inattention, evidence suggests that clinicians need to recognize one dimension of hyperactivity/impulsivity and two distinct dimensions of inattention. The first inattention dimension is the well-known and overwhelmingly established set of inattentive symptoms set forth in the DSM and in many child behavior rating scales. Children with these symptoms can be thought of as impersistent-distractible-forgetful. The second dimension of inattention

reflects a daydreamy-staring-confused quality that is more passive and lethargic in form and associated with slow-inaccurate information processing. This dimension of inattention is not currently addressed by DSM-IV-TR, requiring examiners to take care to evaluate its existence apart from DSM-IV-T- based rating scales and interviews.

Developmentally Inappropriate Behavior

Individuals with ADHD are certainly significantly different than their peers on measures of attention span, activity level, and impulse control (Barkley, 2005; Biederman, 2005; Fischer et al., 2005; Nigg, 2005; Wolraich et al., 2005). However, as mentioned previously, there are different types of inattention, overactivity, and impulsivity, and not all of the numerous ways to measure them have consistently revealed differences between individuals with and without ADHD (Firestone & Martin, 1979; Sandberg, Rutter, & Taylor, 1978). The inattention problems usually exhibited by persons with ADHD-C are the inability to sustain attention and to persist in responding to tasks or play activities for as long as other children of the same age (Barkley, 1997c, 2005; Hoza et al., 2001). An inability to follow through on rules and instructions is also evident. Among the most distinctive symptoms, however, is the proneness to distractibility (Barkley et al., in press; Milich, Widiger, & Landau, 1987). Another common manifestation of inattention is being more disorganized and forgetful than other children the same age (Barkley, DuPaul, & McMurray, 1990). Researchers employing objective measures corroborate their presence in persons with ADHD (Corkum & Siegel, 1993; Luk, 1985; Milich & Lorch, 1994; Schachar, Tannock, & Logan, 1993). These behaviors distinguish them from individuals with learning disabilities (Barkley, DuPaul, & McMurray, 1990) or other psychiatric disorders (Werry, Reeves, & Elkind, 1987). This symptom class correlates significantly with measures of working memory and EF; therefore, it likely represents a broader domain of cognitive impairment, most likely EF, than merely inattention (Barkley et al., in press; Gioia et al., 2000; Matinussen et al., 2006; Matinussen & Tannock, 2006).

Children with ADHD-HI or ADHD-C often exhibit difficulties with excessive activity level.

This is often manifested in greater fidgetiness; not staying seated when it is required; moving about, running, and climbing more than other children; playing noisily; talking excessively; often interrupting others' activities; and being less able than others to wait in line or take turns in games (APA, 1994). A problem with inhibition is also evident in many of these same complaints. Parents and teachers describe the children as being incessantly in motion and unable to wait for events to occur. As noted previously, research has objectively documented that they are more active than other children. Furthermore, children with ADHD-HI or ADHD-C come across as being relatively immature in controlling motor overflow movements (Denckla & Rudel, 1978); have considerable difficulties stopping an ongoing behavior (Hartung, Milich, Lynam, & Martin, 2002; Schachar et al., 1993); talk more than others (Barkley, Cunningham, & Karlsson, 1983); are less able to resist immediate temptations and delay gratification (Anderson, Hinshaw, & Simmel, 1994; Campbell, Pierce, March, Ewing, & Szumowski, 1994; Rapport et al., 1986); and tend to respond too quickly and too often when they are required to wait and watch for events to happen, as is often seen in impulsive errors on continuous performance tests (CPTs; Corkum & Siegel, 1993; Frazier, Demareem, & Youngstrom, 2004).

Although less frequently examined, differences in activity and impulsiveness have been found between children with ADHD and those with learning disabilities (Barkley, DuPaul, & McMurray, 1990) or other psychiatric disorders (Frazier et al., 2004; Halperin, Matier, Bedi, Sharma, & Newcorn, 1992; Werry, Reeves, & Elkind, 1987). Hyperactivity appears to diminish with advancing age; however, impulsivity and related impairments appear to persist for most individuals diagnosed with ADHD during childhood (Biederman et al., 2006; Wilens & Dodson, 2004).

Onset in Childhood

A formal diagnosis of ADHD by DSM-IV criteria requires documentation of early onset, arbitrarily defined as before age 7. There is minimal empirical justification for this cutoff (Applegate et al., 1997; Barkley & Biederman, 1997), with as many as 35% of children and 50% of adults with ADHD having onset of dis-

order after age 7 years (Barkley, Fischer, et al., 2006). We strongly encourage evaluators to use discretion regarding the onset prior to age 7 years requirement, preferring ourselves to use an onset of prior to 16 years of age to capture all legitimate cases of disorder (Barkley, Fischer, et al., 2006).

The key point of the early-onset requirement is that ADHD is usually a chronic disorder, with problems presumably having a biological basis that disrupts functioning in childhood. If inattention or impulsivity emerge suddenly or later in adulthood, then the assessor is advised to consider other disorders (e.g., depression) or to label the case as one of *acquired* ADHD secondary to (specify known etiology). Careful interviewing about the history of impairment is required if an older child or adolescent is presenting for treatment or for functional problems that have "sudden onset."

Studies of the developmental course and outcome of children with ADHD have been numerous and are only briefly summarized here. More detailed reviews are provided by others (Barkley, 2005; Biederman, 2005; Pelham, Fabiano, & Massetti, 2005; Weiss & Hechtman, 1993). Although some children with ADHD are reported to have been difficult in terms of their temperament since birth or early infancy (Barkley, DuPaul, & McMurray, 1990; Campbell et al., 1994), the majority appear to be identifiable as deviating from normal by their caregivers between 3 and 4 years of age (Lahey et al., 2004). However, for a variety of reasons, it may be several years before such children are brought to the attention of professionals (Foy & Earls, 2005).

A diagnosis of ADHD among preschoolers may be more difficult due to higher rates of disruptive behavior among the normal population at this age. Nevertheless, recent studies suggest that a reliable and valid diagnosis can be made for children as young as 3 years, 7 months old (Lahey et al., 2006). However, precision and reliability in diagnosis of subtypes of ADHD do not appear to stabilize until children are about 7 or 8 years old (Barkley, Fischer, et al., 1990; Lahey, Pelham, Loney, Lee, & Willcutt, 2005).

During their preschool years, children with ADHD are often excessively active, mischievous, noncompliant with parental requests, and difficult to toilet train (Campbell et al., 1994; Hartsough & Lambert, 1985; Mash &

Johnston, 1982). They may also already be manifesting some delays in academic readiness skills (Mariani & Barkley, 1997). Parental distress over child care and management is likely to reach its zenith when children are between 3 and 6 years of age, declining thereafter as the deficits in attention and rule-following improve (Barkley, Karlsson, & Pollard, 1985; Mash & Johnston, 1982).

Despite the decline from peak parenting distress in the later preschool years, the stress parents report in raising children with ADHD remains considerably higher than stress levels reported by parents of children in control groups (Anastopoulos, Guevremont, Shelton, & DuPaul, 1992; Bussing et al., 2003; Fischer, 1990). Likewise, parents of teenagers with ADHD report high levels of stress and family conflict with these youth, particularly if the youth carries a comorbid diagnosis of ODD (Barkley, Anastopoulos, Guevremont, & Fletcher, 1992; Barkley et al., 1991; Edwards, Barkley, Laneri, Fletcher, & Metevia, 2001).

By entry into formal schooling (i.e., 5 or 6 years of age), most children with ADHD have become recognizably deviant from normal peers due to poor sustained attention, impulsivity, or restlessness. Difficulties with aggression, defiance, or oppositional behavior may have emerged or will begin to emerge, if they did not manifest earlier in development (Barkley, Fischer, et al., 1990; Barkley et al., 1991). Children with ADHD who develop these oppositional or antisocial behaviors are likely to veer into a more severe path of maladjustment in later years than are children with ADHD who do not develop aggressive-defiant behaviors, or who do so only to a limited degree (Barkley et al., 2004). During these elementary school years, the majority of children with ADHD have varying degrees of poor school performance, usually related to failure to finish assigned tasks in school, relatively high rates of missing homework or long-term assignments, disruptive behavior during class activities, and increasingly poor peer relations. Learning disabilities in areas of reading, spelling, math, handwriting, and language, however, may also become manifest in a significant minority of children with ADHD, requiring additional evaluation and special educational assistance beyond that typically needed to manage the ADHD symptoms (Barkley, 2005; Tannock & Brown, 2000).

Persistent Life Course

Thirty years ago, there was a widespread belief that ADHD was a self-limiting disorder that typically remitted shortly after puberty (Brown & Borden, 1986). In the meantime, several well-conducted longitudinal studies have shown that 40–80% of children continue to have the disorder into adolescence (Barkley, Fischer, et al., 1990; Biederman, Faraone, Milberger, et al., 1996; Hinshaw, Owens, Sami, & Fargeon, 2006; Mannuzza et al., 1991; Weiss & Hechtman, 1993). Many children with ADHD who putatively “outgrow” their symptoms during adolescence may be borderline cases that switch back and forth between a diagnosed and a nondiagnosed status. Moreover, those who have subclinical levels of ADHD as adolescents are often significantly impaired relative to their peers (Molina & Pelham, 2003).

We believe that many of these borderline or impaired cases might be consistently diagnosed with ADHD if more developmentally appropriate diagnostic criteria were employed. Unfortunately, the DSM-IV-TR criteria were written primarily for children and field-tested primarily with elementary school-age students (age range, 4–16 years). As a consequence, some ADHD diagnostic criteria are less relevant to adolescents, who generally show a decline in hyperactive behavior (Barkley, 2005). For example, except in extremely rare cases, statements such as “Runs or climbs excessively” or “Cannot play quietly” no longer apply to postpubescent individuals with ADHD.

For adolescents with ADHD, family conflicts may continue or even increase (Barkley, Anastopoulos, et al., 1992; Fletcher, Fischer, Barkley, & Smallish, 1996) and may now center around failure of the teen to accept responsibility for performing routine tasks, difficulties with being trusted to obey rules when away from home, and impairments in problem-solving. Parents may try to compensate by adopting an authoritarian, highly emotional parenting style with an excessive use of ultimatums (Robin, 1990). This can result in a coercive interaction cycle that increases conflict and strains on the family.

Among the subset of teens with ADHD who have had significant problems with aggressive and oppositional behavior prior to being an adolescent, delinquency and conduct disorder are

likely to emerge, if they have not done so already, because these adolescents spend greater amounts of unsupervised time in the community (Barkley, Fischer, et al., 1990; Satterfield & Schell, 1997; Weiss & Hechtman, 1993). Substance experimentation and abuse are more likely to occur within the adolescent years, mainly among youths diagnosed with ADHD and comorbid conduct disorder (Barkley, Fischer, et al., 1990; Barkley et al., 2004; Molina & Pelham, 2003; Thompson, Riggs, Mikulich, & Crowley, 1996) or bipolar disorder (Biederman, Faraone, Mick, et al., 1996). Thus, although there may not be a clear causal effect of ADHD on the development of alcohol and other drug problems, there does appear to be a clinically meaningful relationship between ADHD and substance use (Smith, Molina, & Pelham, 2002).

Another area of difficulty is increased risk-taking behavior (Flory, Molina, Pelham, Gnagy, & Smith, 2006). An increasing number of studies have replicated and extended the original report by Weiss and Hechtman (1993), suggesting that individuals diagnosed with ADHD in childhood followed into adolescence, and clinically referred teenagers (and adults) with ADHD have a greater number of automobile accidents and speeding citations than their peers (Barkley, Guevremont, Anastopoulos, DuPaul, & Shelton, 1993; Barkley, Murphy, DuPaul, & Bush, 2002).

Studies of other domains of major life activities have shown that teens with ADHD are at risk for a wide variety of impairments, including sexual intercourse at an earlier age, along with a greater risk of teenage pregnancy (Barkley, Fischer et al., 2006), and less likelihood of completing high school and college than their peers (Barkley, Fischer, et al., 2006; Biederman et al., 2006; Weiss & Hechtman, 1993). Even those who do make it to college appear to be more impaired than their peers (Barkley, in press, 2007; Heiligenstein, Guenther, Levy, Savino, & Fulwiler, 1999). Workplace problems include higher than expected unemployment and number of job changes, and elevated levels of ADHD and ODD symptoms, as rated by employers (Barkley, Fischer, et al., 2006; Biederman et al., 2006). People with ADHD also appear to have less stable relationships, including fewer long terms friends and more divorces (Barkley, Fischer, et al., 2006; Biederman et al., 2006; Weiss & Hechtman, 1993).

In contrast to the decline in hyperactivity with age noted earlier, DSM-IV-TR symptoms of inattention and EF appear to be very persistent. Adults with ADHD are highly likely to self-report many of the same symptoms of inattention from the DSM symptom list reported by parents of children having ADHD (Barkley et al., in press). Murphy and Barkley (1996a) found that 83% of adults diagnosed with ADHD reported having difficulties with sustaining attention (vs. 68% of a clinical control group and 10% of a normal sample); 94% reported being easily distracted (vs. 86% of clinical controls and 19% or normative controls); 90% claimed that they often do not listen to others (vs. 57 and 6%, respectively); 91% reported that they often fail to follow through on tasks or activities (vs. 78 and 6%, respectively); and 86% reported that they frequently shift from one uncompleted activity to another (vs. 75 and 12%, respectively). These self-reports are corroborated by others who know the subjects well, such as spouses ($r = .64$) or parents ($r = .75$), as is parents' recall of similar symptoms during their childhood years ($r = .74$ with parent reports) (Murphy & Barkley, 1996b).

Adults with ADHD appear to have many of the same attention problems as children who have the disorder (Barkley et al., in press), especially attention and EF problems (Barkley, Murphy, & Kwasnik, 1996; Epstein, Conners, Sitarenios, & Erhardt, 1998; Hervey, Epstein, & Curry, 2004; Murphy, Barkley, & Bush, 2001; Seidman, Biederman, Weber, Hatch, & Faraone, 1998). Also, results of direct behavioral observations of inattention in adults with ADHD parallel the previously cited research in children, indicating greater off-task behavior during task performance, including driving (Barkley, 2004; Fischer, Barkley, Smallish, & Fletcher, 2005).

Cross-Setting Pervasiveness of Symptoms

The DSM-IV requirement that the symptoms be demonstrated in at least two out of three environments to establish pervasiveness of symptoms is new to this edition of the DSM and potentially problematic. By stipulating that the symptoms must be present in at least two out of three contexts (home, school, work, in the case of DSM-IV; home, school, clinic, in the case of International Classification of Diseases [ICD-10]), the criteria now potentially con-

found settings with sources of information (parent, teacher, employer, clinician). Research shows that the degree of agreement between parents and teacher is modest for any dimension of psychological development, often ranging between .30 and .50 depending on the behavioral dimension being rated (Achenbach, McConaughy, & Howell, 1987; Mitsis, McKay, Schulz, Newcom, & Halperin, 2000). This low degree of agreement sets an upper limit on the extent to which parents and teachers can agree on the severity of ADHD symptoms and, thus, on whether the child has the disorder according to strict interpretation of DSM-IV criteria.

It is noteworthy that disagreements among sources presumably reflects some real differences in the child's behavior in these different settings, probably as a function of differences in situational demands. School, after all, involves quite different expectations, tasks, social context, and general demands for public self-regulation compared to the home environment. A more serious problem for assessment is that the disagreements may also reflect differences in the attitudes, experiences, and judgments between different people. Furthermore, because there is no scientific basis at this time to argue for one reporter's validity over another (e.g., teacher vs. parent), we believe that these views should be considered as providing information on the child in that particular context, from a particular adult's point of view, and nothing more. Cross-informant agreement is not critical for diagnosis. It may inappropriately confound the diagnosis with issues such as comorbid disorders and reporting source, severity, and subtype. For example, there may be a confounding of the ADHD with issues of comorbidity with ODD (Costello, Loeber, & Stouthamer-Loeber, 1991). Parent-identified children with ADHD may have predominantly ODD, with relatively milder ADHD, whereas teacher-identified children with ADHD may have chiefly ADHD and minimal or no ODD symptoms. Children identified by both parents and teachers as having ADHD may, therefore, have not only ADHD but also a higher likelihood of having ODD. Other research suggests that pervasiveness may measure a more severe condition of ADHD than do the home- or school-only cases, which differ in degree rather than in kind (Tripp & Luk, 1997). Furthermore, some studies suggest that the combined subtype (ADHD-C) may be more readily de-

tected by pervasiveness criteria than the other hyperactive, impulsive, or inattentive subtypes (Gaub & Carlson, 1997). Children with defined pervasive ADHD (i.e., impairment at home and at school) may be more likely to have conduct disorder than ADHD identified only at home (Mannuzza, Klein, & Moulton, 2002). The results attest mainly to the validity of teacher reports in identifying a group of children with ADHD and severe behavior problems and, perhaps, a higher risk for adult antisocial disorder; however, it does not suggest that pervasiveness is necessary to diagnose ADHD. Indeed, this trend in the data suggests that pervasiveness is confounded with comorbidity. Clinicians need to keep in mind that DSM was constructed by blending the reports of parents and teachers, and they should do likewise. Thus, we recommend that symptoms reported by one source should be tallied; then, the number of additional symptoms identified by the other source should be added to the tally, totaling the number of different items endorsed across both sources.

Ruling Out Alternative Diagnoses

Many psychiatric disorders may be confused with ADHD. For instance, a depressed child may manifest symptoms of inattention (e.g., poor concentration), or a manic child may have increased activity levels. To clearly distinguish between ADHD and other disorders, examiners need to review with parents the problems that may exist in multiple developmental domains. A review of the following domains of functioning is recommended: motor, language, intellectual, academic, emotional, and social. Careful interviewing about symptom type, onset, duration, strength, and quality is also required to rule out alternative diagnoses. In addition, information about the social context and circumstances of the problem must be gathered (i.e., Can antecedent events such as a loss be identified?).

Accomplishing a differential diagnosis of ADHD versus another disorder requires that the examiner have an adequate knowledge of the diagnostic features of other childhood disorders. Questioning about inappropriate thinking, affect, social relations, and motor peculiarities may reveal another psychiatric or developmental disorder (e.g., Asperger syndrome). Family psychiatric history can provide information that increases or decreases the

likelihood of certain disorders (i.e., bipolar disorder). Also, measures that screen for a wide variety of problems are helpful. We describe later a sample interview that we recommend for use with the parents of children with ADHD. An example of a detailed diagnostic interview for parents of children with ADHD may be found elsewhere (Barkley & Murphy, 2006). Regardless of the particular method chosen, some review of the major childhood disorders in DSM-IV (APA, 1994) is essential for a trustworthy diagnosis, because DSM-IV requires ruling out other diagnoses that most plausibly account for the current complaints. Usually a thoughtful semistructured interview will help with this task. Also, broad-based screening instruments, such as the Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001) and Behavioral Assessment System for Children, Second Edition (BASC-2; Reynolds & Kamphaus, 2005) may help with this important diagnostic consideration.

Over 80% of children with ADHD have a second disorder, and more than 60% have two or more additional disorders. These findings have major implications for both assessment and treatment. For example, the presence of high levels of anxiety specifically, and of internalizing symptoms more generally, has been shown in some instances to be a predictor of poorer responses to stimulant medication (Pliszka, 1989), thus indicating the need for more intensive psychosocial treatment with this population (Jensen et al., 2001). Similarly, the presence of high levels of hostile, defiant behavior or ODD has been shown to be a marker for greater family conflict (Barkley, Anastopoulos, et al., 1992; Barkley et al., 1991). In such cases, specialized and more intensive family-based interventions may be necessary (Barkley, Guevremont, Anastopoulos, & Fletcher, 1992). Also, ADHD has also been shown to be a predictor of risk for conduct disorder, antisocial behavior, and substance misuse (Barkley et al., 2004; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1998). The co-existence of major depressive disorder with ADHD increases the risk of suicidality two to four times, especially during high school, demanding much closer monitoring of such cases by clinicians and possibly the use of adjunctive antidepressant medications (Barkley & Fischer, 2005). Accordingly, treatment for ADHD should involve prevention of high-risk behavior. The foregoing data illustrate the impor-

tance of determining comorbidity as part of the evaluation of a child with ADHD, and its possible impact on treatment selection.

Parenting influences have been implicated as important mediators or moderators of internalizing problems experienced by adolescents with ADHD (Ostrander & Herman, 2006). This is also true for smoking tobacco (Molina, Marshal, Pelham, & Wirth, 2005). Therefore, the assessment of ADHD should also consider the parenting relationship and family-based prevention programs for high-risk adolescents (Dishion & Andrews, 1995; Farrington & Welsh, 2003; Sanders, 2000). Similarly, because peers may have a big influence on a child's conduct problems and substance use (Marshal, Molina, & Pelham, 2003), assessment of comorbid conditions should include an evaluation of the nature of the child's peer group and its level of deviant or antisocial behavior.

Documenting Impairment

Symptoms alone are not sufficient to make a diagnosis. Rather, a diagnosis of ADHD requires that (1) the person have clinically meaningful symptoms and (2) clinically meaningful impairment, and that (3) the symptoms seem to be the most likely cause of the impairment. A multi-axial assessment of ADHD with DSM-IV guidelines provides a Global Assessment of Functioning (GAF) that gives some information about impairment (APA, 2000). Some clinicians and researchers use the GAF (DSM-IV, Axis V) as an outcome measure in ADHD treatment. This type of assessment of functioning is useful but not as precise an index of impairment as we would like. Rather, we strongly recommend gathering specific data on functional impairments, quantifying them whenever possible (e.g., frequency counts or severity ratings), and making the functional impairments as much or more than the ADHD symptoms the target of intervention and outcome evaluation. This requires an individualized approach to assessment. It can be accomplished by instructing parents and/or teachers in the use of relatively straightforward behavioral methods of tracking problem behavior, such as frequency tallies, duration records, or time samples (Sanders, Markie-Dadds, & Turner, 2001; Sanders & Ralph, 2001). For example, a parent can record how long a child takes to complete homework each day (duration re-

cord) or the number of times a child is noncompliant with requests (frequency tally). How often a child fights with a sibling can be recorded during the most problematic times of the day, with a parent noting simply whether or not fighting occurred during half-hour increments in the morning and in the evening (time sample). These measures can begin with the initial assessment and be repeated throughout the treatment period, thus forming the data by which interventions can be evaluated. Another way parents and clinicians can obtain information about impairment is with rating scales that containing specific items on functioning in various major life activities (Pelham, Fabiano, & Massetti, 2005). These types of measures are discussed later in the chapter.

Prevalence Using Clinical Diagnostic Criteria

The only two studies to date reporting a U.S. prevalence rate using DSM-IV criteria found rates of 7.4 and 9.9% (see Barkley, 2005). These estimates of prevalence may be higher than the average for DSM-III-R, most likely due to the inclusion of the new ADHD-C subtype not recognized in DSM-III-R. Adding these subtypes, it would seem, nearly doubles the prevalence of disorder in the United States. In one study that reported the prevalence of ADHD in Australia using DSM-IV criteria by diagnostic interview (Gomez et al., 1999), the Australian prevalence estimate of 6.8% is comparable to those in the United States using these same DSM-IV criteria (Barkley, 2005). A Dutch study yielded a prevalence of 3.8% with children (i.e., 6–8 years old), which is approximately half the rate found in the United States and Australia (Kroes et al., 2001). The reasons for this discrepancy are not clear, but they may be due to methodological issues rather than cultural differences. A study in Brazil that used DSM-IV criteria yielded an ADHD prevalence estimate of 5.8% for a young adolescent age group (Rohde et al., 1999). The discrepancy between the Brazilian and United States/Australian studies may be due in part to the Brazilian study's use of early adolescents. As noted earlier, ADHD symptoms decline with age, thus driving a reduction in prevalence. There is no doubt that ADHD is a worldwide phenomenon. It has been found in every country in which it has been studied (see Barkley, 2005, for a review of 24 prevalence studies using earlier DSM editions).

A recent epidemiological study of U.S. adults has estimated a prevalence of 4.4% for adult ADHD using DSM-IV criteria (Kessler et al., 2006). This is similar to the figure obtained in an earlier study of adults in Massachusetts by Murphy and Barkley (1996a), who found a prevalence of 4.7% for all subtypes of ADHD, also using DSM-IV criteria.

Factors Affecting Rates of ADHD Diagnosis

Several factors affect reports of ADHD symptoms, including the source of information (e.g., parent, teacher, or self-reports), the version of DSM being used, the age and sex of the samples, and the country in which the study is conducted. However, after controlling for these factors, age and sex remain as clearly unique and important determinants of the prevalence of ADHD. Furthermore, socioeconomic status (SES) appears to affect prevalence estimates, but not as reliably as age and gender. More details on age, gender, source of information, and SES effects on ADHD prevalence estimates are given below.

ADHD is more common among males than among females. Epidemiological studies of ADHD typically find rates that are three to seven times greater among males than among females (Barkley, 2005). The discrepancy in clinical studies is even more pronounced, with males predominating by as much as a 9:1 (Barkley, 2005). Although ADHD is clearly more prevalent in boys than girls, the key clinical characteristics do not vary greatly by gender (Biederman et al., 2005).

Regarding SES, one study found that indicators of social class had a low but significant inverse relationship with rates of hyperactivity in a Canadian sample (Boyle & Lipman, 2002). Overall, the results indicated that being male, coming from a single-parent family or a smaller family with fewer children, and living in a disadvantaged neighborhood all significantly increased the likelihood of hyperactivity. Others have found that conditions associated with lower SES increase the risk for ADHD (Velez, Johnson, & Cohen, 1989). Important, however, was the additional finding by Szatmari, Offord, and Boyle (1989) that when comorbidity with other disorders was statistically controlled in the analyses (especially for ODD and CD), gender, family dysfunction, and low SES were no longer significantly associated with occurrence of the disorder. On the other hand,

health problems, developmental impairment, young age, and urban living were uniquely associated with the occurrence of the disorder.

Base-Rate Considerations in Assessing ADHD

It has been known for about 50 years that diagnostic precision is heavily dependent on the base rate of the disorder (Meehl & Rosen, 1955). Three base rate considerations should be taken into account when diagnosing ADHD. The first is the base rate in the general population. Estimates presented previously in the chapter are that a small minority of children in the United States (i.e., about 7–9%) meet current diagnostic criteria for ADHD. Accordingly, when dealing with general populations, such as schools, the diagnosis should be approached with a high degree of scientific skepticism. In such cases, the odds are high that the child does not have ADHD. This consideration is highly relevant to screening or epidemiological studies to avoid false-positive “diagnoses.”

Another base rate consideration is the local base rate among the children referred for evaluation. About half of the children referred to child mental health settings have ADHD (Barkley, 2005). We expect that similarly high base rates of ADHD are found in populations referred to school psychologists and similar professionals. Thus, the odds are pretty good that the child referred by a parent or teacher to a psychologist or psychiatrist due to problems of inattention or impulsivity actually has ADHD. In these situations (i.e., with a 50% base rate of ADHD), equal emphasis should be given to ruling in versus ruling out the disorder. For specialty ADHD clinics, the base rate would be expected to be even higher (80% or more in Barkley’s experience); thus, referrals to such clinics would have a high probability of having the disorder.

A third base rate consideration is the rate of other disorders that might be confused with ADHD, such as major depression or bipolar disorder. Among populations referred for academic or behavior problems, it is very likely that ADHD is the most prevalent disorder. However, sometimes clinicians are swayed by the salience of a novel disorder, even though the base rate is much lower. For example, if the base rate of ADHD is 50% and the rate of bipolar disorder (BPD) (see Youngstrom, Chapter 6, this volume) is 2%, then it is much more

likely that overactivity is due to ADHD rather than BPD. In this case, very strong data are needed to rule out ADHD and rule in BPD.

Implicit in these statistics is that preference in terms of selecting from a list of disorders with similar symptoms should be given to higher base rate disorders. Not clearly stated in DSM, but explicit in Meehl and Rosen (1955) and other noteworthy treatments of the base rate issue, is that professionals should collect data on local base rates to provide appropriate statistical guidance for making diagnostic decisions. This is simple to do. It merely involves keeping a running record of the diagnoses made by clinicians and their colleagues in a particular setting or referral stream over a period of time.

Gender Differences

Historically, so few girls were included in studies of ADHD that there was too little statistical power to examine gender differences. However, as larger scale studies have become available, it has become increasingly clear that a significant number of girls are affected by ADHD, and that many of the findings for boys replicate for girls (for reviews, see Gershon, 2002; Hinshaw & Blachman, 2005). For instance, Hinshaw and Blachman (2005) have undertaken a longitudinal study focusing on girls with ADHD. This program of research and other studies have shown that careful assessment can reliably differentiate between girls with and without ADHD. Also, consistent with research on boys diagnosed with ADHD, Hinshaw and colleagues (2006) have shown that ADHD in girls persists into adolescence.

Researchers have made some progress in understanding the extent to which gender is an important issue in diagnosing and treating ADHD. Indeed there have been enough studies that, if relatively lenient inclusion criteria are used, studies of gender differences and ADHD may be subjected to a quantitative (i.e., meta-analytic) review. The most recent of these reviews found that, in comparison to boys with ADHD, girls with ADHD tend to have lower ratings on hyperactivity, inattention, impulsivity, and externalizing problems. In addition, girls with ADHD appear to have greater intellectual impairments and more internalizing problems than boys with ADHD (Gershon, 2002). Furthermore, some researchers have found “masculine” and “feminine” clusters of

symptoms to be valid characterizations of boys and girls with ADHD (Ohan & Johnston, 2005). Others have speculated that there are unique considerations in treating females with ADHD, for instance, when fluctuating hormones associated with menses might affect behavior (Quinn, 2005).

Taken together, the studies on girls with ADHD suggest a real difference in severity of symptoms and perhaps a different pattern of comorbidity, with more internalizing and learning problems experienced by girls relative to boys. The rate of ADHD is probably about four to nine times lower for girls than boys, and there may be a variety of biases that result in lower rates of identification of females with ADHD compared to males (Reid et al., 2000). Issues such as hormone effects and other gender-specific issues need to be subjected to more rigorous studies.

One possible explanation of differing rates of identification of ADHD in females may be that the ADHD-related problems experienced by girls may be less salient than those typically experienced by boys with ADHD. For instance, some studies indicate that girls with ADHD may employ more relational aggression than non-ADHD peers (Zalecki & Hinshaw, 2004). Relational aggression is more subtle than the overt aggression likely to be used by males, at least to adult observers; thus, it may possibly contribute to a referral bias.

Another consideration related to diagnostic biases is that the comorbidities experienced by girls with ADHD, such as depression, anxiety, and learning problems, may mask the symptoms of ADHD, or at least clinicians' recognition of it. This may lead to an erroneous primary diagnosis that overlooks ADHD, even though the stress of dealing with ADHD might be the reason the girl is anxious or depressed. To support this point, in Australia, the rate of service utilization for boys and girls with ADHD seems to be about the same, but girls were more likely to carry a primary diagnosis of an internalizing disorder (Graetz, Sawyer, Baghurst, & Hirte, 2006).

Yet some studies have found few, if any, clinically meaningful differences between males and females with ADHD. For instance, a classroom-based study of elementary-age students found higher rates of ADHD for boys than for girls, but no major clinical differences between the boys and girls with ADHD (DuPaul, Jitendra, Tresco, & Vile Junod, 2006). Similarly, in a study of ado-

lescents with ADHD, Rucklidge (2006) found practically no gender-linked neuropsychological differences, with the possible exception that boys were more impulsive than girls. This gender difference in impulsivity is called into question by studies of adults that found no remarkable differences in neuropsychological functioning of men and women with ADHD, even though there were differences relative to normal controls (Barkley et al., in press; Seidman et al., 1998). Other studies have found no differences in functional impairments between boys and girls with ADHD, either at home or at school (Breen & Altepeter, 1990).

To summarize, with regard to assessment, assessors should be careful to avoid false negatives when evaluating girls for ADHD. And whereas the treatment implications for girls with uncomplicated ADHD appear to be similar to those for boys, one should be prepared to deal with a differing set of comorbid conditions and social relationship problems for girls and boys with ADHD. A key diagnostic consideration may be the decision to classify the comorbid condition as a primary disorder, or a secondary problem caused by ADHD. Whereas girls have historically been underidentified and treated, more recent studies suggest that there has been a substantial increase in the rate of treatment for girls with ADHD in the United States (Robison, Skaer, Sclar, & Galin, 2002).

Situational and Contextual Factors

As already noted, all the primary symptoms of ADHD show significant fluctuations across various settings and caregivers (Barkley, 2005). Playing alone, washing and bathing, and times when the father is at home are a few of the less troublesome situations for children with ADHD, whereas instances when children are asked to do chores, when parents are on the telephone, when visitors are in the home, or when children are in public places may be times of peak severity of their disorder. Significant fluctuations in activity are evident across these different contexts for children with ADHD and normal controls, with the differences becoming most evident during school classes in reading and math. Despite these situational fluctuations, children with ADHD appear to be more deviant in their primary symptoms than normal children in most settings, yet these differences can be exaggerated greatly as a function of several factors related to the settings and the

tasks children perform in them (Luk, 1985; Zentall, 1985).

Other situational factors, such as the extent to which caregivers make demands on children with ADHD to restrict behavior, appear to affect the degree of deviance of the child's behavior from that of nondiagnosed children. In free-play or low-demand settings, where task complexity is low, children with ADHD are less distinguishable from normal children than in highly restrictive or task-demanding ones (Lawrence et al., 2002; Luk, 1985; Marzocchi et al., 2002). Children with ADHD often appear to be more compliant and less disruptive, and are rated as less symptomatic by fathers compared to mothers (DuPaul et al., 1998; Tallmadge & Barkley, 1983). Problems with sustained responding are also lessened on tasks in which instructions are repeated frequently to the child with ADHD (Douglas, 1980, 1983), at least by an experimenter. Yet parents and teachers frequently complain that repeating their commands and instructions to children with ADHD produces little change in compliance (Danforth et al., 1991). Children with ADHD display fewer behavioral problems in novel or unfamiliar surroundings, or when tasks are unusually novel, but their level of deviant behavior increases with familiarity with the setting (Barkley, 2005; Zentall, 1985). The degree of stimulation in the task also seems to be a factor in the performance of children with ADHD. Research suggests that colorful or highly stimulating educational materials are more likely to improve the attention of these children to such materials than are relatively low-stimulation or uncolored materials (Zentall, 1985). Interestingly, such differences may not affect the attention of typical children or may even worsen it. Activity levels may also be lower while watching television compared to more demanding academic work, such as in reading and math classes at school (Porrino et al., 1983). Yet even with high stimulation activities such as video games or TV, children with ADHD look away from displays more than do normal children, and may still have more problems with their performance than do normal children (Barkley & Ullman, 1975; Landau, Lorch, & Milich, 1992; Lawrence et al., 2002; Tannock, 1998).

Motivational factors also impact ADHD symptoms. Settings or tasks that involve a high rate of immediate reinforcement or punishment result in significant reductions in, or in some

cases amelioration of, attention deficits (Barkley, 1997b; Barkley, Copeland, & Sivage, 1980; Douglas, 1983; Douglas & Parry, 1983). Or when children with ADHD are engaged in activities they find more enjoyable, they may even perform at normal or near-normal levels, perhaps because these children prefer immediate rather than delayed rewards (Barkley et al., 2001; Neef, Bicard, & Endo, 2001). When the schedule and magnitude of reinforcement are decreased, however, the behavior of children with ADHD may become readily distinguishable from non-ADHD peers (Barkley et al., 1980; Luman, Oosterlaan, & Sergeant, 2004). During one-to-one situations, children with ADHD may appear less active, inattentive, and impulsive, whereas in group situations, where there is little such attention, children with ADHD may appear at their worst. Clearly, rules and motivational factors in the setting have a significant impact on ADHD symptom severity (Draeger et al., 1986; Glow & Glow, 1979; Luman et al., 2005).

Fatigue or time of day (or both) may have an adverse impact on the degree of expression of children's ADHD symptoms (Zagar & Bowers, 1983) given that academic tasks are performed significantly better in the mornings but worsen in the afternoons more than is seen in normal children. This is not to say that differences between children with ADHD and normal controls do not exist in the early morning but emerge only as time of day advances, for this is not the case (Porrino et al., 1983). The findings so far suggest that educators would do well to schedule repetitive or difficult tasks that require the greatest powers of attention and behavioral restraint for morning periods, while placing recreational, entertaining, or physical activities in the afternoons (Zagar & Bowers, 1983).

Associated Problems and Impairments

Children with ADHD have a higher likelihood of having other medical, developmental, adaptive, behavioral, emotional, and academic difficulties than do peers who do not have ADHD. Delays in intelligence, academic achievement, and motor coordination are more prevalent in children with ADHD than in matched samples of normal children, or even in siblings (Barkley 2006), as are delays in adaptive functioning more generally (Greene et al., 1996; Roizen, Blondis, Irwin, & Stein, 1994; Stein,

Szumowski, & Blondis, & Roizen, 1995). Problems with peer acceptance and in peer interactions are commonly documented in children with ADHD (Bagwell, Molina, Pelham, & Hoza, 2001; Ernhardt & Hinshaw, 1994; Stroes, Alberts, & Van der Meere, 2003). These social impairments continue into adolescence and adulthood, possibly with escalating consequences that lead to progressively more serious problems, such as school dropout, vocational instability and underachievement, and unstable interpersonal relationships (Barkley, 2005).

As noted earlier, as many as 87% of clinically diagnosed children with ADHD may have at least one other disorder, and 67% may have at least two other disorders (Kadesjo & Gillberg, 2001). Children with ADHD are far more likely than children who do not have ADHD to have coexisting ODD and CD symptoms (Angold, Costello, & Erkanli, 1999). Depression, and possibly BPD, also may be more common in children with ADHD than would be expected in the general population (Biederman, Faraone, Mick, et al., 1996; Jensen, Shervette, Xenakis, & Richters, 1993), especially where CD is present with ADHD (Angold et al., 1999). There is a modest increase in risk for anxiety disorder as well, averaging 25% of clinical cases (Angold et al., 1999; Tannock, 2000). Severity of the ADHD symptoms may in part predict the severity of and risk for these comorbid conditions (Gabel, Schmitz, & Fulker, 1996).

Children with ADHD appear to have more minor physical anomalies than do normal controls (Quinn & Rapoport, 1974) and may be physically smaller than normal children, at least during childhood (Spencer et al., 2006). They may also have more sleep difficulties than normal children (Ball & Koloian, 1995; Cortese, Lecendreux, Mouren, & Konofal, 2006). However, prior beliefs that ADHD may have a higher than normal association with either allergies or asthma have not been corroborated by research (Biederman, Milberger, Faraone, Guite, & Warburton, 1994; McGee, Stanton, & Sears, 1993; see also Pelham et al., 1998, for a brief review). Unfortunately, the well-meaning but ill-advised belief in putative food allergies may itself cause impairment due to restricted activities, social stigma, and escalated parent-child conflict.

ADHD symptoms produce significant alterations in family functioning, particularly in children who also display excessive opposition-

al and defiant behavior (Johnston & Mash, 2001). Children with ADHD have been shown to be less compliant, more negative, and less able to sustain compliance than normal children during task completion with their mothers (for a review, see Danforth et al., 1991). Their mothers are more directive and negative, more lax in their discipline, less rewarding and responsive to their children's behavior, and show lower levels of maternal coping than do mothers of normal children (Cunningham & Boyle, 2002; Keown & Woodward, 2002; McKee, Harvey, Danforth, Ulaszek, & Friedman, 2004). However, these problems also may be more closely aligned with the level of child conduct problems than just the severity of ADHD symptoms (Johnston, Murray, Hinshaw, Pelham, & Hoza, 2002; Kashdan et al., 2004). Although there is less conflict in the interactions of older children and teens with ADHD compared to younger age groups (Danforth et al., 1991), even they remain deviant in their parent-child conflicts (Barkley et al., 1991; Edwards et al., 2001; Fletcher et al., 1996), especially in those with both ADHD and ODD. The greater directive and negative behavior of the mothers of children with ADHD may be in part a reaction to their children's noncompliance and poor self-control rather than a cause of it (Danforth et al., 1991). Moreover, these conflicts in social interactions appear to exist in the relations of children with ADHD and their fathers (Edwards et al., 2001; Tallmadge & Barkley, 1983) and teachers (Cunningham & Boyle, 2002; Whalen, Henker, & Dotemoto, 1980). Yet both children and teens with ADHD do not perceive their relations with parents and teachers as being more problematic than do control children (Edwards et al., 2001; Gerdes, Hoza, & Pelham, 2003; Hoza et al., 2004). These results and others indicate a positive illusory bias associated with the disorder. Children with ADHD may have problems related to limited self-awareness, in which they perceive themselves as functioning as well as others, when clearly they are not.

Parents of children with ADHD report significantly greater stress in their parental roles and higher levels of depression than do parents of samples of normal children (Cunningham & Boyle, 2002; DuPaul, McGoey, Eckert, & VanBrakle, 2001; Harrison & Sofronoff, 2002; Johnston & Mash, 2001). Higher rates of maternal depression may contribute to a biased reporting of severity of children's ADHD symp-

toms as a function of depression-related distortions (Chi & Hinshaw, 2002). Parents of children with ADHD also have more ADHD, and if the child also manifests ODD or CD, parents may also manifest greater rates of mood, anxiety, and substance use disorders (Chronis et al., 2003).

Peer relations of children and teens with ADHD are typically problematic (Bagwell et al., 2001; Cunningham & Siegel, 1987) and involve more rejection and fewer close friendships, especially for the subset with ODD-CD (Bagwell et al., 2001; DuPaul et al., 2001; Mikami & Hinshaw, 2003). Children with ADHD exhibit more negative behavior (DuPaul et al., 2001) and are less socially involved with non-ADHD playmates during conversations. Yet children with ADHD may direct attention to their non-ADHD peers during play activities, receiving more structure in the form of praise and questions from peers during active play (Stroes et al., 2003). Children with ADHD also encode fewer social cues and generate fewer responses than normal children, whereas those with comorbid ODD-CD demonstrate a greater propensity for aggressive responses than do control children (Matthys, Cuperus, & Van Engeland, 1999).

The most reliably associated cognitive and psychomotor difficulties with ADHD include (1) motor coordination and sequencing (Barkley, 1997d; Barkley, DuPaul, & McMurray, 1990; Breen, 1989; Denckla & Rudel, 1978; Mariani & Barkley, 1997); (2) working memory and mental computation (Mariani & Barkley, 1997; Martinussen et al., 2006; Zentall & Smith, 1993); (3) planning and anticipation (Barkley, Grodzinsky, & DuPaul, 1992; Douglas, 1983; Grodzinsky & Diamond, 1992); (4) verbal fluency and confrontational communication (Grodzinsky & Diamond, 1992; Zentall, 1988); (5) effort allocation (Douglas, 1983; Voelker, Carter, Sprague, Gdowski, & Lachar, 1989); (6) application of organizational strategies (Hamlett, Pellegrini, & Conners, 1987; Voelker et al., 1989; Zentall, 1988); (7) internalization of self-directed speech (Berk & Potts, 1991; Copeland, 1979); (8) adherence to restrictive instructions (Danforth et al., 1991); (9) self-regulation of emotional arousal (Cole, Zahn-Waxler, & Smith, 1994; Douglas, 1983; Hinshaw, Buhrmeister, & Heller, 1989); and (10) less mature moral reasoning (Nucci & Herman, 1982). The commonality among most of these seemingly disparate abilities may be EF (Denckla,

1994; Torgesen, 1994) or “metacognition” (Torgesen, 1994; Welsh & Pennington, 1988). All may be mediated in part by the frontal cortex, particularly the prefrontal lobes (Fuster, 1989; Stuss & Benson, 1986)—brain regions implicated in ADHD.

Etiologies

The proposed etiologies for ADHD are too numerous to review here in any detail. Therefore, we concentrate on those for which there is substantial empirical support. More detailed information is available in the text by Nigg (2006). Although the definitive specific and most proximal causes of ADHD have not been established, the larger domains in which these precise causes exist have been much better clarified over the past decade. Substantial evidence points to both neurological and genetic contributions to this disorder, and even specific brain regions and specific genes are now being implicated as contributors. So although the exact neurochemical mechanisms remain to be established for the disorder, and the suites of genes contributing to its striking heritability have yet to be completely catalogued, there is no doubt that these etiological directions hold the greatest promise for understanding the causes of the disorder.

Purely social causes of ADHD can be largely ruled out as contributors to most forms of ADHD—a major advance in itself. Social factors surely moderate the types and degrees of impairments from the disorder, and possibly even risk for comorbid ODD, CD, depression, and anxiety. Social factors may play a role in biases against those having ADHD, as well as potentially moderate access to services for its management. However, social factors in and of themselves appear to have little research support as primary causes of the disorder.

Neurology

A large number of studies that have used neuropsychological tests of frontal lobe functions have detected deficits in children and adults with ADHD (Barkley, 1997d; Barkley, Edwards, et al., 2001; Murphy et al., 2001; Seidman et al., 1998; Seidman, Doyle, Fried, Valera, Crum, & Matthews, 2004), especially in response or “executive” inhibition (Nigg, 2006). The greatest support in meta-analyses of the burgeoning neuropsychological literature

on ADHD is for difficulties with not only the cardinal domains of inattention and inhibition but also working memory (Frazier et al., 2004; Hervey et al., 2004). Less evidence exists for difficulties in other executive abilities, such as planning and verbal fluency, response perseveration, and emotional self-regulation, largely due to far fewer studies of these domains. Difficulties with sense of time have also been convincingly established (Barkley, Edwards, et al., 2001; Barkley, Murphy, & Bush, 2001). Moreover, research shows that not only do siblings of children with ADHD who themselves have ADHD show similar EF deficits, but also even siblings of children with ADHD who do not actually manifest ADHD appear to have milder yet significant EF impairments (Seidman et al., 1995). Such findings imply a phenotypic dimension to the disorder that is present, albeit in milder form, among genetically related individuals. Executive deficits in ADHD appear to arise from the same substantial shared genetic liability as do ADHD symptoms themselves (Coolidge, Thede, & Young, 2000).

Psychophysiological measures of nervous system (central and autonomic) electrical activity (galvanic skin responses, heart rate deceleration, etc.) have proven inconsistent in demonstrating group differences between children with ADHD and control children in resting arousal. Deviations from normal are found more consistently in diminished reactivity to stimulation, as in evoked responses (Beauchaine, Katkin, Strassberg, & Snarr, 2001; Borger & van der Meere, 2000; Herpertz et al., 2001). This may point to impaired right prefrontal mechanisms underlying response inhibition (Pliszka, Liotti, & Woldorff, 2000). Far more consistent have been the results of quantitative electroencephalograph (QEEG) and evoked response potential (ERP) measures, sometimes administered in conjunction with vigilance tests (El-Sayed, Larsson, Persson, & Rydelius, 2002; Monastra, Lubar, & Linden, 1999; see Loo & Barkley, 2005, for a review). Increased slow wave, or theta, activity, particularly in the frontal lobe, and excess beta activity the most common differences noted, are indicative of a pattern of underarousal and underreactivity in ADHD (Monastra, Lubar, & Linden, 2001). Children with ADHD have been found to have smaller amplitudes in the late positive and negative ERP components. These late components are believed to be a function of the prefrontal regions of the brain,

are related to poorer performances on inhibition and vigilance tests, and are corrected by stimulant medication (Johnstone, Barry, & Anderson, 2001; Pliszka, Liotti, et al., 2000). Improvements in these measures that result from stimulant medication may be partly a function of the human dopamine transporter (DAT1) gene allele, particularly in its 10-repeat form (Loo et al., 2003), a polymorphism that may be overrepresented in some forms of ADHD (Levy, Hay, McStephen, & Martin, 2001).

Several studies that have examined cerebral blood flow using single-photon emission computed tomography (SPECT) in children with ADHD and normal children (see Hendren, DeBacker, & Pandina, 2000, for a review) have consistently shown decreased blood flow to the prefrontal regions (particularly in the right frontal area) and pathways connecting these regions to the limbic system via the striatum, specifically, its anterior region known as the caudate, and the cerebellum. Degree of blood flow in the right frontal region has been correlated with behavioral severity of the disorder and with reduced EEG activity, whereas that in more posterior regions and the cerebellum seems related to degree of motor impairment (Gustafsson, Thernlund, Ryding, Rosen, & Ceterblad, 2000).

Studies using positron emission tomography (PET) to assess cerebral glucose metabolism have found diminished metabolism in adults with ADHD, particularly in the frontal region (Schweitzer et al., 2000; Zametkin et al., 1990) but have been far less consistent with teens and children (for reviews, see Ernst, 1996; Tannock, 1998). Using a radioactive tracer that indicates dopamine activity, Ernst and colleagues (1999) found abnormal dopamine activity in the right midbrain region of children with ADHD, with severity of symptoms correlated with degree of abnormality.

Studies using magnetic resonance imaging (MRI) find less brain volume in selected brain regions in those with ADHD relative to control groups (Tannock, 1998), particularly in the anterior right frontal region, caudate nucleus, and globus pallidus (Aylward et al., 1996; Castellanos et al., 2002; Filipek et al., 1997). Besides reduced size, there is some evidence of reduced neurometabolite activity in the right frontal region (Yeo et al., 2003), with degree of this activity associated with degree of attention problems on a CPT. The smaller size of the basal ganglia and right frontal lobe is corre-

lated with a greater degree of impaired inhibition and attention in children with ADHD (Casey et al., 1997; Semrud-Clikeman et al., 2000). Numerous studies (Castellanos et al., 1996, 2001, 2002; Durston, Pol, et al., 2004) also found smaller cerebellar volume in those with ADHD, especially in a central region known as the vermis. The cerebellum plays a major role in EF and in the motor presetting aspects of sensory perception that derive from planning and other executive actions (Diamond, 2000), suggesting why these functions may be deficient in children with ADHD.

Studies using functional MRI find that children with ADHD have abnormal patterns of activation during attention and inhibition tasks in comparison to normal children, particularly in the right prefrontal region, basal ganglia (striatum and putamen), and cerebellum (Rubia et al., 1999; Teicher et al., 2000; Vaidya et al., 1998; Yeo et al., 2003). The demonstrated linkage between brain structure and function, and psychological measures of ADHD symptoms and executive deficits is exceptionally important and permits causal inferences about the role of these brain abnormalities in the cognitive and behavioral deficits comprising ADHD. Durston, Pol, and colleagues (2004) found that the reduced size of the brain (about 3–5%), particularly in the right frontal area, in children with ADHD may be evident as well in their non-ADHD siblings, which is perhaps consistent with the increased familial risk for the disorder and a spectrum of the phenotype for ADHD within these families. But the reduced volume of the cerebellum was found to be specific to the affected child with ADHD and was not evident in unaffected siblings, implying that this region may be directly related to the pathophysiology of the disorder.

Existence of possible neurotransmitter dysfunction or imbalances has been proposed in ADHD for quite some time (see Pliszka, McCracken, & Maas, 1996, for a review). Initially, this rested chiefly on the responses of children with ADHD to dopamine and norepinephrine reuptake inhibitors, such as methylphenidate and atomoxetine, respectively. Studies have used blood and urinary metabolites of brain neurotransmitters to infer deficiencies due to ADHD, largely related to dopamine regulation (Halperin et al., 1997). What limited evidence there is from this literature seems to point to a selective deficiency in the

availability of both dopamine and norepinephrine.

Pregnancy and Birth Complications

Some studies have found a greater incidence of pregnancy or birth complications in children with ADHD compared to normal children (Claycomb, Ryan, Miller, & Schnakenberg-Ott, 2004). Prematurity has been associated with later risk for ADHD (Breslau et al., 1996; Schothorst & van Engeland, 1996). After controlling for other factors that may be associated with low birthweight and ADHD (maternal smoking, alcohol use, ADHD, social class, etc.), Mick, Biederman, Faraone, Sayer, and Kleinman (2002) continued to find low birthweight to be three times more common in children with ADHD than in control children, perhaps accounting for nearly 14% of all ADHD cases. Thus, low birthweight associated with prematurity may be a particularly salient marker for later ADHD. Furthermore, the extent of white matter abnormalities due to birth injuries, such as parenchymal lesions and/or ventricular enlargement, seems especially contributory to later ADHD among babies born prematurely (Whittaker, 1997). Mothers of children with ADHD are likely to be younger when they conceive than are mothers of control children, and such teen pregnancies may have a greater risk of adverse effects (Claycomb et al., 2004; Denson, Nanson, & McWatters, 1975; Hartsough & Lambert, 1985).

Genetics

Evidence for a genetic basis of ADHD is now overwhelming and comes from three sources: family studies, twin studies, and, most recently, molecular genetic studies identifying individual candidate genes. Nearly all of this research applies to ADHD-C, and most of it has occurred with children rather than adolescents. Between 10 and 35% of immediate family members of children with ADHD are also likely to have the disorder, with the risk to siblings of children with ADHD being approximately 32% (Levy & Hay, 2001). If a parent has ADHD, the risk to the offspring is 40–57% (Barkley et al., in press; Biederman, Faraone, Mick, et al., 1996). These elevated rates of the disorder also have been noted in African American ADHD samples (Samuel et al., 1999), as well as in girls

compared to boys with ADHD (Faraone & Doyle, 2001). ADHD with CD may be a distinct familial subtype of ADHD (Faraone, Biederman, Mennin, Russell, & Tsuang, 1998; Smalley et al., 2000). Girls who manifest ADHD may have a greater genetic loading (higher family member prevalence) than do males with ADHD (Faraone & Doyle, 2001; Smalley et al., 2000).

Twin studies of ADHD and its behavioral dimensions have proven strikingly consistent. These studies have found a very high degree of heritability for ADHD, ranging from .70 to .97 (Coolidge et al., 2000; Kuntsi & Stevenson, 2000; for reviews, see Levy & Hay, 2001; Thapar et al., 2000). The average heritability of ADHD (degree of variance in the trait due to genetic effects) is at least .78. These studies consistently find little, if any, effect for shared (rearing) environment on the traits of ADHD, which refutes any effort to attribute ADHD to within-family factors such as poor parenting, family diet, household television exposure, or other popularly held causes of ADHD.

Approximately 9–20% of the variance in hyperactive–impulsive–inattentive behavior or ADHD symptoms can be attributed to such nonshared environmental (nongenetic) factors (Levy & Hay, 2001; Nigg, 2006). Factors in the nonshared environment include those events or conditions that have uniquely affected only one twin or child in a family and not others. Such unique factors include not only those typically thought of as involving the social environment (differing schools, peer groups, etc.) but also all biological factors that are nongenetic in origin (lead poisoning, head injury, etc.). Researchers who are interested in identifying environmental contributors to ADHD should focus on those biological, interactional, and social experiences that are specific and unique to the individual, and are not part of the common family environment to which other siblings have been exposed.

Multiple genes are likely to contribute to risk for the disorder given the complexity of the traits underlying ADHD and their dimensional nature. The dopamine transporter gene (DAT1) has been implicated repeatedly (Barkley, Smith, Fischer, & Navia, 2006; Cook, Stein, & Leventhal, 1997) but not universally (Swanson et al., 1998). The heterozygous 9/10 pairing of this gene has recently been shown to be associated substantially with degree of ADHD symp-

tom and related impairments as well as to response to methylphenidate and atomoxetine, both transporter reuptake inhibitors, relative to the homozygous 9/9 or 10/10 pairings (Barkley, Smith, et al., 2006; Gilbert et al., 2006). The DRD4 gene (dopamine D₄ receptor) has been the most reliably found in samples of children with ADHD (Faraone et al., 1999). The 7-repeat or longer forms (alleles) of this gene have been found to be overrepresented in children with ADHD (LaHoste et al., 1996). This gene has previously been associated with the personality trait of high novelty-seeking behavior, affects pharmacological responsiveness, and impacts on post-synaptic sensitivity primarily in frontal and prefrontal cortical regions (Swanson et al., 1998). More recently, the long allele of the dopamine beta-hydroxylase (DBH) gene has also been implicated in hyperactive children followed to adulthood (Mueller et al., 2003). Future research is likely to show distinct genetic subtypes of ADHD, differential associated risks for impairment and medication responding by genotype, and possibly some value of genetic testing to assist diagnosis.

Environmental Toxins

Apart from genetics, ADHD symptoms may be due to pre-, peri-, and postnatal complications, malnutrition, diseases, trauma, toxin exposure, and other neurologically compromising events that may occur during the development of the nervous system before and after birth. Such events are likely to happen to one child in a family but not to others, so they likely fall under the unique or nonshared variance found in twin studies associated with variation in ADHD symptoms in the population. Several of these biologically compromising events have been repeatedly linked to risk for inattention and hyperactive behavior. One such factor is exposure to environmental toxins, and one such toxin is lead (Needleman, Schell, Bellinger, Leviton, & Allred, 1990). An even stronger case for negative effects has been made for deliberately ingested toxins, such as tobacco (Maughan, Taylor, Caspi, & Moffitt, 2004; Mick et al., 2002; Milberger, Biederman, Faraone, Chen, & Jones, 1996; Streissguth, Bookstein, Sampson, & Parr, 1995). The relationship between maternal smoking during pregnancy and ADHD remains significant even

after symptoms of ADHD are controlled in the parent (Mick et al., 2002; Milberger et al., 1996). Maternal alcohol consumption has been documented as a risk factor for ADHD (Nigg, 2006), albeit less consistently.

Predictors of Outcome

One key predictor of outcomes is comorbidity with other disorders, particularly ODD and CD. Those children with “pure” ADHD (i.e., ADHD that is not associated with significant aggressiveness, comorbid mood disorders, family adversity, or peer relationship problems) are likely to have problems primarily in school performance (Paternite & Loney, 1980); they are typically described as “underachieving.” They may have a higher chance of early remission of the disorder (Biederman, Faraone, Milberger, et al., 1996). On the other hand, teenagers who had childhood ADHD that was associated with aggression and conduct problems apparently fare much worse than those with uncomplicated ADHD (Barkley, Fischer, et al., 1990; Barkley et al., 2004; Weiss & Hechtman, 1993). Not only are school performance problems significant, but difficulties with pre-delinquent or delinquent behavior in the community may also emerge, and peer relationship problems remain significant or increase in severity (Barkley, Fischer, et al., 1990; Fischer, Barkley, Edelbrock, & Smallish, 1990). Likewise, conflict with parents is elevated (Anastopoulos et al., 1992), which is of concern because it is a major predictor of outcomes for teenagers (Hinshaw et al., 2000; Ostrander & Herman, 2006; Reitz, Dekovic, & Meijer, 2006; Wills & Dishion, 2004).

With the exception of comorbid conduct problems, few other predictors are noteworthy. Even those that are statistically significant account for only a small percentage of the variance in outcome (Mannuzza & Klein, 1992). Some studies have identified low intelligence in childhood, poor peer acceptance, emotional instability, and extent of parental psychopathology as predictors of poorer outcomes (Barkley, Fischer, et al., 2006; Fischer, Barkley, Fletcher, & Smallish, 1993; Fischer, Barkley, Smallish, & Fletcher, 2005; Hechtman, Weiss, Perlmann, & Amsel, 1984; Loney, Kramer, & Milich, 1983; Paternite & Loney, 1980).

There is minimal evidence of positive effects of childhood treatment on the eventual adult health and functioning of individuals diag-

nosed with ADHD as children (Wilens & Dodson, 2004). Extensive, long-term treatment during adolescence may improve outcome somewhat (Satterfield, Satterfield, & Cantwell, 1981). However, lesser degrees of treatment limited to childhood provide no measurable benefits in later life (Barkley, Anastopoulos, et al., 1992; Barkley, Fischer, et al., 1990; Hechtman et al., 1984; Paternite & Loney, 1980; Weiss & Hechtman, 1993). Results of the Multimodal Treatment Study of Children with ADHD (MTA) study suggest that effects of intensive intervention, both pharmacological and psychosocial, fade when the treatments are withdrawn (Smith, Barkley, & Shapiro, 2006). Most children and teens therefore do not receive intensive or sustained treatment for ADHD across development, which may account for the lack of measurable treatment effects in adults (Barkley, 2005).

The long-term effects of stimulants have received some attention, but much research is still needed in this area, because high-quality longitudinal treatment studies are lacking (Kupfer et al., 2000). Thus, we are not aware of any conclusive effects of stimulant treatment on adult outcomes, such as ADHD symptoms, functioning, or health. For each report of deleterious effects there seems to be a report of no detrimental, long-term effect. For instance, some studies have reported growth suppression effects (Charach, Figueroa, Chen, Ickovicz, & Schachar, 2006; Jensen, Arnold, Severe, Vitiello, & Hoagwood, 2004), but these findings have been contradicted by other studies (Spencer et al., 2006). Likewise, for each report of positive effects, such as prevention of substance abuse (Wilens, Faraone, Biederman, & Gunawardene, 2003) there is a study that reports no effect of stimulant treatment on substance abuse (Fischer & Barkley, 2003). Thus, the long-term effect of treatment, for better or worse, remains unclear, and more research in this area is badly needed (Wilens & Dodson, 2004).

Yet the complete picture is not so bleak. As noted earlier, longitudinal studies to date that have followed children with ADHD into adulthood and examined them for stimulant-associated problems have, with one exception, not identified any long-term adverse events associated with such treatment. In the one study that claimed to have found such a link (Lambert & Hartsough, 1998), methodological problems were plentiful, and 12 other studies

failed to replicate the linkage (Barkley et al., 2004; Wilens et al., 2003). Also worth noting is that stimulants have been on the market since the 1930s (amphetamines) to 1950s (methylphenidate), and millions of individuals have been treated with them, often over years. There is minimal or no evidence from postmarketing surveillance by the U.S. Food and Drug Administration (FDA) and pharmaceutical companies to indicate that significant health risks are convincingly associated with use of these medications over the short or long term. Recent media reports of suicidal thinking and attempts related to atomoxetine have not been shown to exceed the base rate for the ADHD population, despite the FDA black box warning in the package insert for the drug (Barkley & Fischer, 2005). And the black box warning for this medication concerning hepatotoxicity is based on one case in 3.4 million treated patients, illustrating how such warnings have become virtually meaningless in conveying a sense of risk to patient and clinician alike. Likewise, recent concern over the stimulant and cardiovascular risks and sudden death have been greatly exaggerated in media accounts of this story. Again, the adverse events have not been shown to exceed the base rates for sudden death in the population, thus calling into question any linkage between these events and stimulant treatment. Whereas caution is always in order with use of any medications, and clinical monitoring for such adverse events in treated cases is to be encouraged, especially if there are preexisting structural cardiac abnormalities, there is no evidence that common or widespread health risks are associated with ADHD medication management absent such abnormalities in the patient's history. Hence, whereas more rigorous long-term studies are to be encouraged, the limited number of such studies at present does not mean one cannot make legitimate inferences about long-term safety given these other sources of information that pertain to this issue.

CONCEPTUALIZATION OF THE DISORDER

Until recently, ADHD has lacked a reasonably credible scientific theory to explain its basic psychological nature and symptoms, and to link it with normal developmental processes. The field of ADHD treatment has reached a point, however, where the neuropsychological,

neuroimaging, and genetic studies cited earlier are setting clear limits on theorizing about not only the origins of ADHD but also theories about its nature. Any credible theory on the nature of ADHD must now posit neuropsychological constructs related to the normal development of inhibition, self-regulation, and executive functioning, and explain how they may go awry in ADHD. Such a theory will need to argue that these constructs arise from the functions of the prefrontal-striatal network and its interconnections with other brain regions, such as the cerebellum, that appear to underlie EFs and self-control. Those cognitive functions will be shown to have a substantial hereditary contribution to individual differences in the population according to the results of twin studies on the genetic contribution to variation in ADHD symptoms.

Barkley worked on just such a theoretical conceptualization of ADHD over the past 12 years (see Barkley, 1997b, 2006). It is briefly discussed below, followed by its implications for the management of ADHD. Research continues on the merits of this model for ADHD, but we include it here because of its far greater implications for evaluation with an eye toward treatment than any prior theories founded solely on ADHD arising from deficits in response inhibition (Quay, 1988), delay aversion (Solanto et al., 2001), or arousal and energetic pools (Sergeant & Van der Meere, 1989).

The model is founded on the premise that ADHD comprises mainly a developmental delay in or acquired impairment of the behavioral inhibition networks of the brain that disrupt self-regulation—an assertion for which there is substantial research support (see Barkley, 1997b; Nigg, 2006). This theory links behavioral inhibition to the EFs and shows them to provide for self-regulation. Behavioral inhibition occupies a foundation in relationship to self-control and four executive functions that are dependent upon it for their own effective execution. “Self-regulation” is defined as any self-directed action to change one's own behavior to alter the probability of a delayed (future) consequence. The EFs are forms of behavior-to-the-self—the actions one uses to change oneself so as to change their future.

Four executive functions are theorized to bring behavior progressively under the control of internally represented information (forms of self-directed action), time, and the probable future (delayed consequences), and wresting it

from the control of the immediate external context and the prepotent responses it generates. Appropriate self-control functions to maximize future consequences for the individual over merely immediate ones. The model applies only to ADHD-C to date.

“Behavioral inhibition” involves the capacity to inhibit prepotent responses, creating a delay in the response to an event (response inhibition). There may be two other inhibitory processes related to it, at least for the moment, that Barkley has combined into a single construct concerning inhibition. These two other processes are (1) the capacity to interrupt ongoing responses, given feedback about performance, particularly those response patterns that are proving ineffective; and (2) the protection of this delay in responding, the self-directed actions occurring within it, and the goal-directed behaviors created from interference by competing events and their prepotent responses (interference control). Through the postponement of the prepotent response and the creation of this protected period of delay, the occasion is set for the four executive functions (covert, self-directed actions) to act effectively in modifying the individual’s eventual response(s) to the event. The chain of goal-directed, temporally governed, and future-oriented behaviors set in motion by these acts of self-regulation are then protected during their performance by interference control. And even if disrupted, the individual retains the capacity or intention (via working memory) to return to the goal-directed actions, until the outcome is successfully achieved or judged to be no longer necessary. We list the four executive functions below, using both their more common label in the neuropsychological literature, followed by Barkley’s redefinition of the self-directed action (in parentheses) that each comprises.

1. *Nonverbal working memory* (covert self-directed sensing). Nonverbal working memory is the ability to maintain nonverbal, largely visuospatial mental information online that is used subsequently to control a motor response toward a goal. These mental representations are achieved by the self covertly sensing (especially visual imagery) information that serves to recall past events for the sake of preparing a current response. They represent *hindsight* or the *retrospective function* of working memory (Fuster, 1999). Past events are retained in a

temporal sequence that contributes to the *subjective estimation of psychological time* (Michon, 1985). Analysis of these sequences for recurring patterns is used for conjecture about hypothetical future events—the individual’s best guess as to what may happen next, or later in time, based on the detection of recurring patterns in past event sequences. This extension of hindsight forward into time also creates *forethought*, or the *prospective function* of working memory (Fuster, 1999). From this sense of the future arises anticipatory action in preparation for that future once it arrives. It likely explains the progressively greater valuation of future consequences over immediate ones that takes place throughout child development into young adult life (Green, Fry, & Meyerson, 1994). In so doing, individuals are then capable of the cross-temporal organization of behavior, that is, the linking of events, responses, and their eventual consequences via their representation in working memory despite what may be considerable gaps among them in real time.

2. *Verbal working memory (internalized, self-directed speech)*. During the early preschool years, speech, once developed, is initially employed for communication with others. Language is a means of influencing the behavior of others. But around age 3 years, it becomes self-directed, thereby eventually providing a means of reflection (self-directed description), as well as a means for controlling one’s own behavior (Berk & Potts, 1991). Self-directed speech progresses from being public, to being subvocal, to finally being private, all over the course of perhaps 6–10 years. With this progressive privatization of speech comes the increasing control it permits over behavior. Self-speech now provides a tremendously increased capacity for self-control, planning, and goal-directed behavior that further augments that being provided by the first EF, chiefly imagery.

3. *Self-regulation of affect–motivation–arousal (self-directed emotion)*. The self-regulation of affect, motivation, and arousal can now develop through the use of the first two executive abilities (self-sensing and self-speech). Individuals now possess the capacity to present images (and other sensory information) along with words to themselves that can be used to manipulate emotional states. These images and other sensory information from the past come with emotional valences automati-

cally welded to them (how one felt about them) (Damasio, 1995). Yet it is not just one's affect that is being managed by the use of self-speech and self-sensing. Emotion is, by definition, a motivational state. And so this re-presenting of words and images to the self creates a capacity for self-motivation (Fuster, 1999) via self-emotion (Ekman & Davidson, 1994; Lang, 1995). By privately manipulating and modulating emotional and motivational states, the child can induce drive or motivational states that may be required for the initiation and maintenance of goal directed behavior (Barkley, 1997b).

4. *Planning or reconstitution (self-directed play)*. Bronowski (1977) reasoned that the use of images and language to represent objects, actions, and their properties that exist in the world around us provides a means by which we can take the world apart. These pieces can then be combined to create novel recombinations, some of which yield truly innovative, functional response options. Internal speech and imagery permit *analysis* (taking apart), and out of this process comes its complement *synthesis* (recombination) to create entirely new ideas about the world (Bronowski, 1977), and entirely new responses to that world. It provides a means to synthesize novel behavioral sequences in the service of problem solving and goal-directed action, particularly when obstacles are encountered in pursuit of a goal and new behaviors must be generated to solve the problem (Barkley, 1997b; Fuster, 1999). Barkley has hypothesized that, like the other executive functions, this one is also a form of self-directed behavior that becomes turned on the self during development and eventually is privatized. That action-to-the-self is based on play in childhood that progresses from manual-verbal play to private mental manipulation of images and words that generates new ideas and related behavior to use in goal-directed problem solving.

Such internal control over behavior creates not only a greater purposefulness or intentionality to behavior but also a greater flexibility. The EFs grant behavior a more determined, persistent, reasoned, intentional, and purposive quality, while permitting greater shifting of behavior as needed to achieve one's goals—an appearance of volition, choice, and will arising from internally guided behavior (James, 1890).

The impairment in behavioral inhibition occurring in ADHD is hypothesized to disrupt the efficient performance of these EFs, thereby delimiting the capacity for self-regulation. The result is impairment in the cross-temporal organization of behavior, and in the guidance and control of behavior by internally represented information. This inevitably leads to a reduction in the maximization of long-term consequences for the individual. This theory, if correct, provides a much deeper insight into the nature of the disorder and a much broader perspective on its likely impairments, along with a litany of implications for its management (see below). In essence, ADHD is not so much an attention disorder as a disorder of executive functioning or of internally guided and regulated behavior across time and toward future events. This leaves the affected individual more controlled by external events in the moment and more governed by concerns for immediate than for delayed gratification.

Implications for Assessment

Several implications for assessment arise from Barkley's model of ADHD. First, a complete picture of ADHD and its impact on a child's functioning are difficult to capture in office evaluations. Some degree of inhibitory difficulties may be exhibited in an office setting, but not always, and not in most children presenting for evaluation of ADHD. The disruption in the four EFs prove even harder to pin down given that few psychological tests assess these functions, as described earlier, for clinical purposes, and few rating scales contain items focusing explicitly upon them. Compared to the clinician, caregivers have had far longer spans of time over which to evaluate the child's deficiencies in self-regulation, disorganization regarding time, ineffective cross-temporal organization of goal-directed behaviors, impersistence in task- or goal-directed behavior (inattention), and failure to defer gratification and to maximize longer-term consequences over short-term or immediate ones. Therefore, considerable weight should be given to parent and teacher opinions, initially via ratings, when assessing ADHD (Pelham et al., 2005).

Another important implication is that multiple observations of the child's behavior and task performance in natural settings may prove more informative about the presence and degree of ADHD than a brief office evaluation or

psychological testing. Therefore, information provided by parents and teachers must also take into account variability due to setting, task, and time of day. When feasible, direct observations (e.g., classroom performance) as a part of school psychological evaluations are to be strongly encouraged so as to provide information collateral to that obtained via parent and teacher report.

To further encumber the assessment of ADHD, the complexity of ADHD is likely to increase over development given that the four EFs that are disrupted by the child's poor behavioral inhibition emerge in a staggered fashion across development. The older the child at the time of evaluation, the more likely the clinician is to find that caregivers are complaining about not only the child's hyperactivity or poor inhibition but about deficits in those EFs that normal children have recently developed. For instance, parents of 3- to 5-year-old children with ADHD are unlikely to complain about the children's poor sense of time, planning, and forethought, but parents of 10- to 16-year-olds with ADHD are far more likely to note such problems. This becomes especially problematic for the adult with the disorder (Barkley et al., in press). Thus, the scope and complexity of impairments broaden in children with ADHD as their development proceeds. This makes it essential for the clinician to ask the parents of an older child with ADHD about deficiencies in these EFs and their impact on the child's adaptive functioning at home and in school.

This model suggests that the full impact of ADHD on the child's adaptive functioning requires a longer span of time to appreciate than is likely to be evident in an initial evaluation of only a few hours. Using measures of adaptive functioning, besides the usual methods of interviewing and obtaining behavior ratings, will probably prove useful to some degree in capturing this impact of ADHD on the child's daily life. An evaluation of an individual with ADHD that appropriately documents the deficiencies in behavioral inhibition, EFs, and self-control is likely to lead to a number of suggestions for treatment, as discussed elsewhere (Barkley, 2005). These suggestions should be evaluated as part of an ongoing assessment process, because it is impossible to predict in advance precisely what treatments will work for an individual with ADHD, even though base rates of successful treatment are relatively

high (i.e., 65–80% for medications, 35–75% for psychosocial treatments, etc.). Thus, state-of-the-art treatment for ADHD involves enlightened trial and error. The success of treatment must be documented as part of an ongoing assessment process, and lack of success should lead to a modification of the treatment plan.

Parents who bring their child for a clinical assessment of ADHD are often demoralized (Anastopoulos et al., 1992; Campbell et al., 1994; Hoza et al., 2000; Ostrander & Herman, 2006). They have usually been struggling with the child's impairments related to ADHD and associated problems for years, have tried multiple solutions without success, feel defensive about their role in their child's behavior, often have issues of their own (e.g., marital conflict), and are ambivalent about changing their own behavior (e.g., establishing and maintaining clear rules and consequences) even if it is clearly directed at the well-being of their child. Accordingly, a major consideration in assessment as a prelude to intervention should be the caregivers' knowledge about ADHD and effective interventions, and the caregivers' stage of readiness for change. This issue is addressed in our description of the ACU. Prior to that description, we provide guidelines for a minimally acceptable assessment of ADHD for diagnostic purposes.

RECOMMENDED ASSESSMENT PROCEDURES

In this section we describe (1) the state of assessment of ADHD, (2) methodological considerations in assessing ADHD, and (3) a checklist of considerations required to complete a minimally sufficient evaluation of ADHD. Finally, we briefly describe two promising approaches to evaluating ADHD that are based on motivational interviewing and response to intervention.

The State of ADHD Diagnosis

The "gold standard" diagnosis refers to accepted "proof" that the patient does or does not have the target disorder (Meehl & Rosen, 1955). Ideally, the "gold standard" provides objective criteria (e.g., a laboratory test not requiring interpretation) or a current clinical standard for diagnosis (e.g., an imaging technique that requires some interpretation, such as

an MRI). Such “gold standards” do not exist for mental disorders, including ADHD (Kupfer et al., 2000), so diagnosis of this disorder is based on descriptions of behavior coupled with history, course, and knowledge of differential diagnosis. The current “silver standard” for diagnosis is DSM-IV.

A large gap exists between the assessment procedures used in research and in practice settings (Wolraich, 2002). Many of the procedures in research settings are not even remotely feasible in practice settings, because they are expensive, take hours or days to complete, and require specialized training not offered in most graduate education programs (e.g., coding of structured interviews or parent-child interactions). For instance, the initial assessment procedures for the Multimodal Treatment Study of Children with ADHD (MTA) occurred over several days and averaged 7–10 hours, during which the following data were gathered: rating scales from parents and teachers, clinical interviews with parents and children, structured diagnostic interviews covering a full range of disorders, intellectual and academic performance measures, measures of affective and social functioning, computerized assessments of attention, behavioral observations in clinic and school settings, and semistructured clinical interviews regarding parent psychopathology (MTA Collaborative Group, 1999). This is not acceptable or feasible in typical applied settings.

Despite the limitations in the current state of the art for assessment of ADHD, there is broad consensus that ADHD is a “real” disorder (Barkley, Cook, et al., 2002 [International Consensus Statement]; Kupfer et al., 2000). Dealing with uncertainty in diagnosis is not a unique problem. There are vagaries and disagreements even in most medical diagnoses (Kupfer et al., 2000). Nevertheless, as with other psychiatric disorders, there is consensus that it is possible to achieve a valid diagnosis of ADHD even though the diagnosis may be based on a variety of different procedures.

But one encounters some unique challenges when diagnosing ADHD. For instance, self-report of the core symptoms of ADHD (i.e., inattention, impulsivity, and hyperactivity) does not appear to be very dependable in children, even when followed to young adulthood (Barkley, Fischer, Smallish, & Fletcher, 2002; McCann & Roy-Byrne, 2004). The reports of clinic-referred adults diagnosed with ADHD,

however, are more reliable (Barkley et al., in press). A high degree of within-person variability is also endemic to ADHD and may indeed be one of the hallmarks of the disorder (Barkley, 2005). Still another challenge is the key informants’ (i.e., teachers and parents) varying perspectives that are governed by a wide array of influences. All of these factors, and more, need to be considered to achieve a valid diagnosis of ADHD.

Measurement Theory Pertinent to ADHD

Classic true score theory divides variance into three major components (Lord, 1965). First is “true score variance,” which is the variance of substantive interest (e.g., variance due to ADHD). Second is systematic error, the biases or irrelevant variance likely to be repeated across measurement occasions (e.g., an idiosyncratic teacher perspective, maternal depression, or unique setting effects). Third is random error, or psychometric noise in the assessment process (e.g., careless mistakes when filling out questionnaires, lapses by observers when coding behavior, or items that are so vague that they produce a broad range of responses). All three types of variance need to be considered when assessing ADHD.

Understanding Within-Subject Variability

A common mistake when measuring ADHD is to confuse the high within-subject variability typical of many persons with ADHD and random error, thus totally ignoring the potential information captured by within-subject variability. Unfortunately, most social scientists are trained to characterize groups using a measure of central tendency, usually the arithmetic average (i.e., group mean). Accordingly, assessment decisions are often based on comparing individuals to a group mean. In such comparisons, within-group variability is used to determine where an individual falls relative to his or her peer group. Commonly used statistics for diagnostic decisions, such as *z*-scores and *T*-scores, are based on central tendency and within-group variability. Such scores are the basis for cutoffs on standardized rating scales for ADHD (e.g., a *T*-score greater than 70).

The normative approach to evaluating ADHD has its place, especially when the items describe behavior over a broad range of situations (e.g., school and home) and a representa-

tive period of time (e.g., weeks or months). However, such assessments routinely fail to capture clinically and theoretically meaningful variance in within-person behavior. We are not aware of any scales that present data on deviant levels of variability in behavior, so this phenomenon is not well documented in the research literature, though it has been gleaned in laboratory tasks that use numerous repeated trials, such as reaction time tasks, CPTs, and even driving simulators.

In some instances it might be useful to understand the prognostic and treatment implications for within-subject variance. This issue has been explored in some behavior-analytic case studies, and within-subject variability has been used as an outcome variable in some treatment studies (Pelham, 1993). However, empirical investigation of the practical implications of within-subject variability has been neglected in the voluminous literature on ADHD. From a single-case standpoint, evaluating the existence and functional significance of fluctuations in performance can be critically important.

It is reasonable that treatment goals for ADHD address both central tendency and variability. Of interest should be (1) changes in variability of behavior and (2) moving averages or trends in behavior. Such an assessment requires much more frequent data gathering than the pre-, post-, and follow-up measure strategies that dominate the treatment literature on ADHD. Much more frequent data collection, such as daily or weekly intervals when feasible, is useful—a reasonable number of assessments (e.g., at least six occasions) can provide a decent moving picture of performance. The availability of online symptom and impairment tracking websites (e.g., *Symptomtracking.com* or *Myadhd.com*) that patients—parents, teachers, and clinicians can access and report on behavior repeatedly may go along way toward making such repeated measurements more feasible and cost-effective. The recent use of handheld personal data assistants for repeated measurement in home or school settings may eventually provide a similar advantage (Whalen et al., 2006).

Setting and Observer Influences on Scores

Research on interrater agreement in the child psychopathology literature has consistently found significant but relatively small correlations between informants. For example, in a

classic review on the topic, Achenbach and colleagues (1987) found a correlation of only about .30 between parent and teacher ratings of child psychopathology. This means that studies were finding only about 10% shared variance in behavior ratings between key informants. The small, positive correlations between parent and teacher ratings on standardized child behavior scales have been replicated in research on ADHD (Andrews, Garrison, Jackson, Addy, & McKeown, 1993; Stranger & Lewis, 1993).

The low correlations between parent and teacher ratings of ADHD have been used (speciously) by some critics to question the validity of ADHD diagnoses (Barkley, Fischer, et al., 2002). However, we believe these correlational studies merely highlight the differences in child behavior at home compared to school, and the need for well-structured assessments of ADHD. Appropriately structured evaluations should account for major influences on behavior, including activity, setting, and rater effects. It is well known that persons with ADHD can focus nearly as well as persons without ADHD on activities that are intrinsically interesting. As reviewed previously in this chapter, setting effects such as structure, novelty, and behavioral contingencies have all been shown to have large effects on ADHD and related problems. Furthermore, rater effects, such as expectations of the use of the measure, knowledge of ADHD, wording of questions, and the rater's mood that day, can all have a large effect on assessment scores.

Given the strong influences on scores that can be directly attributed to activity, setting, and rater, it should not be surprising that there is wide variability in cross-informant ratings. Documenting activity, setting, and rater influences on scores can be tremendously informative (e.g., revealing why a student thrives in one class and languishes in another). Unfortunately, most assessments of ADHD do not systematically provide a mechanism for resolving cross-informant discrepancies, even though this information is critically important for (1) judging the validity of the ratings and (2) understanding the key influences on the behavior of the person being assessed for ADHD. Fortunately, some procedures can be added to an ADHD assessment to deal with these issues. These include (1) gathering data from multiple informants, (2) conducting structured interviews about reasons for cross-informant disagree-

ment, and (3) observing standardized behavior samples where feasible.

One of the requirements for a minimally adequate assessment of ADHD is to gather data from multiple raters. This is often accomplished by obtaining information from at least one parent and one teacher. More raters are even better, especially if they sample unique settings, relationships, or perspectives. Thus, it is usually best to have each parent complete ratings when possible, and to have various teachers complete ratings, such as those teaching core subjects requiring protracted mental effort—English, math, and history. Understanding why the child does better with one parent compared to the other, or in one school activity compared to another, is important information that can usually be gleaned from a well-structured interview with parents.

The confounding influences of activity and setting effects can be untangled through several methods, including (1) structured interviewing, (2) direct observation, and (3) functional assessments when evaluating ADHD. We fully understand that most clinicians do not have time to engage in direct observation or to conduct functional assessments, so our focus here is primarily on interviewing. Questions about ADHD symptoms should be specifically designed to illuminate influences such as setting, activity, and raters. For instance, rater effects may be evident if one rater stands out as being much more negative than others. Diplomatically discussing the reason for such a discrepancy can illuminate whether the difference is due to setting or rater effects.

Another important way to reveal influences on behavior is to ask very specific questions. For instance, asking the global question, “Does the child have problems with sustained attention?” may lead to a variety of confusing answers. Respondents might say “no,” if they were thinking about computer games, or “yes,” if they were thinking about doing homework. Thus, it is best to ask for a range of behaviors:

“When does your child pay attention?”

“When does your child seem to have trouble paying attention?”

“Why do you think there is a difference across these activities?”

A proper interview about setting influences can also help to untangle some putative rater

influences on ratings. Toward this end, assessments of ADHD should include asking the rater to describe typical activities he or she shares or directs with the person being assessed. For example, one teacher may rate a child as more inattentive than another, because that teacher is leading the class through repetitive math drills, whereas the other teacher is leading the student through interactive, hands-on Web-based activities. Similarly, a mother might rate her child as problematic because she supervises all of the chores and homework, whereas the father might not see the child as problematic, because he is primarily involved in novel projects or leisure activities with the child.

Structured interviewing with a parent is a minimum condition for an adequate assessment of ADHD. In some cases, more interviewing may be necessary with a teacher. In others, such as interviewing school-based professionals, it might be worthwhile to supplement the interviewing with direct observation. This is a major assessment issue because (1) ADHD must be shown to be pervasive across settings and raters, and (2) interventions can target settings, activities, and raters.

Benchmark samples of behavior are important here and can be gathered from one informant and used as reference points with other informants who witness the behavior. For instance, a mother might be asked to describe a typical behavior related to ADHD, such as behavior when doing homework. Then, the father and teachers may be asked about their observations of homework completion or self-directed seat work. Probing the key informants about the degree of problems and success with the task, the influences on behavior in the task, and the developmental appropriateness of the behavior can be very informative. Of note, this approach to assessment is not only person-centered (e.g., what symptoms the child with ADHD exhibits) but also examines the person-environment fit (e.g., the influences on the person’s behavior and how the person influences the environment).

After examining potential variation across settings, it is very important to consider the unique variance of the rater’s knowledge, beliefs, and circumstances on the ratings. Unfortunately, despite widespread understanding that unique variance due to raters has a large effect on ratings, there is no widely agreed-upon procedure for controlling idiosyncratic

rater variance in assessments of ADHD. Ideally, rating scales for ADHD should have correction factors that adjust for potentially biasing influences such as parental depression, knowledge of typical development, and understanding of ADHD. At best, the current state-of-the-art assessment involves a qualitative synthesis of such information, if it is collected at all. This can be ascertained in a well-constructed interview for ADHD, such as the ACU, described later.

In addition to controlling for rater bias, collecting information on parents' mood, knowledge, resources, social support, and motivation for change is critically important assessment information. What the parent chooses to do with the evaluation data is probably an important consideration when doing an assessment for ADHD. Therefore, such information is structured such that (1) the parent understands the conclusions, (2) understands how the recommendations arise from the conclusions, and (3) feels personally willing and able to carry out key recommendations arising from the evaluation. Unfortunately, many parents are informed that their child has a diagnosis, but they may not understand it (e.g., ADHD-C subtype) and may be told to pursue treatment they do not necessarily want (e.g., "parent training" or medication). Fortunately, there are ways to evaluate ADHD that overcome these common oversights in assessment and treatment recommendations.

Within-Person Variability

Assessment approaches that do not control for within-subject variability and systematic differences in ratings from multiple informants can yield assessment data that appear to be full of random error. With appropriate measurement procedures, however, it is possible to learn quite a bit of important information from these sources of information that appear to be random, if not approached properly. True random error, on the other hand, is pure noise, with no redeeming measurement value. Some studies suggest that self-report of ADHD may be essentially random noise. At the very least, it is not clear whether children with ADHD can provide useful information to the assessment of their symptoms or impairments beyond what is provided by collateral informants (e.g., parents). Self-reports may be more valid in clinic-referred adults (Barkley et al., in press). This

section briefly reviews the validity of self-report of ADHD.

Children under the ages 9–12 years are not especially reliable in reports of their own problems or those of other family members. Furthermore, developmentally appropriate threats to the validity of self-report of ADHD symptoms are compounded by the frequently diminished self-awareness and impulse control typical of children with ADHD (Hinshaw, 1994). Nevertheless, many self-report rating scales that address ADHD symptoms are normed on ages as young as 8 years. These include the widely used Youth Self-Report version of the CBCL (Achenbach, 2001) and BASC-2 (Reynolds & Kamphaus, 2005). Unfortunately, these and similar scales have significant limitations in assessing ADHD and until more compelling psychometric data are presented, they should not be used to rule in or rule out a diagnosis of ADHD. They may, however, reveal levels of insight or motivation to change. For instance, showing parents that their child has a low hyperactivity self-report score may help convince them that extrinsic motivators will be necessary to deal with this issue.

It is common practice to interview a child about ADHD. Unfortunately, children with ADHD often show little reflection about the examiner's questions and may lie or distort information in a socially pleasing direction. Despite evidence to the contrary, some children report having many friends and no interaction problems at home with their parents, and that they are doing well at school, in direct contrast to the extensive parental and teacher complaints about the inappropriate behavior of these children. The problem is so ubiquitous to children with ADHD that some have argued that a hallmark of ADHD is an inordinately large disparity between self-evaluations and actual functioning in that setting or task, most likely due to a positive illusory bias (Hoza et al., 2004). This has also been shown in adults with the disorder (Knouse, Bagwell, Barkley, & Murphy, 2005). Accordingly, there may be a fundamental deficit in self-evaluation of inattention or impulsivity and its consequences (Barkley, 2005). Thus, lengthy structured or semistructured interviews with children with ADHD symptoms is probably a waste of time. Brief interviews to establish rapport and cooperation with intervention, however, might be worthwhile.

Adolescent self-report may be more reliable and valid for assessing externalizing symptoms

(Smith, Pelham, Gnagy, Molina, & Evans, 2000). However, self-reports about externalizing symptoms by adolescents with ADHD add little incremental information beyond parent or teacher report. Nevertheless, adolescents' reports of their internalizing symptoms (e.g., anxiety and depression) do seem to contribute incrementally valid information to assessment and should therefore play an important role in the diagnosis of comorbid anxiety or mood disorders in adolescents with ADHD (Hinshaw, 1994).

Some studies have found that clinic-referred adults with ADHD report more symptoms of inattention and impulsivity than do comparison groups. Although initial research on self-report of ADHD symptoms in adults was promising, more recent studies have raised questions about the validity of this source of information, and the problem appears to be double-edged. On the one hand, there may be tendency of adults who do not have ADHD to overreport symptoms of ADHD. For instance, Murphy, Gordon, and Barkley (2002) found that 80% of a sample of 719 adults recruited from motor vehicle license renewal sites reported six symptoms of ADHD at least sometimes during childhood, and this only dropped to 25% when more stringent criteria were imposed. Clearly the term "often," as used in DSM-IV symptoms, needs to be emphasized to underscore the excessive, persistent, and developmentally inappropriate nature of the behavior before it should be counted as a symptom. On the other hand, there appears to be a tendency for individuals diagnosed in childhood as having ADHD to underreport these symptoms as adults. For example, in one study, 46% of the sample of young adults who had been followed for ADHD since childhood met criteria for ADHD based on parent or other collateral report, but only 5% met diagnostic criteria based on self-report (Barkley, Fischer, et al., 2002).

In a study of college students (Smith, Cole, Ingram, & Clement, 2004), low kappas for classification as ADHD for self-ratings and semistructured interviews suggested considerable inconsistency in self-report of ADHD. In the same study, when parent report of diagnosis of ADHD was used as a criterion, specificity of self-report and interview was .72 and .83, respectively. Sensitivity was .50 and .21, respectively. Such findings clearly emphasize a point we risk reiterating repeatedly here: the

need for collateral information other than self-reports concerning symptoms and impairment.

Taken together, these findings suggest two major problems with self-reported symptoms of ADHD by adults. The first problem has to do with the patient source. Children with ADHD followed to adulthood may be underreporting current ADHD symptoms relative to parent reports about their current functioning. Clinic-referred adults, in contrast, often report more symptoms than do others who know them well. The other problem is overreporting of retrospective (i.e., childhood) symptoms among those who do not have ADHD. Accordingly, adult self-report data should be used with some caution and should never be the sole source of information used in diagnosis.

To summarize, although research comparing self-report of ADHD symptoms among adults and objective measures is lacking, this type of research with children and adolescents shows that there is little or no incremental validity of self-report of externalizing symptoms by individuals with ADHD. Self-report can add a large amount of error and, if taken too seriously, confusion to the assessment battery. Thus, self-report of ADHD symptoms by children can be detrimental to the assessment process, and clinicians should avoid wasting precious time and energy on lengthy structured or semistructured interviews that focus on self-report of ADHD symptoms. On the other hand, brief interviews to build rapport or to examine other psychiatric conditions, such as anxiety or depression, are recommended. Therefore, assessment for ADHD should include some self-report interviewing, but the decision about the diagnosis of ADHD in children should focus heavily on collateral report (e.g., parent ratings), and self-report should be viewed very cautiously.

Multimodal Assessment of ADHD

The purpose of this section is to provide our recommendations for completing an acceptable evaluation for ADHD. This includes describing assessment tools and the procedures for using those tools. In some cases we compare and contrast various assessment options; however, this is not intended to be a comprehensive overview of a broad range of assessment options. Rather, we focus on specific methods that we believe are the best options available. As promised earlier, we provide empirical justification for our

choices as often as possible and make it clear when our recommendations are based on consensus or professional experience.

Although we recommend collecting a significant amount of information, we have selected measures and procedures that should be feasible and clinically meaningful in the “real world.” The procedures for the ACU should take about 4 hours of parent time, 30–45 minutes of teacher time, and 5 hours of clinician time. Parent time includes an hour for completing questionnaires and about 3 hours for meeting with the clinician. Teacher time is devoted to completing questionnaires. Clinician time includes helping the parents and teachers complete the ratings, collecting collateral information from the school (e.g., grades), scoring measures, conducting semistructured interviews, and providing feedback to the family. This level of assessment has been deemed to be reasonable in field trials in clinical settings (Foy & Earls, 2005).

Goals of Assessment

There are several goals to bear in mind in the evaluation of an individual suspected of having ADHD. One is determination of the presence or absence of ADHD, with careful attention to differential diagnosis of ADHD as opposed to other psychiatric disorders. This requires extensive clinical knowledge of these other psychiatric disorders. Pertinent information on other childhood disorders is found in other chapters of this volume. Also, more information on differentiating between ADHD and other disorders is found in DSM-IV and Barkley (2005).

A second goal of the evaluation is to begin delineating the types of interventions needed to address the psychiatric disorder(s) and psychological, academic, and social impairments identified in the course of assessment. As we note later, these may include individual counseling, parent training in behavior management, family therapy, classroom behavior modification, stimulant or antidepressant medications, and formal special educational services, to name just a few (see Smith et al., 2006, for a recent review of treatments for ADHD, and Barkley, 2005, for more extensive coverage of each).

Another important goal of the evaluation is determination of comorbid conditions and whether or not these may affect prognosis or decisions about treatment. For instance, the

presence of high levels of anxiety specifically, and of internalizing symptoms more generally, has been shown in some instances to be a predictor of poorer responses to stimulant medication (DuPaul, Barkley, & McMurray, 1994; Jensen et al., 2001; Pliszka, 1989). Other studies, however, argue that this may not be the case, making this a current point of contention (Abikoff et al., 2005). Similarly, high levels of hostile, defiant behavior or ODD have been shown to be a marker for greater family conflict (Barkley, Anastopoulos, et al., 1992; Barkley et al., 1991) that may interfere with successful parent training or family therapy.

A further goal of the evaluation is to identify the pattern of the child’s psychological strengths and weaknesses, and to consider how these may affect treatment planning. This may also include gaining some impression of the parents’ own abilities to carry out the treatment program, as well as their social and economic circumstances, and the treatment resources that may (or may not) be available within their community and cultural group. The evaluation also usually needs to determine the child’s potential eligibility for special educational services within the school district. Such eligibility has been granted to ADHD children under federal legislation over the past 20 years via the Individuals with Disabilities in Education Act and Section 504 of the Rehabilitation Act (DuPaul & Stoner, 1994; Latham & Latham, 1992), but particular state regulations that institute these federal policies in a child’s home school district may vary.

A key issue in assessing ADHD, especially in children and adolescents, is evaluating the primary caregiver’s knowledge of intervention options and motivation to change. Matching treatment options with the caregiver’s level of readiness for change may make the difference between assessment that is an exercise in developing insight versus an experience that prompts effective behavior change. We think the emphasis should be on promoting the right kind of change when change is needed (Miller & Rollnick, 2002). Therefore, we recommend a guided participatory process that (1) matches information and strategies according to the caregiver’s stage of readiness for change, and (2) provides ongoing tracking of target behaviors using individual case study methods designed to assess response to treatment. We review these two strategies following consideration of some basic issues in assessing ADHD.

Minimally Acceptable Evaluation of ADHD

There is consensus regarding the elements of a minimally acceptable evaluation of ADHD but there are several ways to accomplish such an assessment. Experts agree that the following data should be collected: (1) parent ratings of ADHD symptoms, other psychiatric disorders, and related impairment; (2) teacher ratings of ADHD symptoms and functioning at school; (3) a semistructured interview with a parent to ascertain influences on behavior, parental skills and knowledge, and the developmental history of ADHD-related impairment, comorbid conditions, and various treatments or efforts to change behavior; and (4) if the history so indicates, an examination by a physician to rule out plausible physical causes for putative ADHD symptoms (Foy & Earls, 2005; Pelham et al., 2005). In the following sections, we elaborate on these four cornerstones of ADHD assessment by recommending specific tools and the rationale for including those tools.

During the assessment process we ask parents to complete the measures listed in Table 2.2. It should take most parents less than an hour to complete these measures. Ideally, these

TABLE 2.2. Recommended Self-Report Measures to Be Completed by Parents

-
1. The Parent Rating Scale (PRS) of the Behavioral Assessment System for Children, Second Edition (BASC-2; Reynolds & Kamphaus, 2005).
 2. A checklist of DSM-IV symptoms using the Disruptive Behavior Disorders Scale (Pelham, Fabiano, & Massetti, 2005).
 3. The Home Situations Questionnaire (HSQ; Barkley & Murphy, 2006).
 4. A brief ADHD scale such as the Conners Global Index (CGI; Conners, 1997) or ADHD Rating Scale-IV (DuPaul et al., 1998).
 5. A brief index of impairment such as the Children's Impairment Rating Scale (CIRS; Fabiano et al., 2006).
 6. The Beck Depression Inventory (BDI; Beck, Steer, & Brown, 1996) or Symptom Checklist-90—Revised (Derogatis, 1995).
 7. The Alcohol Use Disorders Identification Test (AUDIT; Saunders, Aasland, Babor, Delafuente, & Grant, 1993).
 8. Married or cohabitating caregivers should be asked to complete the Parenting Experiences Inventory (Sanders & Ralph, 2001). See Appendix 2.1.
-

may be mailed to parents before the assessment process starts, or parents may complete them between initial assessment meetings scheduled on two or more occasions. Because some parents will not complete these on their own, such as those with limited linguistic or intellectual competence, without some explanation, prompting, and support, it is often best to ask such parents to complete the measures between the first and second sessions or within the sessions.

The purpose of having the parent complete the Parent Rating Scale (PRS) of the BASC-2 is because it is important to use a standardized, well-normed, psychometrically sound instrument to conduct a broad screening for psychopathology and adaptation (Reynolds & Kamphaus, 2005). There are different versions of the PRS that allow the parent to provide developmentally appropriate information from preschool to college. The computerized scoring of the scale is readily interpreted and highly informative. The areas of psychopathology covered by the PRS vary with age group. For the child (ages 6–11) and adolescent versions (ages 12–21) the PRS provides the following clinical scales: aggression, anxiety, attention problems, atypicality, conduct problems, hyperactivity, somatization, and withdrawal. The PRS for these age groups also provides adaptive scales in the areas of activities of daily living, adaptability, functional communication, leadership, and social skills.

The major viable alternative to the PRS, the Child Behavior Checklist (CBCL; Achenbach, 1991, 2001; Achenbach & Rescorla, 2001), is probably the most widely used “broad-band” screening measure for child psychopathology. However, two studies by independent research groups have shown that the PRS is better than the CBCL at discriminating between children with and without ADHD (Ostrander, Weinfurt, Yarnold, & August, 1998; Vaughn, Riccio, Hynd, & Hall, 1997). Moreover, the PRS provides information on adaptive functioning.

It is noteworthy that there have been revisions to the CBCL since the aforementioned studies were published. Currently, the CBCL provides normed scales for attention problems and attention deficit/hyperactivity problems, including hyperactivity/impulsivity and attention problems subscales (Reynolds & Kamphaus, 2005). In summary, the revised CBCL appears to be a good measure, but the PRS still has the advantage of providing adap-

tive functioning scales that are lacking in the CBCL.

The second measure we recommend, the Disruptive Behavior Disorders Scale (DBD), captures data specific to ADHD, ODD, and CD (Pelham et al., 2005). A very similar scale is provided in the clinical manual by Barkley and Murphy (2006). This scale rephrases symptom descriptions taken from DSM-IV and has the parent rate them on a 0- to 3-point scale (see Table 2.1 for ADHD symptoms; the DBD also measures ODD and CD symptoms). This type of rating scale is used widely in ADHD research and should be familiar to many clinicians who work with individuals with ADHD. Various cutoffs can be applied to the scores. In most applications, scores of 2 or 3 are considered to be clinically significant, whereas scores of 0 or 1 are not. Tallying these symptom counts can readily assist in evaluating DSM-IV diagnoses of ADHD, ODD, or CD. Psychometric data on the DBD supports its use (Pelham et al., 2005). Furthermore, mean item scores of less than 1 on the inattention, hyperactivity/impulsivity, and ODD scales have been used as a criterion for clinically significant change in major treatment studies of ADHD (Swanson et al., 2001).

The major alternatives to the DBD are (1) scales similar to the DBD that focus on ADHD symptoms from the DSM, but not ODD or CD, such as the ADHD Rating Scale-IV (DuPaul et al., 1998), and (2) scales that focus on ADHD symptoms and related problems, such as the various Conners ratings scales (Conners, 1997). We are not aware of studies that have compared directly the incremental validity or other psychometric considerations of the DBD-type scales relative to other “narrow-band” ADHD rating scales. They are likely to be equivalent in detecting ADHD at least, because norms are available from the ADHD Rating Scale-IV, which can be used to score the ADHD portion of the DBD scale by Barkley and Murphy (2006).

The pervasiveness of the child’s behavior problems within the home and school settings should also be examined, as such measures of situational pervasiveness appear to have as much, if not more, stability over time as do the aforementioned scales (Fischer et al., 1993). The Home Situations Questionnaire (HSQ; Barkley & Murphy, 2006) requires parents to rate their child’s behavior problems across 16 different home and public situations. Such in-

formation may assist in planning behavioral interventions for children with ADHD and accounting for cross-informant discrepancies in ratings of ADHD symptoms and related problems. We are not aware of the development of any alternatives to the HSQ for the purpose of assessing situational pervasiveness of ADHD.

We recommend instituting some brief measures that are likely to be sensitive to response to treatment. For this reason, we ask parents to complete the Conners Global Index (CGI) and the Children’s Impairment Rating Scale (CIRS) on a weekly basis. Along with tracking of specific problem behaviors, these brief rating scales provide important guidance in assessing intervention efforts.

The CGI, a 10-item scale with ratings on the familiar 0- to 3-point scale used by ADHD researchers (Pliszka, Liotti, et al., 2000), can be completed quickly and has been shown to be responsive to treatment (Pliszka, Liotti, et al., 2000). It is too much to ask parents to complete longer scales such as the BASC-2 on a weekly basis; furthermore, the validity of the broad-band scales (e.g., BASC-2) is unknown in the context of weekly administration. Other brief scales, such as the IOWA Conners (see Pelham et al., 2005), do not map directly onto DSM symptom lists and the research history seems to be stronger for the CGI. It might be reasonable to repeat DBD subscales (e.g., inattention symptoms) or items from the HSQ on a weekly basis, but when used repeatedly over short durations, the psychometrics of such measures need to be studied.

It is critically important to document impairment, which refers to the consequences of the ADHD symptoms for various domains of major life activities, such as home and school functioning, peer relations, and so on. We recommend the parent version of the CIRS. This scale covers key domains of impairment identified by parents, including relationship with peers, relationship with siblings, academic progress, effect on family, self-esteem, and overall functioning. Each area is rated on a 0- to 6-point scale (0, *no problem, no need for treatment*; 6, *severe problem, definite need for treatment*). This yields a clinically meaningful metric (i.e., scores less than 3 suggest that the child does not need intervention in that area). Recent validity studies support use of the CIRS with children with ADHD (Fabiano et al., 2006).

There are some alternatives to the CIRS. One approach is to use a single global measure,

such as the Children's Global Assessment of Functioning Scale (C-GAS) described in DSM-IV. The C-GAS has been shown to be responsive to treatment and, like the CIRS, is brief enough to be given on a weekly basis. Although little research specifically supports this assumption, we hypothesize that the CIRS has greater clinical relevance and incremental validity over the C-GAS, so the CIRS is our measure of choice for impairment at this time. Another is to examine the adaptive functioning items from the CBCL individually for parent and teacher responses on items concerning home, school, and peer functioning.

Other alternatives to the CIRS are very detailed measures of adaptive functioning that are not usually clinically cost-effective. The Vineland Adaptive Behavior Scales (Sparrow, Balla, & Cicchetti, 1984) is probably the most commonly used measure for assessing adaptive functioning. The scales have been used in studies that identified impairment in children with ADHD relative to peers. Another option for assessing this domain is the Normative Adaptive Behavior Checklist (Adams, 1984), because of its greater ease of administration. Unfortunately, these detailed measures take a long time to complete (usually at least 40 minutes) and may add little important information beyond what is obtained from the CIRS as far as clinical diagnosis and treatment planning are concerned.

Of note, the BASC-2 provides Adaptive Functioning subscales, for example, in the areas of activities of daily living, adaptability, functional communication, leadership, and social skills. This portion of the BASC-2 is far shorter than the more extensive Adaptive Behavior scales noted earlier and is therefore more cost-effective. However, for initial evaluation of impairment, the CIRS seems most suitable. Such information can be incorporated into the assessment summary. Furthermore, we recommend using the CIRS in conjunction with the CGI, both of which can be completed daily to give an index of symptoms and impairment.

Asking caregivers to report on their own problems is a delicate issue, but one that must be explored to understand fully critical influences on child behavior and the ability of the parent to take a major role in the treatment of ADHD, whether providing medication or managing behavioral contingencies. We recommend having parents complete self-report measures that screen for the major dimensions of

psychopathology, such as the Symptom Checklist-90—Revised (SCL-90-R; Derogatis, 1995), and especially for major depression and alcohol use disorders. These prevalent disorders in the adult population have elevated rates in families of children with ADHD and are likely to impair caregiving (Barkley, 2005). Furthermore, treatment of depressed mothers appears to have a positive effect on childhood behavior disorders (Weissman et al., 2006). When parents have a partner in caregiving, measures of relationship satisfaction with parenting is an important issue to assess (Sanders, 1999).

In view of the high heritability of the disorder, we strongly recommend that biological parents of children with ADHD be screened for possible ADHD themselves. There is a non-trivial probability that one parent is likely to have the disorder (25–35%), and it can interfere with intervention for the child, as noted earlier. The easiest means for doing so is to employ an adult ADHD screening scale, such as that available in the manual by Barkley and Murphy (2006) or the lengthier Conners Adult ADHD Rating Scale (Conners, Erhardt, & Sparrow, 2001).

When screening for problems experienced by parents, it is important for parents to understand why information on their own functioning is important in the context of assessment of their child's behavior. The reason for such screening must be explained in a clear, supportive, and empathic manner prior to administration of these types of measures. Sending these measures without explanation in a screening packet might be off-putting for many parents. Rather, the rationale for collecting these data should be explained in person after some rapport has developed.

There are many options for screening for parental depression. A scale often used to provide a quick assessment of parental depression is the Beck Depression Inventory (BDI; Beck, Steer, & Brown, 1996). A more "broad-band" measure for assessing this area of parental difficulties, the SCL-90-R (Derogatis, 1995; Derogatis & Cleary, 1977), has not only a scale assessing depression in adults, but also contains scales measuring other dimensions of adult psychopathology and psychological distress. Parents of children with ADHD often have higher scores on the Depression, Hostility, Anxiety, and Interpersonal Difficulties subscales (Barkley, Anastopoulos, et al., 1992; Barkley et

al., 1991; Murphy & Barkley, 1996b). However, the SCL-90-R may be measuring general distress, and may lack specificity for depression and other specific psychological conditions (Hafkenscheid, 1993). Therefore, we recommend that when depression is specifically of interest, use of shorter, more specific scales, such as the BDI, may be better.

As with depression measures, there are many choices for screening for alcohol use disorders. Research suggests that the Alcohol Use Disorders Identification Test (AUDIT) may be superior to other brief measures due to construct and external validity advantages (Bush et al., 2003; Cook, Chung, Kelly, & Clark, 2005; Knight, Sherritt, Harris, Gates, & Chang, 2003; MacKenzie, Langa, & Brown, 1996). Therefore, we recommend use of the AUDIT, a 10-item scale that measures alcohol consumption and alcohol-related problems. Cutoffs for the AUDIT have been published, with score of 8 or higher indicating a need for further evaluation of alcohol-related difficulties.

Next would be measures that assess the parent's interpersonal functioning. If the caregiver is married or cohabitating, completing the Dyadic Adjustment Scale (DAS) can provide important contextual information for assessment and treatment planning. Many instruments evaluate marital discord in parents. The one most often used in research on childhood disorders has been the Locke-Wallace Marital Adjustment Scale (Locke & Wallace, 1959). Research has indicated that parents of children with ADHD, regardless of child gender, have lower ratings of marital satisfaction than do parents of normal children (Breen & Barkley, 1988; Murphy & Barkley, 1996b), especially in the subgroup of children with ADHD and ODD or CD (Barkley, Anastopoulos, et al., 1992; Barkley et al., 1991; Befera & Barkley, 1985).

It is important to assess the level of discord between parenting partners, because it may play a role in how interventions are perceived and delivered. For example, a high degree of discord may portend significant disagreement between partners over the presence and/or management of behavioral problems in children. Depression, partner discord, and child behavioral problems are a common triad (Dawson et al., 2003; Low & Stocker, 2005; Sugawara et al., 2002). Moreover, it is possible that changes in one domain may result in changes in all three domains (DeGarmo,

Patterson, & Forgatch, 2004; Sanders & McFarland, 2000).

Sanders and Ralph (2001) developed a brief index of marital satisfaction, called the Parenting Experiences Survey, that may be more amenable for screening purposes compared to some of the more detailed measures mentioned earlier. This 11-item scale provides a measure of the degree of success with parenting and comfort with coparenting (see Appendix 2.1). The first eight items focus on parenting satisfaction. The last three items assess the degree of comfort with coparenting. These items are taken from the DAS (Spanier & Cole, 1976) and have been shown to discriminate between distressed and nondistressed couples (Sharpely & Rogers, 1984).

It may be worthwhile to assess other areas of the parents' interpersonal functioning should time and resources permit (e.g., parent-child interactions). However, there is limited time and motivation to complete screening measures, especially about issues specific to the caregiver. Therefore, we relegate exploration of some issues of parental psychopathology and interpersonal functioning to the structured interview. The recommended foci of the parent self-report rating scales are ADHD, depression, alcohol use, and marital functioning.

TEACHER RATINGS

Obtaining information from teachers is crucially important for several reasons. First of all, a child who does not have any academic or behavioral problems at school most likely does not have ADHD. Second, teachers are probably better judges of developmentally appropriate behavior than parents, assuming it is not the first few days or weeks of school. This is matter of opportunity and experience, because teachers simply see more children. Third, teachers are likely to be involved in the intervention process, so engaging them early in the assessment phase and getting a solid baseline of behavior benefits later treatment plans.

The measures we recommend for teachers (see Table 2.3) parallel those for parents, with the same justification as was made for the parent measures. Thus, we ask teachers to complete the Teacher Rating Scale (TRS) of the BASC-2, a teacher version of the DBD, the School Situations Questionnaire (SSQ), the CGI, and the CIRS. Due to professional boundaries, we do not directly inquire about teacher

TABLE 2.3. Recommended Teacher Ratings

1. The Teacher Rating Scale (TRS) from the Behavioral Assessment System for Children, Second Edition (BASC-2)
2. The Disruptive Behavior Disorders checklist of DSM-IV symptoms (DBD)
3. The School Situations Questionnaire (SSQ)
4. The Conners Global Index (CGI)
5. The Children's Impairment Rating Scale (CIRS)

functioning (e.g., depression or substance use). Also, because of sensitivity to the response burden on teachers, every effort should be made to keep the data demands as slight as possible. Our clinical experience has been that this packet is very feasible for routine clinical use with teachers.

Elementary school teachers, who spend quite a bit of time with the child, can be key informants. However, as children get older, teachers may not know them as well, and teacher reports may be less reliable in middle and high school (Evans, Allen, Moore, & Strauss, 2005). Therefore, the evaluator should inquire how well the teacher knows the student prior to asking the teacher to complete the ratings. Even elementary school teachers may not know students very well in the first few weeks of the school year or shortly after moving to a new school.

As mentioned previously, cross-informant agreement may be low for parents and teachers, often because the parents and teachers observe different behaviors. Accordingly, the parent and teacher versions of the BASC-2 overlap on some scales and diverge on others. This is appropriate, considering that teachers and parents observe students in different contexts. Indeed, teachers often report difficulty in answering some questions. It is advisable to instruct teachers to make their best effort to answer questions and indicate "DK" (don't know) next to items that they do not have a basis for answering. Also, teachers might be advised that some items may seem shocking (e.g., "taking advantage of another sexually," which is a CD item on the DBD). They should be told that although such behavior is rare, its occurrence is so important that the clinician should know about it, so the item is included in the questionnaire.

The clinician directing the assessment usually has to take a very active role in getting in-

formation from teachers. Unless the parents have an exceptionally good relationship with teachers or a very organized and cooperative school, it is likely that the clinician will encounter many barriers when seeking ratings. Therefore, he or she should provide teachers with Health Insurance Portability and Accountability Act (HIPAA) compliant release of information forms, a note from the parent personally requesting the information, a note from the therapist explaining the scales and how they are used (including confidentiality considerations), very clear instructions, contact information, and a deadline for completion (usually 1 week), along with a self-addressed, stamped envelope. School visits and other direct contact bolster the chances for cooperation and allow the clinician to collect some incidental and qualitative information. When this is not possible, indirect contact by phone, mail, or the Internet is important.

CHILD SELF-REPORT MEASURES

As mentioned previously, we believe the research suggests that the incremental validity of child self-report measures of ADHD symptoms is questionable; therefore, self-report should receive minimal weight in an assessment of ADHD (Barkley, Fischer, et al., 2002; McCann & Roy-Byrne, 2004; Smith et al., 2000). However, child self-report of other areas, such as depression and anxiety, might provide unique and important information during the assessment process (Baxter & Rattan, 2004; Hope et al., 1999). Furthermore, having the child with ADHD provide input into the assessment process might make the child feel more involved or invested in the assessment, thus increasing the likelihood of cooperation with recommendations for intervention (Dishion & Kavanagh, 2003).

For individuals ages 8–21, we recommend using the Self-Report of Personality (SRP) from the BASC-2. The BASC-2 SRP includes self-report scales on inattention and hyperactivity. Factor-analytic studies apparently support the validity of these scales (Reynolds & Kamphaus, 2005), but the incremental and construct validity of self-reported attention problems and hyperactivity on the SRP have not yet been established. In contrast, evidence for the validity of the other BASC-2 self-report scales seems to be quite good (Reynolds & Kamphaus, 2005).

Another “broad-band” self-report measure, the Youth Self-Report (YSR; Achenbach, 1991, 2001), is designed and normed for children ages 11–18 years; thus, it has a restricted age range relative to the BASC SRP. Most items are similar to those on the parent- and the teacher-report form of the CBCL, except that they are worded in the first person. The Cross-Informant Version (Achenbach, 1991) permits direct comparisons of results among the parent, teacher, and youth versions of this popular rating scale. The BASC-2, on the other hand, does not have such complete overlap of scales. However, because evidence suggests that the BASC is superior to the CBCL for assessing ADHD, we advocate the use of the BASC scales.

THE ADHD CHECKUP

The semistructured interview we recommend is incorporated into a broader assessment framework of the ACU. Where time and resources permit, we recommend using the entire ACU protocol; otherwise, use of the aforementioned minimum assessment protocol is suggested when time is of the essence. The ACU is based on the Family Checkup (Dishion & Kavanagh, 2003), a parent-focused assessment process that we have modified in an effort to provide the best impact of a multimodal assessment of ADHD. The ACU comprises four phases: (1) telephone contact prior to the first session; (2) semistructured interview with the parent(s) to evaluate interpersonal functioning, major presenting problems, developmental history, and other background information; (3) videotaped interactions between the family members to assess parenting relationships; and (4) collaborative feedback with the parent(s) regarding diagnosis and treatment recommendations. Adolescents can be included in some or all of the feedback session, but it is probably best to work individually with the parent for some portions of the ACU, especially when there is a high degree of parent–child or parent–parent conflict. This section reviews the background and history, and the general procedures for conducting the ACU. More detailed descriptions of procedures pertinent to the ACU are found in Dishion and Kavanagh (2003), Miller and Rollnick (2002), and Sanders and Lawton (1993).

History and Background

The ACU is based on an earlier brief family intervention designed to prevent substance use and behavior problems among children and adolescents. The theory underlying the ACU, called “motivational interviewing” (Miller, 1998), is consistent with the principles of the “transtheoretical model of change” (Prochaska, DiClemente, & Norcross, 1992). This intervention theory is well established and empirically supported for problems related to substance abuse (Miller & Rollnick, 2002). The ACU represents the first application of this theory to family therapy (Dishion & Kavanagh, 2003). However, ACU procedures are consistent with the best applications of Behavioral Parent Training (Patterson & Forgatch, 1987; Sanders & Lawton, 1993) and the client-centered approach of Carl Rogers (1951). Thus, many ACU principles and procedures have been supported by a number of well-regarded experts who work with high-risk teenagers and their families. Nevertheless, we believe the reader will be impressed and agree that the proposed ACU is sufficiently novel to be called a unique approach.

A guiding principle in motivational interviewing, and hence in the ACU, is to expect ambivalence about change (Miller & Rollnick, 2002). In the context of family therapy, multiple levels of ambivalence are possible, because change can pertain to (1) the behavior of the target child, (2) the behavior of a parent, (3) the interactions between parent and child, (4) the interactions between siblings and the target child, and (5) the major interactions between the family and other systems (e.g., with a pediatrician or a school). Thus, during the phone contact process, the clinician should be on the alert to detect and deal with ambivalence about the change that is needed to solve problems related to ADHD.

Another important guiding principle in the ACU is to develop congruence between the family’s expectations and the procedures in the assessment and recommendations. A theory supports this notion, the transtheoretical model of change proposed by Prochaska, DiClemente, and Norcross (1992). This theory, with its attendant stages and processes of change, is by now quite familiar to those who work in the field of addictions (Miller, 1998). Unfortunately, researchers have only begun to

apply this very promising approach to problems other than addictive behaviors. Therefore, a brief introduction to this approach is warranted.

The roots of the transtheoretical model of change are found in the frequent result that promising treatments do not work equally well with all persons. Sometimes the poor outcomes are attributed to client factors; at other times, poor outcomes are attributed to therapist factors (Prochaska et al., 1992). Examples of patient factors associated with poor outcomes are lack of awareness, denial, inadequate motivation, and poor relational skills. Examples of therapist factors associated with poor outcomes are lack of empathy, inadequate diagnosis or treatment planning, and poorly implemented or otherwise inadequate techniques. However, there are many cases where therapy failed even though the client appeared to be engaged and the therapist seemed to be competent. The unique insight from the transtheoretical model of change is that therapy outcomes might be dependent on the match between stage of readiness for change, the treatment prescribed, and how the treatment is presented to the persons responsible for change. The five commonly accepted stages of readiness for change (Prochaska et al., 1992) are briefly described.

In the *precontemplative* stage, the person has no intention to change. This condition may be due to factors such as ignorance, denial, or hopelessness about the possibility of change. For example, someone might believe that hyperactivity is normal (e.g., “Boys will be boys, it’s not a problem”) or that there is nothing that can be done about it (e.g., “All the boys in our family are rowdy, that’s just the way we are”).

In the *contemplation* stage, the person is aware of the problem and is seriously thinking about overcoming the problem but has not yet made a commitment to take action. This stage is characterized by knowing where one wants to go (i.e., to make changes) but not being quite ready to go there. A common phenomenon in the contemplation stage is weighing the pros and cons of the problem and the solution to the problem. A parent in the contemplation stage might say something like, “I know that inattention is a problem, but the things we have tried haven’t worked and I don’t know if it is worth trying something new.”

In the *preparation* stage, the individual intends to take action or has been trying to take action. The person is beginning to make small behavioral changes, but nothing that would constitute effective action, such as abstinence from smoking. He or she intends, however, to take substantial action in the near future. A caregiver in the preparation stage may take some preliminary steps toward change, such as making an appointment for therapy or reading a book on ADHD and selecting some of the recommended techniques to try in the near future. Of note, many parents who schedule appointments for evaluations for ADHD are ready for their child’s behavior to change, but they may not be in the preparation or action stage with regard to changing their own behavior. Other parents might be waiting for some revelation or insight that will provide a “magic bullet” to alleviate their child’s problems. Such parents may engage in endless assessment and “doctor shopping” but never really implement any change strategies.

In the *action* stage, the person modifies his or her behavior or environment to overcome the problem. Modification of the target behavior or significant overt effort to change is the hallmark of the action stage. A caregiver who puts up a behavior chart and starts giving rewards based on the chart is in the action stage. The best-established interventions for ADHD involve behavioral intervention (Smith et al., 2006), and most assume that the parents are ready to put up a behavior chart after the first meeting (Sanders & Ralph, 2001). However, if the parent is not in the action stage, the behavioral instructions can create a mismatch or incongruence with the parent, thereby straining the rapport and threatening the viability of the intervention.

Maintenance is the stage in which a person works to consolidate gains attained during the action stage. The hallmarks of the maintenance stage are stabilizing behavior change and promoting generalization. For example, caregivers who achieve success with one particular task (e.g., independently completing academic tasks at home) start reinforcing the use of successful methods at other times, sometimes with the help of other caregivers (e.g., individual study time at school). Training in self-regulation, such as developing self-sufficiency, self-efficacy, and problem-solving skills that generalize to new issues and developmental levels, appear to

be important goals for effective maintenance (Halford, Sanders, & Behrens, 1994).

Ordinarily, the more action that has been taken to change the problem, the better the prognosis (Prochaska et al., 1992). However, *the key and uniquely insightful contribution of the transtheoretical model of change is the attention to the match between therapist behavior and the client's stage of readiness for change*. Within this view, change is promoted by helping the individual advance from one stage to the next. A key task for the therapist is to sense the emotional, behavioral, and cognitive shifts that need to occur for the client to progress toward change (Miller, 1998). If a client is ready for action, the therapist may prescribe action-oriented therapy and the best outcomes are achieved. If a mismatch occurs, such as an action-oriented intervention prescribed to a client in the contemplation stage, results are expected to be poor. An ill-matched prescription may result in premature termination and loss of the therapist's opportunity to assist in the change process.

Telephone Contact

An important concept incorporated into the ACU is that treatment begins with the first phone contact between a family and a therapist (Coatsworth, Santisteban, McBride, & Szapocznik, 2001; Dakof et al., 2003; Santisteban, Suarez-Morales, Robbins, & Szapocznik, 2006). Thus, rather than viewing the initial phone call as a perfunctory exercise in scheduling, the initial phone call should be regarded at the start of the parent-therapist relationship. This early relationship can have a major effect on retention and engagement in therapy. Thus, one of the major goals of the ACU is to develop a positive relationship between the family and the therapist from the very beginning. A telephone call can create a positive relationship by increasing the congruence between a family's perspective on the ACU and the therapist's behavior. During a telephone call, a therapist can clearly define the process of obtaining services, invest the family in the help-seeking process, and explore any other barriers the family may be facing (McKay, McCadam, & Gonzales, 1996).

A recent review of the literature (Snell-Johns, Mendez, & Smith, 2004) identified three empirical studies that examined the effectiveness of telephone-based strategies (McKay et al.,

1996; Santisteban, Szapocznik, & Perez-Vidal, 1996; Szapocznik et al., 1988). The importance of phone contact can be summarized by the expression "Call early and often." Moreover, the quality and structure of the phone conversation can be very important. These calls are the first step in the change process. As such, phone contact should draw the family into the therapy process and socialize family members into behavior patterns that are productive in therapy and promote change. Thus, phone interactions should be guided by evidence-based procedures, especially those derived from motivational interviewing. Although these procedures have not yet been tested for specific relevance to ADHD, they are supposed to cut across disorders; therefore, they should be appropriate for use with families in which the target child has ADHD.

Overall, the key considerations in ACU phone contacts are to engage caregivers in the change process and to begin to develop a collaborative therapeutic relationship. Motivational interviewing techniques that apply here include (1) expressing empathy, and (2) rolling with resistance (Miller & Rollnick, 2002). Accordingly, the major goals of the ACU phone calls are to (1) communicate genuine interest and concern over the family's difficulties, (2) promote a positive therapeutic relationship by developing congruence between the family and the therapist's goals and procedures, (3) overcome ambivalence about change and engage the family in the ACU assessment process, and (4) begin to socialize family members toward the most effective interactions in assessment and therapy.

To prepare for the telephone contact, the clinician should review all available data previously completed by the family. Usually the call from the therapist is not the very first contact with the family, and some screening or background information on the reason for the referral should be available. In some settings, there may be intake forms, screening questionnaires, or records from previous contact with the clinic. Parents may be dismayed if the therapist is unaware of information they provided previously, so knowing information from prior contacts may help to build rapport.

The Semistructured Interview

To emphasize the importance of the caregiver in the evaluation and treatment process, we re-

fer to the clinician directing the ACU as a parent consultant. However, we use the conventional term “therapist” in this chapter. The point is that in all meetings with caregivers, the therapist should promote self-regulation and promote the type of therapeutic relationship such that the parent is the primary decision maker.

Direct contact with the therapist occurs in three meetings. The getting-to-know-you (GTKY, which we pronounce “get key”) session is the initial semistructured interview designed to get to know the family and to get key information. The goals of the GTKY meeting with the parent(s) are to (1) develop rapport and trust with caregivers; (2) better understand the caregiver’s interest and concerns as they apply to the target child and to the family in general; and (3) motivate interest in completing all three steps of the ACU. The steps of the GTKY session are described in the following section. The major activities of this first session of the ACU are given in Table 2.4. The second and third sessions, Family Assessment Task (FAST) and feedback sessions, are described in subsequent sections but are referred to several times in the GTKY session.

The GTKY session begins with setting an agenda and providing a rationale for completing three separate assessment sessions. It is crucially important, both during the initial phone call and early in the GTKY session, to create a link between concerns and assessment, thus engaging the caregiver in the evaluation process. Thus, immediately after setting the agenda, the

caregiver is asked to work with the therapist to complete a description of the parent’s and child’s social network. This combination of genogram and ecomap provides key information on social influences on behavior, caregiver social support and stressors, and family history of ADHD and other issues, including the parent’s own past and present issues (Shapiro & Smith, 2002). A subtle implication of this phase of the assessment is to frame the behavior of the child with ADHD in a broader social context rather than as an individually based problem. Also, this discussion of social influences should draw on strengths, protective factors, and resources that will eventually be key considerations in suggesting interventions.

After spending 10 to 20 minutes on the social influences on the genogram and ecomap (longer with larger or complicated families), we ask the parent to complete a checklist of concerns, using a list based on surveys of parents regarding their top concerns about their adolescents (Sanders & Ralph, 2001). Other lists are available (see Dishion & Kavanagh, 2003), and a commonly used measure developed by Prinz, Foster, Kent, and O’Leary (1979) is available in Robin and Foster (1989). The most common problems include fighting with siblings, arguing with parents, noncompliance, failing to do homework, and behavior problems at school.

The next step in the GTKY session is to have the caregiver pick the top few problems, then, starting with the most distressing problem, conduct a detailed analysis of each (see Appendix 2.2). When multiple caregivers complete the GTKY checklist, they may disagree on some of the problems. Usually, the caregivers agree on at least one of the top three problems and, in such cases, agreed-upon problems should be discussed first. When caregivers completely disagree, the therapist can ask who owns the problem, and whether it is reasonable for that caregiver to work on the problem, separate from the other caregiver.

Problems should be discussed from an ABC (Antecedents–Behaviors–Consequences) framework, similar to the questioning described by Sanders and colleagues in the Triple-P Positive Parenting Program (Sanders, 1999; Sanders & Lawton, 1993; Sanders & Ralph, 2001) and other evidence-based parenting approaches based on social learning theory (Bank, Patterson, & Reid, 1987). This involves asking for the most recent example of the problem behav-

TABLE 2.4. Getting-to-Know-You (GTKY) Session with Parents

-
- Assessor meets with parents for up to 90 minutes, uses the “Getting to Know You” (GTKY) form.
 - Complete a Problem Checklist.
 - Complete a genogram and diagram of social supports.
 - Rank-order the top problems.
 - Complete a thorough discussion of top problems.
 - Developmental and school history (emphasize influences on behavior).
 - Confirm the appointment for the Family Assessment Task (FAST).
 - Identify a conflict to discuss during the FAST.
 - Identify a problem to discuss during the FAST.
 - Explain the questionnaires that need to be completed prior to the FAST.
-

ior, inquiring whether it is typical of the problem being discussed, and, if so, finding out what happened before, during, and after the behavior. If the most recent example of the behavior is not typical, a more typical example is elicited for a discussion of the social context of the problem (i.e., antecedents and consequences). The discussion centers on the influences of the behavior, especially those that are modifiable and under the caregivers' control. Past attempts to change behavior are noted, and expectations about behavior change in the future are considered. After reviewing the problems, the therapist completes a brief school and developmental history with the caregivers (see Appendix 2.2).

The key function of the GTKY session (and the feedback session) is to help build a foundation for change. During these semistructured interviews, the caregiver and the therapist collaborate to establish a shared perspective on the child's behavior, and on the family situation as it applies to the child. The therapist is constantly evaluating the caregivers' stage of readiness for change and attempting to move them forward toward action, but in a gentle and subtle manner.

During the ACU it may become clear that some of the caregivers' outcome expectations are unrealistic (e.g., behavior therapy does not work, but sugar restriction does). Furthermore, there may be unrealistic self-efficacy expectations (e.g., "I can't be consistent with behavioral interventions, but I can control sugar intake"). Thus, it is important to instill a reasonable understanding of effective interventions and the expectation that caregivers can perform, or learn to perform, the desired behaviors. A person's belief in the possibility of changing ADHD-related behavior is an important motivator (Bor, Sanders, & Markie-Dadds, 2002).

Family Assessment Task

The second of the three meetings between the caregiver and the therapist is optional and is called the Family Assessment Task, or FAST. This session begins with setting the agenda, which includes making sure that the questionnaires given to the family at the end of the GTKY session have been completed (see Table 2.2). These questionnaires must be completed and scored prior to the feedback session, so it is important to spend the first part of the FAST

emphasizing the importance of completing these measures. This may be a delicate situation, because caregivers may feel embarrassed because they did not complete all of the measures recommended in Table 2.2. As was done in the GTKY session, the therapist should reward effort and link concerns with assessment.

When the caregivers have completed the forms, the family is asked to complete a series of standardized tasks, the FAST, while being videotaped. Basically, the therapist lets the family members interact among themselves without providing any immediate feedback. A brief outline of the current FAST is given in Table 2.5. The detailed version with verbatim instructions for the therapist and cue cards, as well as scoring instructions, may be obtained from Dr. Smith at smithbrad@sc.edu.

The FAST interactions are videotaped for later review by the therapist and discussion with the family. The use of the FAST makes the ACU overtly different

compared to many other assessments that do not include direct, structured observation of family management practices. Thus, many therapists may feel that they do not have the resources or expertise to code the FAST interactions. Furthermore, performing an unusual task in which family members are videotaped can strain subject families. Given that the incremental validity of the FAST in the ACU process has not been established, administering the FAST may not be necessary. Nevertheless, the use of structured videotaped interactions to assess close relationships builds on the vast literature of family and marital assessment (Granic, Hollenstein, Dishion, & Patterson, 2003).

We recognize that it takes considerable time and effort to conduct and code the FAST, and that it may not be feasibly implemented in many clinical settings, such as in primary care, family medicine, pediatric practices, or where case volume is high. The procedure may be more feasible as part of psychological evaluations, particularly those based in universities or medical schools. Yet there are some very important reasons to consider including the FAST in the ACU. First, one of the ACU goals is to promote self-regulatory skills that include self-awareness and self-sufficiency. Second, the FAST provides unique insights into family interaction patterns, especially the opportunity to compare family members' perceptions of interactions and management practices with directly observed interpersonal behavior. A third

TABLE 2.5. Family Assessment Task (FAST)

Part 1: For two parents or caregivers (skip if not applicable).

1. *Parenting discussion.* Discuss what you are currently trying to teach and how much you agree or disagree on these things.

Part 2: For parent(s) and target child.

1. *Encouraging growth.* In this interaction the therapist presents the area of growth to the parents that had been identified during the GTKY session.
2. *Monitoring and listening.* The adolescent describes a time when he or she spent 60 minutes or longer alone with peers without adult supervision. Adults listen, then ask questions and comment. This task is designed to have turn taking, with the adolescent speaking first, followed by comments and questioning by the parent.
3. *Family conflict.* Talk about a disagreement in the past month. This task is designed to be interactive, with the parent and adolescent contributing when they see fit.

Five-minute break (optional, decided by family)

Part 3: For the whole family.

1. *Problem solving.* Remind family of a problem discussed during the GTKY session. The family should talk about the problem and come up with at least one solution. This task should be interactive with family members contributing as they see fit.
 2. *Substance use.* Parents talk about their beliefs about using tobacco, then alcohol, then marijuana and other drugs. They also talk about their specific drug-related expectations for the adolescent. Then siblings add their point of view. *This task is not appropriate for young children, so children younger than an adolescent should not be in the room for this task.* This is designed to have turn taking, with each family member stating his or her perspective starting with the parents, then the target child, then the sibling(s).
 3. *Planning an activity.* Make detailed plans for a fun family activity. This task should be interactive with family members contributing as they see fit.
 4. *Positive recognition.* Talk about what they like about the family and each other. This task should be interactive with family members contributing as they see fit.
 5. *Debriefing.* The therapist asks two questions and gives the family time to answer them. This is the only task when the therapist is in the room. *During this task, and when administering all other family assessment tasks, the therapist should project neutral affect and body language, answer questions for clarification purposes only, and refrain from making any suggestions or evaluative statements.*
-

reason to use the FAST is to avoid false negatives in detection of families that need to improve family management skills. Due to factors such as denial, lack of information, and an effort to present the family in an overly positive light, self-report data in interviews and questionnaires can portray families as functioning very well, when actually they are struggling. In activities such as the FAST, it is much more difficult for a family in distress to “fake good” and very unlikely that a nondistressed family will “fake bad.” A fourth reason to use FAST is to allow families an opportunity for self-reflection and self-discovery.

Consistent with these points, administration of the FAST should be as nondirective as possible. Before each task, when the therapist is reading the directions and soliciting questions about procedural issues, family members are likely to comment or offer opinions. When giving instructions and answering questions, the

therapist should focus conversation on the procedural issues and avoid making any interpretive comments on the process or content revealed during the task. Nondirective techniques, such as restating, are acceptable. More directive techniques, such as reframing, should be avoided. Highly directive techniques, such as normalization, should be strenuously avoided. In general, the therapist should focus on providing instructions to the family for completing the task, with as little additional interaction as possible.

Of note, the ACU described in this section is for adolescents. Dishion and colleagues (Shaw, Dishion, Supplee, Gardner, & Arnds, 2006) have recently developed FAST procedures for preschool children and their mothers. No set protocol has been developed for elementary school-age students, but this is mostly relevant to the FAST. The GTKY and feedback sessions of the ACU should not vary much with age.

Pending development of a FAST specifically for elementary school-age children, the procedures described for adolescents will probably work for most children age 8 and older, as long as some developmentally appropriate considerations are implemented (e.g., eliminating the talk on substance use). For younger children (i.e., below age 8), the procedures described in Shaw and colleagues should be appropriate.

Feedback

The ACU includes 1 or 2 hours of therapist time used to gather collateral information, most notably teacher ratings and preparation for feedback. Preparation for feedback includes scoring questionnaires, evaluating the FAST, and the graphing this information. The therapist should bring these graphs, completed questionnaires, and markers (red, yellow, and green) to use on the Feedback from Family Checkup form (Appendix 2.3) to the feedback session. Providing feedback and discussing a menu for change are the primary considerations of the feedback meeting. The goal of this session is to put families in an active role, such that they take responsibility for change, without being blamed or left feeling helpless. Accordingly, the entire ACU should be presented as a collaborative effort, such that caregivers are the experts on their family and the therapist has a novel perspective that can be used to refresh caregivers' best efforts to address the needs of their children.

The feedback session begins with the caregivers providing a self-assessment. Then four areas of functioning are reviewed: (1) child strengths and need for improvement, (2) caregiver/family strengths and need for improvement, (3) contextual protective/risk factors, and (4) the menu of available resources. During the feedback discussion, the therapist must be sincere, credible, and highlight two or three areas of strength for every problem area. At the end of the feedback meeting, caregivers should commit to pursuing one or more items on the menu. The menu choices should match stages of readiness for change for each parent. For example, one caregiver might be at a precontemplative stage and require experiences that develop a realistic awareness of a problem, or awareness of their influence on the problem. The other caregiver might be in the action stage, so the appropriate recommendation would be to engage in a change process, such as

learning parenting skills and developing a new behavioral management system for the children.

The feedback session may be divided into four phases. The first phase, *self-assessment*, is an opportunity for parents to discuss their own self-assessment, based on their experiences in the assessment process. Parents' discussion of their self-assessment is an opportunity for the therapist to (1) appreciate the parents' approach to behavior change, (2) assess their level of insight, (3) learn more about the dynamics of the family, and (4) discover issues not covered in the assessment. In the second phase, *clarification and support*, the therapist uses empathic, reflective listening techniques to establish a clear understanding of the self-assessment. The third phase focuses on *summarizing feedback* to families, based on the information they have provided. During this phase, the therapist discusses the graphs prepared for the feedback session with the caregivers, soliciting reactions and opinions.

The feedback phases are repeated multiple times during the feedback process as each major issue is considered. We want to emphasize some general guiding principles that need to be addressed in the feedback process. The mnemonic FRAMES highlights six elements frequently present in effective, empirically supported brief interventions (Miller, 1998): Feedback on family status, emphasis on family Responsibility for change, Advice about change options listed on the menu, collaborative listing of change options or a Menu by which change might be achieved, an Empathic counseling style, and messages supporting Self-efficacy for change. Excellent considerations of the FRAMES approach are presented elsewhere, and we encourage the reader to review these resources, especially Miller and Rollnick (2002).

Symptoms of ADHD

First, the parents are asked to describe their understanding of ADHD and whether that diagnosis fits their child. Misunderstandings about ADHD need to be addressed as part of clarification and support from the therapist. Next, the caregivers are shown graphs summarizing the rating scales. We recommend using the BASC-2 ratings of inattention and hyperactivity for all respondents (i.e., parent, child, and teacher), all on one graph. There should be a similar graph for parent and teacher ratings on

the DBD, but this can often be held in reserve and used primarily by the therapist to decide on the formal diagnosis of ADHD. Once the parents seem to understand the metric of the graph, the therapist should review the information portrayed on the graph with each family. Summarizing feedback and getting consensus from the parent(s) can lead directly into goal development.

After selecting the goal, the therapist and family members can “brainstorm” a list of intervention options. The role of the therapist is first to model brainstorming to generate options, then, in the final stages of the feedback session, to promote discussion of the pros and cons of each option. Options for menu items might include reading about an issue, getting a self-help book, consulting with a teacher, meeting with the school’s intervention team, or receiving a referral for family or marital therapy. In building a viable menu, therapist knowledge of school and community resources is critical.

Feedback about Comorbid Conditions

More often than not, children diagnosed with ADHD also meet criteria for other mental health disorders that may affect parenting and response to treatment. These disorders are reviewed with the parent(s) and their implications are discussed. The therapist should follow the same four phases of feedback as with ADHD symptoms, including (1) caregivers’ assessment, (2) clarification and support, (3) summarization of feedback, and (4) goal setting and methods for change.

Adult Functioning and Relationship Quality

The functioning of adult caregivers is crucially important to understand, because intervention for ADHD is usually heavily dependent on the adult caregiver. Therefore, is it important to provide feedback about how contextual factors in the form of adult mental illness, substance abuse, or marital problems might influence the child’s behavior and efforts to change it. Every effort should be made to avoid having the parent feel blamed for the problems related to ADHD. Rather, it should be emphasized that the caregiver is an important part of the solution, and that it is legitimate to attend to the needs of the caregiver, as well as those of the child with ADHD.

The four-phase process of feedback regarding caregiver psychopathology or substance use centers on the ADHD and depression rating scales and AUDIT. However, the GTKY should also address these and other psychopathology or substance abuse issues, especially during completion of the genogram. Other screening measures (e.g., anxiety scales) or semistructured interviews (e.g., for anxiety disorders) may be pursued as needed.

When conflict between caregivers is evident, or when the status of the relationship is unclear, there are often divergent viewpoints. It is usually surprising that partners disagree about the quality of their marriage, or at least the quality of certain aspects of the relationship. Ignoring a marital problem and the status of the parents’ relationship may be tantamount to overlooking the source of family difficulty and may have long-term negative effects on a young child’s positive adjustment. To prepare for this discussion, the therapist should score and summarize the DAS completed by both parents. Also, for parenting and other relationships, such as mother–grandmother, data from the GTKY session and the first FAST session interaction are very important.

It is important to frame the marital issues as contextual factors, but still focus parents’ attention on their common goal of helping the child. Also, it is helpful to point out to parents that differences of opinion about parenting may occur for many reasons, including differences in relationships between families of origin, their own experience and education as parents, and the nature of their typical interactions with the child, which may be very different for fathers and mothers, or for custodial and noncustodial parents.

Parent–Child Interactions

Following the discussion of the marriage, it should seem logical to talk about the relationship between the parents and the child. After clarification and support, information on this issue can be taken from the CIRS, the BASC-2, and the FAST. With regard to the FAST, some of the interactions might be briefly reviewed to refresh caregivers’ recall of the task and how it went. Because the CIRS and FAST scales have separate metrics, they need to be presented separately, with explanations of their metrics. After reviewing the parent–child relationships and parenting practices, the therapist should

help caregivers identify goals, and methods for achieving these goals. Some of these goals should ideally be positive and support current activities.

Adjustment at School

After discussing parent management skills, it is helpful to transition into a discussion of relationships with teachers. This allows the therapist to draw parallels to other adults, thus generalizing findings and, in some cases, helping parents feel less blamed or defensive about their problematic dealings with their child. This also allows for reframes that highlight the influence of specific contexts or structures that positively influence the behavior of the child with ADHD. Data for discussing relationships with teachers can be taken from the appropriate CIRS and Teacher Report Form of the BASC-2.

Peer Relations

Peer functioning is a good concluding topic, because it almost always includes areas of strengths, as well as potential weaknesses. A variety of available multi-informant assessment data supports this discussion, including relevant BASC-2 scores (parent, child, and teachers), and the impairment rating scale (parent and teachers). In addition to talking about peers in general, it may be important to discuss best friends in terms of the depth and stability of the relationship.

Feedback with the Child or Adolescent

Following the feedback session with the caregivers, it is helpful to have a feedback session with the child, and especially with an adolescent. If the caregivers direct the feedback to the child, then this is an opportunity to reinforce caregivers' responsibility and knowledge in dealing with their child. The feedback to the child or adolescent should be an abbreviated version of the feedback given to the parents. Thus, it should have four phases: (1) self-assessment, (2) support and clarification, (3) feedback, and (4) selection of goals and change options. Parents who decide to give feedback themselves should be coached on these steps. In conjoint sessions, the therapist should allow the parents to give most of the feedback.

Finally, the child or adolescent should review the problems, goals, and options developed by the parents. Using his or her own feedback sheet, the child or adolescent should be allowed to add additional problems, state personal goals, and suggest his or her own solutions. Then, the therapist should discuss how the adolescent will communicate his or her own goals and menu of change options to the parents. The child or adolescent can rehearse this presentation with the therapist, self-evaluate the presentation, and receive feedback from the therapist regarding the rehearsal of the conversation with parents. Then, the therapist can support the child or adolescent by facilitating the presentation of what was rehearsed.

ADDITIONAL COMMENTS ON ASSESSMENT METHODS

In many cases, intelligence and achievement testing may already have been conducted by the child's public school. This information is important for review and when there are concerns about low IQ or significant learning disabilities. A psychoeducational evaluation may be one of the recommendations on the ACU menu. Brief screening tests are recommended as a first pass evaluation of the child. When evidence on the screen suggests deficiencies in the child's intelligence or achievement, more thorough testing may be conducted for these domains or the child may be referred to a professional more expert in such evaluations.

A more thorough discussion of useful psychological tests for ADHD may be found in Gordon, Barkley, and Lovett (2006). Although some of these methods may be valid, they are not practical for most applied settings, or they do not have demonstrated incremental or clinical utility in the context of the measures we do recommend (i.e., parent and teacher ratings, observation of brief structured family interactions, a structured interview with parents and, briefly, with children or adolescents, IQ screening and achievement testing, if not done previously, and a physical examination).

We do not recommend the routine use of CPTs as part of the standard evaluation for ADHD despite their popularity. Several of the CPTs available commercially to clinicians have norms that permit the clinical interpretation of their scores: the Conners Continuous Performance Test (Conners, 1995), the Gordon Diag-

nostic System (Gordon, 1983), and the Test of Variables of Attention (Greenberg & Kindschi, 1996), among others. CPTs are among the most reliable measures that discriminate between groups of individuals with ADHD and the general population (Barkley, 1991; Barkley, Grodzinsky, & DuPaul, 1992; Corkum & Siegel, 1993); are sensitive to stimulant drug effects (Barkley, 1997c; Rapport & Kelly, 1993); and correlate significantly with teacher ratings of inattention and hyperactivity, as well as other laboratory measures of attention and impulse control. However, the magnitude of these associations is low to moderate (typically .25–.35), suggesting limited ecological and construct validity for such instruments (Barkley, 1991). It is noteworthy that although these measures may be sensitive to the effects of stimulant medication on groups of children with ADHD, they are less sensitive to low doses of medication than are parent and teacher ratings (Barkley, Fischer, Newby, & Breen, 1988; Barkley, McMurray, Edelbrock, & Robbins, 1989). This means that using a CPT to titrate medication may result in overmedication, thus exposing children to greater risk for negative side effects. Furthermore, children with ADHD find this task to be very aversive. Given these results, it is not appropriate to use CPT as the basis for determining medication response. Also, because the incremental validity of the CPT for diagnostic purposes is questionable, we do not recommend use of the CPT in the routine assessment of ADHD.

A new addition to this chapter is the emphasis on evaluating the effectiveness of interventions, such that assessment becomes an ongoing process. This approach, often called response to intervention (RTI), is becoming the new standard for evaluating learning disabilities (Fuchs & Fuchs, 1998; Speece & Hines, Chapter 13, this volume). Although this type of assessment may be beyond the scope of practice for most clinicians, it is important for those who work with children with learning problems to be familiar with this growing movement in academic assessment. RTI is becoming common practice for assessing students who fall behind academically. Indeed, RTI is starting to replace traditional cognitive assessments (i.e., intelligence and achievement testing) for diagnosing learning disabilities. For a detailed description of RTI, the reader is referred to Speece and Hines, Chapter 13, this volume.

MENU OF TREATMENT OPTIONS

When a child is diagnosed with ADHD there is by definition at least one area of significantly impaired functioning related to ADHD. A well-conducted evaluation for ADHD provides a clear understanding of the functional impairment(s) and a sound basis for initiating treatment, including which problems to prioritize. Because response to treatment for ADHD is highly idiosyncratic (Pelham & Milich, 1991), competent intervention includes monitoring of the target problems and other relevant areas of functioning. Thus, each intervention needs to evaluate using appropriate case study methodology (Kazdin, 1990). For present purposes, we describe a menu of treatment options. Given the focus of this chapter on evaluation, this review of treatment is very succinct. More detailed reviews of our treatment may be found in Barkley (2006) and Smith and colleagues (2006).

Treatments abound for children with ADHD, but only a few have demonstrated efficacy (Kazdin, 1990; Pelham et al., 1998). Treatment recommendations may range from just parent counseling about the disorder in the case of children with few or no impairments, to residential treatment for children with ADHD and severe, chronic, or even dangerous forms of conduct problems or depression. Between these extremes, treatment recommendations may focus on reducing the primary ADHD symptoms through medication or classroom behavioral interventions; improving the oppositional behavior of children with ADHD through parent training in effective child management procedures; or addressing the conflicts of teenagers with ADHD and their parents through a behavioral problem-solving approach to family therapy. Many children with ADHD have peer relationship problems that may benefit from individual or group social skills training, provided that such training is implemented within the school or neighborhood settings in which such skills should be used, and that aggressive and nonaggressive children are not mixed into such groups (due to the side effect of deviancy training).

In most cases, evaluation will reveal the need for multiple interventions for a child and, in some cases, for other family members, to address fully the functional problems found during the evaluation. Thus, clinicians should approach intervention from the stand-

point of a matrix of needs for intervention and prevention. When multimodal treatments are selected, they should be evidence-based and designed to complement each other by creating a synergy of effectiveness, or by targeting unique aspects of the disorder. Simply throwing myriad treatments at a problem has not been particularly effective. Moreover, it might not always be best to try to change everything at once, or to tackle the most difficult problem first.

When selecting treatment options, it is important to consider that using medication first might potentially lower parent motivation to get involved in behavioral interventions, thus leaving some important gaps in the matrix of needed interventions (Adelman & Taylor, 1998). In other cases, medication alone may be all that is required for relatively uncomplicated cases of ADHD, in which comorbidity is not an issue. Similarly, it is important to select treatment options that result in success and enhanced parent motivation and parenting efficacy (Sanders, 2000). Trying to deal with a complicated problem such as misbehavior in the classroom leaves parents dependent on factors beyond their control, which may be counterproductive. Therefore, if the goal is to engage parents productively in the change process, working on behavior that occurs at home may be the best way to start.

Medications

Two types of medications are FDA approved for use by children and adolescents with ADHD: stimulants (methylphenidate, amphetamines) and the nonstimulant, atomoxetine (Strattera). There is overwhelming evidence for the efficacy of these medications in the treatment of children and adolescents with ADHD (Barkley & Murphy, 2006; Pelham et al., 1998; Smith et al., 2000, 2006). However, these medications are neither necessary nor sufficient to treat ADHD because (1) at least 10–25% of children with ADHD do not benefit from treatment with stimulant medication (Smith et al., 2006), and (2) even among positive drug responders, stimulant drugs are not able to address all of the myriad difficulties of children and adolescents with ADHD. Nevertheless, medication can be an indispensable part of a total treatment program and often its most effective component.

The primary effects of the ADHD medications are improved attention span, decreased impulsivity, diminished task-irrelevant activity (especially in structured situations), and generally decreased disruptive behavior in social situations (see chapters by Conner for stimulants and Spencer for nonstimulants in the text by Barkley, 2005). Secondary effects of these changes appear to include increased compliance to commands and instructions; increased productivity on academic assignments; improved peer interactions and increased peer acceptance; and decreased parent and teacher reprimands, supervision, and punishment.

Although medication may appear to be equally effective compared to combined treatment (i.e., medication and intensive psychosocial interventions) in terms of reducing ADHD symptoms, the effects of combined treatment appear to be better than those for medicine alone in treating ancillary problems associated with ADHD (Smith et al., 2006). Thus, it is important for those concerned with children or adolescents with ADHD to be familiar with nonpharmacological treatments for ADHD. Of note, these may form a synergy with medication or treat problems not addressed by medication.

Parent Training in Contingency Management

The decision to employ parent training procedures should be based on the information obtained in the initial evaluation with respect to the child's primary symptoms of ADHD, as well as the level of noncompliant, oppositional, or defiant behaviors at home. Other key considerations are the parents' educational and intellectual level, the degree of motivation for training, and the absence of complicating factors, such as parental depression, stress, personal psychopathology, or sufficient marital discord to interfere with training.

There are several excellent parent training programs, and age of the child is a major factor in the choice of approach. Barkley (1997d) has developed a program specifically for parents of children ages 2 to 11 with ADHD. It includes sessions to provide information to families about ADHD; to train them in increasing attention and praise; to establish home token reinforcement systems; to implement time-out, response cost, and other mild disciplinary tac-

tics; and to teach them to deal with misbehavior in public places.

Robin and Foster (1989; Robin, 1990) have designed a useful approach to resolving parent–adolescent conflicts in families with teenagers with ADHD that emphasizes negotiating with adolescents. The approach is often combined with advice to parents on contingency management methods appropriate to this age group (point systems, behavioral contracts, etc.; see also Barkley, Edwards, & Robin, 1999; Sanders & Ralph, 2001). Patterson and Forgatch (1987) designed a similar approach for addressing parent–teen conflicts. Another promising approach is the Triple P–Positive Parenting Program (Triple-P) recently developed by Sanders (1999).

Classroom Interventions

Given that the majority of children and adolescents with ADHD exhibit behavior problems in school, classroom interventions are likely to be employed. These may include training teachers in contingency management methods (see Pfiffner, Barkley, & DuPaul, 2006). Token reinforcement programs, home-based evaluation/reinforcement programs, increased attention to child compliance by teachers, in-class time-out procedures, and behavioral contracts may all be employed in the reduction of ADHD behaviors in the classroom. In extreme cases, some children or adolescents may need the intensive structure of special classrooms, afterschool programs, or therapeutic schools to succeed.

The choice and intensity of interventions should be based on a number of findings from the evaluation, including the level of the child's school behavior and performance problems, the degree of parent and teacher commitment to complying with these methods, the extent of previous school interventions, the degree to which stimulant medication may address these difficulties, and the eligibility of the child for special educational programs under federal and state statutes. Much evidence exists for the effectiveness of behavior modification techniques in reducing classroom behavior problems and improving the productivity of children with ADHD (DuPaul & Stoner, 2003). Less clear, however, is the extent to which these methods may normalize the behavior of children with ADHD, and the extent to which treatment gains persist once the behavioral techniques are

withdrawn or the children move on to another grade, classroom, or teacher. Some evidence suggests that behavior, although improved, is not brought into the normal range of non-ADHD peers (Abikoff & Gittelman, 1984).

Summary of Treatments

This review has focused on the empirically supported treatments identified by numerous, high-profile reviews and treatment guidelines. Some promising treatments mentioned in previous editions, such as self-control training, have not been well supported in recent research. Some new treatments that have emerged, such as neurofeedback, have not yet established a credible database. Other putative treatments for ADHD, such as dietary restriction of sugar or food additives, have not lived up to the expectations of anecdotes and do not appear to be effective for treating the typical child with ADHD (Pelham et al., 1998; Smith et al., 2006). Moreover, there is some risk of making ADHD-related problems worse, due to stigma and parent–child conflict. Thus, we strongly recommend that parents, teachers, and clinicians focus on mainstream treatments for ADHD that include parent training, classroom contingency management, and stimulant medication. Indeed, this combination of treatments may be the best (Smith et al., 2006).

EVALUATING INDIVIDUAL RESPONSES TO INTERVENTION

As with medication, children's responses to parenting interventions and classroom contingencies may be highly variable. The previously mentioned studies that provide empirical support for medication, parent training, and classroom management indicate that individuals with ADHD, as a group, tend to respond positively to these interventions. However, the intervention in many cases needs to be individualized, and some children may not respond (e.g., estimates of nonresponse to stimulant medication are usually around 30%). Therefore, treatment for ADHD must be evaluated on a case-by-case basis using individual case study methods. This is not as difficult as it may sound, because we are recommending (1) collection of data on a frequent basis, either daily or weekly, and (2) summarization of data with

widely available graphing procedures. Some more detailed recommendations based on concepts previously introduced in this chapter are given below.

Individual Variability

Due to the high variability of children and adolescents with ADHD, individualized case studies may require long baselines and the use of moving averages or trend lines to summarize highly variable behavior. This issue is illustrated in Figure 2.1, which depicts hypothetical data from a child participating in a reversal study. In this example, the target behavior is interrupting a teacher, and the intervention is selective attention (i.e., ignoring inappropriate interruptions and attending to appropriate efforts to gain attention). The reversal design in this example, also known as an ABAB study, is appropriate for evaluating many behavioral or pharmacological interventions for ADHD.

What we intend to make clear in Figure 2.1 is that multiple data points are needed for each phase of individualized evaluation of response to treatment. This is contrasted with the pre- and posttest evaluations often conducted to evaluate response to treatment. To illustrate our point, one of the pairs of points selected in Figure 2.1 shows a favorable response; another

pair shows no response; and still another pair of points shows an adverse response. On the other hand, the trend lines in the data show a more coherent and dependable evaluation of response to treatment, a favorable response in this case.

Choice of Measures

A key consideration in repeatedly collecting data is to find measures that are sensitive to change, valid, and feasible to administer frequently. Rather than relying on self-report or laboratory measures, the evaluation must use collateral reports or objective measures of performance in the target setting. A collateral report usually comprises parent or teacher ratings on standardized measures. Objective measures may include direct observation of frequencies of behavior, often provided by parents, teachers, or schools. Institutional records, such as daily homework completion, weekly grades, or disciplinary reports, can be good measures.

When measuring problems related to ADHD, particularly disruptive behaviors, the CGI has proven to be a sensitive and valid measure of change (Conners, 1997). This 10-item scale is easy to complete and may be administered on a daily or weekly basis. Another feasi-

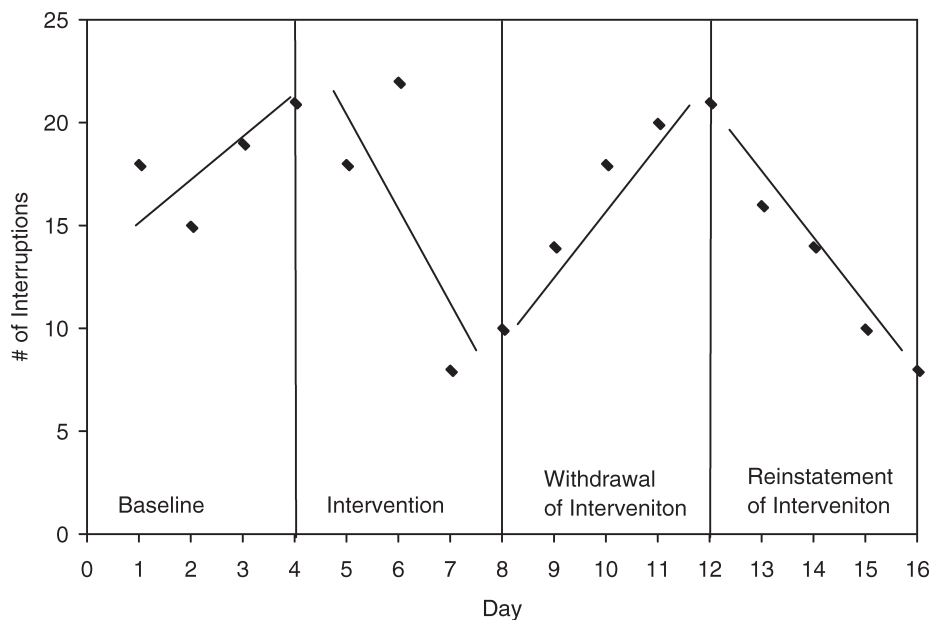

FIGURE 2.1. Number of interruptions per day.

ble and informative brief measure is behavioral tracking, such as frequency counts or duration records (also see one of the Triple P practitioner's manuals for an excellent description of several tracking procedures; e.g., Sanders & Ralph, 2001).

A detailed description of a protocol to assess response to treatment is provided in Smith and colleagues (2006). We should remind the reader that there need to be multiple repetitions of measurement in each treatment condition (see Figure 2.1). Also, double-blinds, or at least blinded raters, are helpful for controlling expectancy effects. Other methodological considerations, such as holding all but one variable as constant as possible, should allow for more confidence in the case study. Too often, multiple variables are changed at once (e.g., changing the dose of one medication while adding another), thus creating confusion about which variable produced the change. Although a "shotgun" approach of multiple changes at once may sometimes result in a quicker response, the resulting uncertainty about which intervention worked can hamper future management of ADHD.

LEGAL AND ETHICAL ISSUES

Several of the various legal and ethical issues involved in the general practice of providing mental health services to children may be more likely than usual to occur in the evaluation of children with ADHD. The first of these, the issue of custody or guardianship of a child who may have ADHD, pertains to who can request an evaluation of the child. Children with ADHD are more likely than those without the disorder to come from families in which the parents have separated or divorced, or in which significant marital discord may exist between the biological parents (DeGarmo, Patterson, & Forgatch, 2004; Sanders & McFarland, 2000; Sugawara et al., 2002). As a result, clinicians must take care at the point of first contact with such a family to determine who has legal custody of the child and, particularly, who has the right to request mental health services on behalf of the minor.

One must also determine in cases of joint custody (an increasingly common status in divorce/custody situations) whether the nonresident parent has the right to dispute the referral for the evaluation, consent to the evaluation,

attend on the day of appointment, and/or have access to the final report. This right to review or dispute mental health services may also extend to the provision of treatment to the child with ADHD. Failing to attend to these issues before the evaluation can lead to great contentiousness, frustration, and even legal action among the parties to the evaluation, much or all of which could have been avoided had greater care been taken to resolve these issues beforehand.

A second issue that commonly arises in evaluations of children but may be more likely in cases involving ADHD is a clinician's duty to report to state agencies any suspicion of physical or sexual abuse, or neglect of a child that arises or is reported during an evaluation. *Before* starting formal evaluation procedures, clinicians should routinely forewarn parents of this duty to report as it applies in a particular state. In view of the greater stress that children with ADHD appear to cause for their parents, as well as the greater psychological distress their parents are likely to report, the risk for abuse of children with ADHD may be higher than average. The greater likelihood of parental ADHD or other psychiatric disorders may further contribute to this risk, resulting in a greater likelihood that evaluations of children with ADHD may involve suspicions of abuse. Understanding this legal duty as it applies in a given state or region, and taking care to exercise it properly yet with sensitivity to the larger clinical issues likely to be involved, are the responsibilities of any clinician involved in providing mental health services to children.

A third legal consideration is federal and state laws related to providing for children with disabilities. Increasingly over the past two decades, children with ADHD have gained access to government entitlements that make it necessary for clinicians to be well informed about these legal issues if they are to advise properly and correctly the parents and school staff involved in each case. For instance, children with ADHD are now entitled to formal special educational services in the United States under the "Other Health Impaired" category of the Individuals with Disabilities in Education Act, if their ADHD is sufficiently serious to interfere significantly with their academic performance. Less commonly understood is that such children also have legal protections and entitlements under Section 504 of the Rehabilitation Act of 1973, as it applies to the

provision of an appropriate education to disabled children. Should children have sufficiently severe ADHD and reside in low-income families, they may also be eligible for financial assistance under the Social Security Act. Space precludes a more complete explication of these legal entitlements here; the reader is referred to the excellent texts by DuPaul and Stoner (2003) and Latham and Latham (1992) for fuller accounts of these matters. Suffice it to say here that clinicians working with children with ADHD need to familiarize themselves with these various rights and entitlements if they are to be effective advocates for the children they serve.

A final legal issue related to children with ADHD pertains to their legal accountability for their own actions in view of the argument made earlier that ADHD is a developmental disorder of self-control. Should children with ADHD be held legally responsible for the damage they may cause to property, the injury they may inflict on others, or the crimes they may commit? In short, is ADHD an excuse to behave irresponsibly, without being held accountable for the consequences of one's actions? The answer is unclear, and issues related to the legal status of an offender and competence to engage in legal proceedings may also be relevant. It has been the opinion of Barkley that ADHD provides an explanation for why certain impulsive acts may have been committed, but it does not constitute sufficient disturbance of mental faculties to serve as an excuse from legal accountability (e.g., as might occur under the insanity defense). Nor should it be permitted to serve as an extenuating factor in the determination of guilt or the sentencing of an individual involved in criminal activities, particularly violent crimes. This opinion is predicated on the fact that the vast majority of children with ADHD do not become involved in violent crimes as they grow up. Moreover, studies attempting to predict criminal conduct within samples of children with ADHD followed to adulthood have either not been able to find adequate predictors of such outcomes or have found them to be so weak as to account for a paltry amount of variance in such outcomes. Variables that may make a significant contribution to the prediction of criminal or delinquent behavior much more often involve parental and family dysfunction, as well as social disadvantage; they involve ADHD symptoms much less often, if at all. Until this matter receives

greater legal scrutiny, it seems wise to view ADHD as one of several explanations for impulsive conduct, but not as a direct, primary, or immediate cause of criminal conduct for which the individual should not be held accountable.

CONCLUSION

Our purpose in this current chapter has been to present a feasible and practical method for assessing ADHD. We have described several approaches depending on time and resources available to the clinician. The first is a minimally acceptable assessment for ADHD, which is appropriate when only a diagnosis is needed or when time is of the essence. The second approach, the ACU, is a more thorough method of assessment that engages caregivers in the ADHD treatment process. The third approach is evaluating response to treatment for ADHD. The resources and expertise to conduct such evaluations should be within the grasp of most mental health professionals who are qualified to work with children.

The heterogeneous nature of ADHD and numerous additional problems that coexist with both types of ADHD make the assessment of the disorders a complex and challenging affair. The minimally acceptable assessment of ADHD in children includes (1) parent ratings of ADHD symptoms, other psychiatric disorders, and related impairment; (2) teacher ratings of ADHD symptoms and functioning at school; (3) a semistructured interview with a parent to ascertain influences on behavior, parental skills and knowledge, and the developmental history of ADHD-related impairment, comorbid conditions, and various treatments or efforts to change behavior; and (4) an examination by a physician to rule out plausible physical causes for putative ADHD symptoms (Barkley, 2005).

We should emphasize that even if the criteria for a minimally acceptable assessment for ADHD are met, one office visit and a discussion are hardly likely to change behavioral problems related to ADHD. Therefore, we recommend the ACU. The key consideration of the ACU is to provide an assessment experience that is imbued with motivational interviewing and to engage parents in the intervention process. This type of evaluation, coupled with appropriate ongoing evaluation of response to in-

ervention, is the most promising approach to achieve therapeutic change related to ADHD. However, even when assessment and treatment are successful, it is important to note that the persistent nature of ADHD means that periodic assessment and intervention will be needed throughout the lifespan of individuals with the disorder.

APPENDIX 2.1. Parenting Experiences Inventory

Below is a list of issues related to being a parent. Please circle the number describing the response that best describes how you honestly feel.

1. In an overall sense, how difficult has your teenager's behavior been over the past 6 weeks?

Not at All	Slightly	Moderately	Very	Extremely
1	2	3	4	5

2. To what extent do the following statements describe your experiences as a parent in the last 6 weeks?

	Not at All	Slightly	Moderately	Very	Extremely
Parenting is rewarding	1	2	3	4	5
Parenting is demanding	1	2	3	4	5
Parenting is stressful	1	2	3	4	5
Parenting is fulfilling	1	2	3	4	5
Parenting is depressing	1	2	3	4	5

3. In the past 6 weeks, how confident have you felt to undertake your responsibilities as a parent?

Not at All	Slightly	Moderately	Very	Extremely
1	2	3	4	5

4. How supported have you felt in your role as a parent over the past 6 weeks?

Not at All	Slightly	Moderately	Very	Extremely
1	2	3	4	5

If you have a partner, please complete the following items:

5. To what extent do you both agree over methods of disciplining your child?

Not at All	Slightly	Moderately	Very	Extremely
1	2	3	4	5

6. How supportive has your partner been toward you in your role as a parent over the past 6 weeks?

Not at All	Slightly	Moderately	Very	Extremely
1	2	3	4	5

7. In an overall sense, how happy are you with your relationship with your partner?

Not at All	Slightly	Moderately	Very	Extremely
1	2	3	4	5

APPENDIX 2.2. Getting to Know You

Parent Name: _____

Child Name: _____

Instructions: Here is a variety of questions regarding your child's peer relationships, school preferences, family interactions, support networks, involvement in community activities, and hobbies. Please answer each question as completely as possible. When asked to provide a number of hours spent on an activity, please give your best guess. It is acceptable to give a range or provide more information on the back of this sheet.

PEERS

- 1. My child has a best friend. Yes No
- 2. My child makes friends easily. Yes No
- 3. My child shows strong leadership skills most of the time. Yes No
- 4. My child enjoys organized youth activities (e.g., sports, scouts, church activities). Yes No
- 5. My child is good at sports (e.g., is athletic). Yes No
- 6. My child's favorite sports are _____

- 7. My child spends an average of ____ hours exercising each week.

SCHOOL

- 8. My child's best academic subjects are _____ and _____

- 9. My child's favorite part about school is _____

- 10. My child spends ____ hours on homework each night.

FAMILY

- 11. My child has regular contact with extended family
- 12. My child has contact with the following adults on a regular basis (include parents in list, and list relationship of each person to your child; do not include teachers unless your child sees them regularly outside of school):

RELIGION

- 13. My child is active in the church community. Yes No
- 14. My child attends church regularly Yes No

ACTIVITIES

- 14. My child enjoys the following pastimes/hobbies: _____, _____,
and _____.
- 15. If your child was not attending CHP, what would they be doing or where would they be going instead? _____

- 16. My child uses the computer for ____ hours a day during the week and ____ hours a day on weekends.
- 17. My child watches TV for ____ hours a day during the week and ____ hours a day on weekends.
- 18. My child plays videogames for ____ hours a day during the week and ____ hours a day on weekends.

19. My child listens to music for ____ hours a day during the week and ____ hours a day on weekends.
20. My child does chores for ____ hours a day during the week and ____ hours a day on weekends.
20. My child spends ____ hours doing _____ each weekday and ____ hours doing that activity on the weekends (please list any other activity not mentioned that your child engages in regularly, excluding necessary activities like eating, sleeping, or showering).
21. Please list any other information you feel we should know about your child:

2. Family Stresses

Please identify any stressors (issues or events) over the past year in the family that relate to the presenting problems or get in the way of making changes.

<input type="checkbox"/> Parent has health problem <input type="checkbox"/> Parent work schedule <input type="checkbox"/> Stress between home and school <input type="checkbox"/> Child has reading problems <input type="checkbox"/> Domestic violence <input type="checkbox"/> High-crime neighborhood <input type="checkbox"/> Spending time with friends <input type="checkbox"/> Death in the family <input type="checkbox"/> Past traumatic experience (abuse or other event) <input type="checkbox"/> Drug use by parent <input type="checkbox"/> Drug use by sibling <input type="checkbox"/> Ongoing conflict between caretakers	<input type="checkbox"/> Parent not in home, uncooperative or unavailable <input type="checkbox"/> Unstable home situation <input type="checkbox"/> Parent has mental health problem <input type="checkbox"/> Separation/divorce <input type="checkbox"/> Recent remarriage <input type="checkbox"/> Other stressors _____ _____ _____ _____
--	--

Now that the guardian(s) have completed their ratings independently, have them each choose the three most troubling teenager behaviors out of those they identified as problematic or “of concern.”

Female guardian’s choices:

Male guardian’s choices:

Establish approximate frequency of each of those problem behaviors (per minute, hour, or month).

Establish approximate duration of each occurrence of problem behavior.

Note other relevant information (date of onset of the problem behavior, changes over time, how the behavior is dealt with by other caretakers).

3. Developmental History

Note any significant deviations from normal developmental milestones and any factors that may affect the teenager's development.

4. Health Status

Note general information regarding health status that may influence the teenager's behavior and/or the parent's/s' ability to implement a parenting plan (e.g., current medical conditions or disabilities; significant previous illness, operations, or hospitalizations; medication).

Is a medical examination indicated? (Yes/No)

If so, why?

5. Educational History

List any significant events relating to school that may have a bearing on the teenager's present problems. Explore academic performance, behavior at school, and peer relationships.

6. Family Relationships and Interactions

Explore the teenager's family unit and living arrangements (e.g., family members, caregivers). Explore the nature of parent-teenager relationships and the teenager's relationships with other family members. Check for any other family issues that may create obstacles to therapeutic change (e.g., parental adjustment problems, financial concerns, other stressors).

7. Observation of Parent-Teenager Interaction (where appropriate)

Note any significant observations about parent-teenager interaction in the session or in the waiting room, such as praise comments (descriptive vs. general), instructions (specific vs. vague), accidental rewards for problem behavior, and discipline strategies used. Try to note strengths and weaknesses, and record specific examples of interactions.

Conduct and Oppositional Disorders

Robert J. McMahon
Paul J. Frick

Conduct problems (CPs) in youth have been a major focus of research and practice in child psychology for a number of reasons. CPs are some of the most common reasons that children and adolescents are referred to mental health clinics (Frick & Silverthorn, 2001), cause significant disruptions for the child at home (Frick, 1998) and school (Gottfredson & Gottfredson, 2001), and are the form of psychopathology most strongly associated with delinquency (Moffitt, 1993). An extensive body of research has led to an increased understanding of the many processes that may be involved in the development of severe CPs (Dodge & Pettit, 2003; Frick, 1998; Loeber & Farrington, 2000; Raine, 2002) with important implications for designing more effective interventions to prevent or treat these problems (Conduct Problems Prevention Research Group, 2000; Frick, 1998, 2001, 2006).

Unfortunately, little attention has been paid to the implications that this research may have for improving the methods for assessing children and adolescents with severe CPs (McMahon & Frick, 2005). However, if the field is to continue to improve its intervention technology by being guided by advances in research, it is critical that assessment strategies used in practice also be informed by research findings.

An exhaustive review of recent research on CPs and their implications for the clinical assessment of antisocial youth is not possible within the space limitations of this chapter. However, in the next section we provide an overview of four sets of findings from research that have clear and important implications for the evidence-based assessment of children with CPs: (1) heterogeneity in the types and severity of CPs, (2) CPs and comorbid problems in adjustment, (3) the multiple risks associated with CPs, and (4) the multiple developmental pathways of CPs. This is followed by an overview of assessment issues and a more extended discussion of the implications of the research on CPs for guiding clinical assessments within each of the four areas. We also identify key measures that we believe have potential for contributing to the evidence-based assessment of CPs. We conclude with a summary and recommendations for future research.

KEY FINDINGS FROM RESEARCH ON CHILDHOOD CPs

Heterogeneity in the Types and Severity of CPs

CPs constitute a broad spectrum of “acting-out” behaviors, ranging from relatively minor oppositional behaviors, such as yelling and

temper tantrums, to more serious forms of antisocial behavior, such as aggression, physical destructiveness, and stealing. When displayed as a cluster, these behaviors have been referred to as “oppositional,” “antisocial,” “conduct-disordered,” and “delinquent” (see Hinshaw & Lee [2003] for a thorough discussion of terminology). Our conceptualization of CPs is consistent, but not isomorphic, with the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition, text revision [DSM-IV-TR]; American Psychiatric Association [APA], 2000) diagnostic categories of oppositional defiant disorder (ODD) and conduct disorder (CD). ODD is a pattern of negativistic (e.g., deliberately doing things that annoy other people, blaming others for one’s own mistakes), disobedient (e.g., defying or not complying with grownups’ rules or requests), and hostile behaviors (e.g., losing one’s temper). CD consists of more severe antisocial and aggressive behavior that involves serious violations of others’ rights or deviations from major age-appropriate norms. The behaviors are categorized into four groups: aggressiveness to people and animals (e.g., bullying, fighting); property destruction (e.g., firesetting, other destruction of property); deceptiveness or theft (e.g., breaking and entering, stealing without confronting the victim); and serious rule violations (e.g., running away from home, being truant from school before age 13).

In addition to the DSM-IV-TR distinction between ODD and CD, other methods have been used to separate different types of CP behaviors. Frick and colleagues (1993) conducted a meta-analysis of over 60 published factor analyses on more than 28,401 children and adolescents. They found that CPs may be described by two bipolar dimensions. In the first, an overt–covert dimension, the overt pole comprises directly confrontational behaviors such as oppositional defiant behaviors and aggression. In contrast, the covert pole comprises behaviors that are nonconfrontational in nature (e.g., stealing, lying) (see also Patterson & Yoerger, 2002; Tiet, Wasserman, Loeber, Larken, & Miller, 2001; Tolan, Gorman-Smith, & Loeber, 2000; Willoughby, Kupersmidt, & Bryant, 2001). However, a second dimension also seemed to be important for explaining the covariation of CPs. This destructive–nondestructive dimension divides the overt behaviors into those that are overt–destructive (aggression) and those that are overt–

nondestructive (oppositional), and it divides the covert behaviors into those that are covert–destructive (property violations) and those that are covert–nondestructive (status offenses; i.e., behaviors that are illegal because of the child’s or adolescent’s age).

The clustering of CPs into these four symptom patterns has proven to be useful for three purposes. First, this division of CPs is fairly consistent with the distinctions made in many legal systems for differentiating types of delinquent behaviors, which generally distinguish between violent offenses (overt–destructive), status offenses (covert–nondestructive), and property offenses (covert–destructive; e.g., Office of Juvenile Justice and Delinquency Prevention, 1995). Second, this grouping of CPs can aid in distinguishing between youth who show a single type of CP (e.g., aggressive behavior only) and those who show a more varied pattern of CP behavior (e.g., both aggression and status offenses) (see Christian, Frick, Hill, Tyler, & Frazer, 1997). This distinction is important, because the more varied pattern of CP is associated with a poorer outcome (Frick & Loney, 1999; Loeber et al., 1993). Third, there may be differences in the etiology of different types of CP. For example, a twin study found that genetic factors seem to play a greater role in the development of the destructive behaviors (i.e., property violations and aggression) than in the development of the nondestructive behaviors (i.e., oppositional, status offenses) (Simonoff, Pickles, Meyer, Silberg, & Maes, 1998).

Two specific forms of CP behavior—noncompliance and aggression—deserve additional attention. Noncompliance (i.e., excessive disobedience to adults) appears to be a keystone behavior in the development of CPs. It appears early in the progression of CPs and continues to be manifested in subsequent developmental periods (e.g., Chamberlain & Patterson, 1995; Loeber et al., 1993; McMahon & Forehand, 2003), playing a role in subsequent academic and peer relationship problems. Low levels of compliance are also associated with referral for services in young children with CPs (Dumas, 1996). Furthermore, intervention research has shown that when child noncompliance is targeted, there is often concomitant improvement in other CP behaviors as well (Russo, Cataldo, & Cushing, 1981; Wells, Forehand, & Griest, 1980).

The importance of aggression as a CP dimension is supported by research showing that aggressive behavior in children and adolescents is often quite stable and very difficult to treat (Broidy et al., 2003). Importantly, there appear to be several different forms of aggressive behavior (Crick & Dodge, 1996; Poulin & Boivin, 2000). The first type of aggression, often referred to as retaliatory, hostile, or reactive aggression, is viewed as a defensive reaction to a perceived threat and is characterized by anger and hostility (Crick & Dodge, 1996). The second type of aggressive behavior is generally unprovoked, and is used for personal gain (instrumental) or to influence and coerce others (bullying and dominance). This type of aggressive behavior is referred to as instrumental, premeditated, or proactive aggression (Poulin & Boivin, 2000).

These different types of aggression often co-occur, with correlations ranging from $r = .40$ – $.70$ in school-age samples (Frick & Marsee, 2006). Despite this high degree of association, many studies have documented different correlates to the two forms of aggression. For example, reactive aggression has been associated with higher risk for social isolation and social rejection by peers (Dodge & Pettit, 2003), and a temperamental propensity for angry reactivity and emotional dysregulation (Hubbard et al., 2002). Reactively aggressive youth also show a number of deficits in their social information processing, such as difficulty employing effective problem-solving skills in social situations and a hostile attributional bias to ambiguous provocation situations (Crick & Dodge, 1996). Proactively aggressive youth, on the other hand, associate more positive outcomes with their aggressive behavior and report significantly fewer symptoms related to anxiety than do reactively aggressive youth (Schwartz et al., 1998). In addition to proactive and reactive forms of aggression, both of which are overt in nature, Crick and colleagues have identified a form of indirect aggression, called “relational aggression,” that involves strategies such as social isolation and exclusion, and behaviors that include slandering, rumor spreading, and manipulating friendships (e.g., Crick & Grotpeter, 1995). Evidence suggests that relational aggression occurs more frequently in girls (Underwood, 2003), and it may be possible to divide it into instrumental and reactive forms as well (Little, Jones, Henrich, & Hawley, 2003).

CP and Comorbid Problems in Adjustment

Another important finding from research is that youth with CPs are at increased risk for manifesting a variety of other adjustment problems as well. There are a number of possible reasons for this high rate of comorbidity. It is possible that the CP behaviors disrupt the child’s or adolescent’s psychosocial context, resulting in other problems in adjustment, such as anxiety and depression (Capaldi, 1992; Frick, Lilienfeld, Ellis, Loney, & Silverthorn, 1999). It is also possible that the CP itself is a result of the comorbid conditions, such as the result of impulsivity associated with attention-deficit/hyperactivity disorder (ADHD) (Burns & Walsh, 2002). Finally, it is also possible that the same risk factors (e.g., deficits in social cognition) may lead to the CPs and co-occurring problems in adjustment, such as peer rejection (Dodge & Pettit, 2003). Whatever the reason, understanding the common comorbid problems has proven to be very important for understanding and treating children and adolescents with CPs.

ADHD, the comorbid condition most commonly associated with CPs, is thought to precede the development of CPs in the majority of cases. In a meta-analytic study, Waschbush (2002) reported that 36% of boys and 57% of girls with CPs had comorbid ADHD. Some investigators consider ADHD (or, more specifically, the impulsivity or hyperactivity components of ADHD) to be the “motor” that drives the development of early-onset CPs, especially for boys (e.g., Burns & Walsh, 2002; Moffitt, 1993). Importantly, the presence of ADHD usually signals the presence of a more severe and more chronic form of CPs in children (see Waschbush, 2002). For example, children with both ADHD and CD seem to show a greater variety of delinquent (Loeber, Brintaupt, & Green, 1990) and aggressive (Moffitt, 1993) behaviors in adolescence, and more violent offending in adulthood (Klinterberg, Andersson, Magnusson, & Stattin, 1993).

Internalizing disorders, such as depression and anxiety, also co-occur with CPs at rates higher than expected by chance (Zoccolillo, 1992). In most cases, CPs precede the onset of depressive and anxiety symptoms (Loeber & Keenan, 1994), although in a minority of cases depression may precede CP behavior (e.g., Kovacs, Paulauskas, Gatsonis, & Richards, 1988). However, this relationship between CPs

and depression may be due to common risk factors as opposed to a causal relationship (Fergusson, Lynskey, & Horwood, 1996). Also, the relationship appears to differ for boys and girls, at least during middle to late adolescence. Wiesner (2003) found a reciprocal relationship between delinquent behaviors and depressive symptoms for girls, whereas for boys, the effect of delinquent behavior on depressive symptoms was unidirectional. Regardless of the temporal sequencing, the co-occurrence of CPs and depression appears to increase the risk for suicide in youth (e.g., Capaldi, 1991, 1992), and this risk appears to be higher for girls than for boys (Loeber & Keenan, 1994).

Additionally, Loeber and Keenan (1994) indicated that the co-occurrence of anxiety disorders with CPs is also especially likely for girls. The implications of comorbid anxiety have been unclear. In some studies, youth with CPs and a comorbid anxiety disorder are less seriously impaired than are youth with CPs alone (e.g., Walker et al., 1991); in other studies, the presence of a comorbid anxiety disorder has not been shown to have a differential effect (e.g., Campbell & Ewing, 1990); still other studies indicate that comorbid anxiety is associated with increased impairment (e.g., Serbin, Moskowitz, Schwartzman, & Ledingham, 1991). In trying to explain these inconsistent findings, Frick, Lilienfeld, and colleagues (1999) demonstrated that low levels of anxiety in some children with CPs may be a sign of a more severe type of disturbance, in which the child is not distressed by the consequences of his or her behavior whereas, in other children with CPs, higher levels of anxiety may be due to the greater levels of impairment and stress caused by more severe behavioral problems.

Both longitudinal and cross-sectional studies have documented that having CPs constitutes a significant risk factor for substance use (e.g., Hawkins, Catalano, & Miller, 1992). The comorbidity between CPs and substance abuse is important, because when youths with CPs also abuse substances, they tend to show an early onset of substance use and are more likely to abuse multiple substances (Lynskey & Fergusson, 1995). Although most of the research on the association between CPs and substance abuse prior to adulthood has been conducted with adolescents, the association between CPs and substance use may begin much earlier in development (Van Kammen, Loeber, & Stouthamer-Loeber, 1991).

With preschool-age children, language impairment may be associated with increased levels of CPs. Wakschlag and Danis (2004) suggest that if the CPs appear to result primarily as a reaction to frustration, or if the child's non-compliance appears to be due to a failure to understand directions from parents or teachers, then a language impairment may be implicated. An association between CPs and academic underachievement has also been documented in research. Approximately 20–25% of youth with CD underachieve in school relative to a level predicted by their age and intellectual abilities (Frick et al., 1991). In a comprehensive review, Hinshaw (1992) concluded that during preadolescence, this relationship is actually a function of comorbid ADHD rather than of CPs per se. In adolescence, the relationship is more complex, with preexisting ADHD (and perhaps other neuropsychological deficits), a history of academic difficulty and failure, and long-standing socialization difficulties with family and peers all playing interacting roles.

Multiple Risks Associated with CPs

Most researchers agree that CPs are the result of a complex interaction of multiple causal factors (Frick, 2006; Hinshaw & Lee, 2003; McMahon, Wells, & Kotler, 2006). Identifying the important causal agents and how they interact to cause CPs is an area in need of more research. Past research has uncovered a large number of factors *associated* with CP and that *may* play a role in their development and/or maintenance. These factors may be summarized in five categories: biological factors, cognitive correlates, family context, peers, and the broader social ecology.

As noted earlier, a number of researchers have proposed that early hyperactivity is a significant (and perhaps necessary) risk factor for development of CPs (e.g., Loeber & Keenan, 1994; Moffitt, 1993). Moffitt has suggested that subtle neuropsychological variations in the central nervous system increase the likelihood that an infant will display characteristics such as irritability, hyperactivity, impulsivity, and negative emotionality. These temperamental dimensions measured early in life have proven to predict CPs later in preschool (Keenan, Shaw, Delliquadri, Giovannelli, & Walsh, 1998), in childhood (Raine, Reynolds, Venables, & Mednick, 1997), and even into adolescence (Caspi, Henry, Moffitt, & Silva, 1995). There

are a number of other biological correlates (e.g., neurochemical and autonomic irregularities) of CPs in children and adolescents (see Dodge & Pettit, 2003; Raine, 2002) that, although crucial for developing causal theories, are not reviewed here, because the current state of knowledge is not sufficiently developed to have clear implications for assessment.

In contrast, several aspects of a youth's cognitive and learning styles that have been associated with CPs may be important to the assessment process (see Frick & Loney, 2000). First, in general, youth with CPs tend to score lower on intelligence tests, especially in the area of verbal intelligence (Loney, Frick, Ellis, & McCoy, 1998; Moffitt, 1993). Furthermore, these scores are predictive of the persistence of childhood-onset CD and of engagement in delinquent behaviors during adolescence (Frick & Loney, 1999). Second, many children and adolescents with serious CPs tend to show a learning style that is more sensitive to rewards than punishments. This has been labeled as a reward-dominant response style, and may explain why many of these youth persist in their maladaptive behaviors despite the threat of serious potential consequences (Frick, Cornell, Bodin, et al., 2003; O'Brien & Frick, 1996). Third, many youth with CPs show a variety of deficits in social cognition, which is the way they interpret and use social cues to respond in social situations (Crick & Dodge, 1994; Webster-Stratton & Lindsay, 1999). For example, children and adolescents with CPs have been shown to have deficits in encoding (e.g., lack of attention to relevant social cues, hypervigilant biases), to make more hostile attributional biases and errors in the interpretation of social cues, to have deficient quantity and quality of generated solutions to social situations, to evaluate aggressive solutions more positively, and to be more likely to engage in aggressive behavior (Dodge & Pettit, 2003).

These dispositional characteristics (i.e., difficult temperamental style and deficits in social information processing) may then place the youth at risk for developing an insecure attachment to his or her parent (Greenberg, Speltz, & DeKlyen, 1993) and/or a coercive style of parent-child interaction (Patterson, Reid, & Dishion, 1992). Both of these problems in the parent-child relationship have been implicated in the development of CPs, although the

relationship between insecure patterns of attachment in infancy and later CPs is probably mediated or moderated by other risk or protective factors (e.g., parenting practices, maternal depression, family adversity) over time (e.g., Greenberg et al., 1993; Lyons-Ruth, 1996). The critical role of parenting practices in the development and maintenance of CPs has been well established (e.g., Chamberlain & Patterson, 1995; Loeber & Stouthamer-Loeber, 1986). Types of parenting practices that have been closely associated with the development of CPs include inconsistent or irritable, explosive discipline; low supervision and involvement; and inflexible, rigid discipline (Chamberlain, Reid, Ray, Capaldi, & Fisher, 1997).

In addition to parenting practices, various other risk factors may have an impact on the family and serve to precipitate or maintain CPs. These include familial factors such as parental social cognitions (e.g., perceptions of the child), parental personal and marital adjustment, and parental stress, as well as parental functioning in extrafamilial social contexts (McMahon & Estes, 1997). Less clear are the mechanisms by which these factors exert their effects on CPs. For example, these risk factors may have a direct effect on CPs or they may exert their effects by disrupting parenting practices (Patterson et al., 1992). Furthermore, in some cases, the familial "risk" factor may be a *result* of CPs, rather than a potential cause, such as a child or adolescent with CPs being more difficult to monitor and supervise (Stattin & Kerr, 2000). With these caveats in mind, we note some of the relationships of these factors to CPs.

Parents of children with CPs display more maladaptive social cognitions and experience more personal (e.g., depression, antisocial behavior) and interparental (e.g., marital problems) distress, and greater social isolation (e.g., insularity) than do parents of nonreferred youth. Parents of clinic-referred children with CPs more likely misperceive their children's behaviors (e.g., Holleran, Littman, Freund, & Schmalting, 1982; Wahler & Sansbury, 1990), have fewer positive and more negative family-referent cognitions (Sanders & Dadds, 1992), and perceive CP behaviors as intentional and attribute them to stable and global causes (Baden & Howe, 1992). Sense of parenting efficacy has been shown to relate negatively to

CPs in both clinic-referred and nonreferred samples (e.g., Johnston & Mash, 1989; Roberts, Joe, & Rowe-Hallbert, 1992).

Parental personal adjustment has been implicated in the development of CPs. Maternal depression may adversely affect parenting behavior and may also negatively bias maternal perceptions of children and adolescents with CPs (e.g., Dumas & Serketich, 1994; Fergusson, Lynskey, & Horwood, 1993). Mothers of youth presenting with comorbid CPs and ADHD have been shown to be at increased risk for a history of childhood ADHD themselves (Chronis et al., 2003). Parental antisocial behavior has received increasing attention as both a direct and an indirect influence on the development and maintenance of CPs. Links between parental criminality, aggressive behavior, and a diagnosis of antisocial personality disorder (APD), and childhood delinquency, aggression, and CD/ODD diagnoses have been reported by a number of investigators (see Frick & Loney, 2002, for a review). Some evidence suggests that parental antisocial behavior may play a more central role than other risk factors in its effect on parenting practices and CPs (e.g., Frick & Loney, 2002; Patterson & Capaldi, 1991). For example, parenting and marital status were not associated with CPs independently of parental APD (Frick et al., 1992).

Similarly, parental substance abuse has been associated with children's CPs, at least in part, because of its association with disrupted parenting practices (Patterson et al., 1992; Wills, Schreiberman, Benson, & Vaccaro, 1994). In families with parental alcohol problems, the parents are less able to engage their children and are less congenial (Jacob, Krahn, & Leonard, 1991; Whipple, Fitzgerald, & Zucker, 1995). In addition, children's inappropriate behavior increases parental alcohol consumption (for parents with a positive family history of alcohol problems) and distress (for all parents) (Pelham & Lang, 1993).

Marital distress and conflict have been shown to be associated with CPs, negative parenting behavior, and parental perceptions of youth maladjustment (Amato & Keith, 1991; Cummings & Davies, 1994). The most commonly offered hypothesis for the relationship has been that marital distress and conflict interfere with the parents' ability to engage in appropriate parenting practices, which then leads

to CPs.¹ More narrowly focused constructs that relate directly to parenting, such as disagreement over childrearing practices, marital conflict in a child's presence, or the strength of the parenting alliance, may demonstrate stronger relationships to CPs than many broader constructs, such as marital distress (e.g., Abidin & Brunner, 1995; Jouriles et al., 1991; Porter & O'Leary, 1980).

Parents of children or adolescents with CPs also appear to experience higher frequencies of stressful events, both minor ones (e.g., daily hassles) and those of a more significant nature (e.g., unemployment, major transitions) (Patterson, 1983; Webster-Stratton, 1990). The effects of stress on the development of CPs may be mediated through parenting practices such as disrupted parental discipline (e.g., Snyder, 1991) and maladaptive parental social cognitions (e.g., Johnston, 1996a).

In addition to the family context, the child's or adolescent's relationship with peers plays a significant role in the development, maintenance, and escalation of CPs. Research has documented a relationship between peer rejection in elementary school and the later development of CPs (Roff & Wirt, 1984). In addition, peer rejection in elementary school is predictive of an association with a deviant peer group (i.e., one that shows a high rate of antisocial behavior and substance abuse) in early adolescence (e.g., Fergusson, Swain, & Horwood, 2002). This relationship is important, because association with a deviant peer group leads to an increase in the frequency and severity of CPs (Patterson & Dishion, 1985), and it has proven to be a strong predictor of later delinquency (Patterson, Capaldi, & Bank, 1991) and other negative outcomes, such as substance abuse (Dishion, Capaldi, Spracklen, & Li, 1995; Fergusson et al., 2002). Therefore, peer rejection may not only be directly related to the development of CPs but it also may indirectly influence CPs by increasing the child's or adolescent's chance of associating with a deviant peer group.

¹However, other explanations are possible (see Rutter, 1994), including direct modeling of aggressive and coercive behavior, and the cumulative stressful effects of such conflict (e.g., maternal depression). It has been suggested that both youth CPs and parental marital distress/conflict may be the result of parental antisocial behavior in some cases (Frick & Jackson, 1993).

Finally, factors within a youth's larger social ecology may play a causal role in the development of CPs. One of the most consistently documented of these correlates has been low socioeconomic status (SES) (Frick, Lahey, Hartdagen, & Hynd, 1989). However, several other ecological factors, many of which are related to low SES, such as poor housing, poor schools, and disadvantaged neighborhoods, have also been linked to the development of CPs (see Frick, 1998; Peeples & Loeber, 1994). In addition, the high rate of violence witnessed by youth who live in impoverished, inner-city neighborhoods has also been linked to the development of CPs (Osofsky, Wewers, Hann, & Fick, 1993).

Some parents of children with CPs may be quite isolated from friends, neighbors, and the community. Wahler and his colleagues have developed a construct called *insularity*, which is defined as a "specific pattern of social contacts within the community that is characterized by a high level of negatively perceived coercive interchanges with relatives and/or helping agency representatives and by a low level of positively perceived supportive interchanges with friends" (Wahler & Dumas, 1984, p. 387). Insularity is positively related to negative parent behavior directed toward children and oppositional child behavior directed toward parents (Dumas & Wahler, 1985; Wahler, 1980). It has also been associated with poor maintenance of parent management training effects (e.g., Dumas & Wahler, 1983). Thus, when a mother has a large proportion of aversive interactions outside the home, interactions between mother and child within the home are likely to be negative as well.

Multiple Developmental Pathways to CPs

One final area of research that is critical for understanding children and adolescents with CPs has focused on the many different causal pathways through which youth may develop these behaviors, each involving different constellations of risk factors and somewhat different causal processes (Frick, Cornell, Bodin, et al., 2003; Frick & Morris, 2004; Lahey, Moffitt, & Caspi, 2003; Thornberry & Krohn, 2003). This area of research may be most important for developing guidelines for assessment for at least two reasons. First, the different developmental mechanisms that operate in specific subgroups of youth with CPs may help to ex-

plain some of the differences in the type and severity of CPs, the presence of comorbid conditions, and the operation of multiple causal factors (Frick, 2006; Frick & Morris, 2004). Second, this area of research suggests that treatments likely need to be tailored to the youth's specific needs, which necessitates an adequate assessment to implement such individualized interventions (Frick, 1998, 2006).

The most widely accepted model for delineating distinct pathways in the development of CPs distinguishes between childhood- and adolescent-onset subtypes of CPs; that is, the DSM-IV-TR (APA, 2000) makes the distinction between youth who begin showing severe CP behaviors before age 10 (i.e., childhood onset) and those who do not show severe CP behaviors before age 10 (i.e., adolescent onset). This distinction is supported by substantial research documenting important differences between these two groups of youth with CP (see Moffitt, 2003, for a review). Specifically, youth in the childhood-onset group show more severe CPs in childhood and adolescence, and are more likely to continue to show antisocial and criminal behavior into adulthood (Frick & Loney, 1999; Moffitt & Caspi, 2001). More relevant to causal theory, most of the dispositional (e.g., temperamental risk, low intelligence) and contextual (e.g., family dysfunction) correlates associated with CPs are more strongly associated with the childhood-onset subtype. In contrast, the youth in the adolescent-onset subtype do not consistently show these same risk factors. If they do differ from other youth, then it is primarily in showing greater affiliation with delinquent peers and scoring higher on measures of rebelliousness and authority conflict (Moffitt & Caspi, 2001; Moffitt, Caspi, Dickson, Silva, & Stanton, 1996).

The different characteristics of youth in the two CP subtypes have led to theoretical models that propose very different causal mechanisms operating across the two groups. For example, Moffitt (1993, 2003) has proposed that youth in the childhood-onset group develop CP behavior through a transactional process involving a difficult and vulnerable child (e.g., impulsive, with verbal deficits, with a difficult temperament) who experiences an inadequate rearing environment (e.g., poor parental supervision, poor quality schools). This dysfunctional transactional process disrupts the child's socialization, leading to poor social relations

with persons both inside (i.e., parents and siblings) and outside (i.e., peers and teachers) the family, which further disrupts the child's socialization. These disruptions lead to enduring vulnerabilities that may negatively affect the child's psychosocial adjustment across multiple developmental stages. In contrast, Moffitt views youth in the adolescent-onset pathway as showing an exaggeration of the normative developmental process of identity formation that takes place in adolescence. Their engagement in antisocial and delinquent behaviors is conceptualized as a misguided attempt to obtain a subjective sense of maturity and adult status in a way that is maladaptive (e.g., breaking societal norms) but encouraged by an antisocial peer group. Given that their behavior is viewed as an exaggeration of a process specific to the adolescent developmental stage, and not due to enduring vulnerabilities, their CPs are less likely to persist beyond adolescence. However, they may still have impairments that persist into adulthood as a consequence of their CPs (e.g., a criminal record, dropping out of school, substance abuse) (Moffitt & Caspi, 2001).

This distinction between childhood- and adolescent-onset trajectories to severe CPs has been very influential for delineating different pathways through which youth develop CPs, although it is important to note that clear differences between the pathways are not always found (Lahey et al., 2000) and the applicability of this model to girls requires further testing (Silverthorn & Frick, 1999). Researchers have begun extending this conceptualization in a number of important ways. Specifically, they have begun to test whether additional distinctions can be made in youth who follow the childhood-onset pathway to (1) identify groups based on the severity, type, and stability of CPs exhibited; (2) identify groups that have distinct vulnerabilities that can make them more difficult to socialize by parents, teachers, and other important socializing agents; and (3) more clearly specify the developmental processes that can be disrupted by the transactional process that takes place between a vulnerable child and a nonoptimal socializing environment.

For example, research has identified a subgroup of youth that shows high rates of callous and unemotional (CU) traits (e.g., lacking empathy and guilt). Importantly, Frick and Dickens (2006) reviewed 22 published studies, showing that CU traits either co-occurred with ($n = 10$) or predicted ($n = 12$) serious antisocial

and aggressive behavior, and five studies showing that CU traits were related to poorer treatment response among youth with CPs. There is also evidence that the CP subgroup of youth with CU traits also exhibits a temperamental style distinct from other youth with CPs (for reviews, see Blair, Peschardt, Budhani, Mitchell, & Pine, 2006; Frick & Morris, 2004). Specifically, compared to other antisocial youth, youth with CU traits are more likely to show deficits in their processing of negative emotional stimuli (Blair, 1999; Blair, Colledge, Murray, & Mitchell, 2001; Kimonis, Frick, Fazekas, & Loney, 2006; Loney, Frick, Clements, Ellis, & Kerlin, 2003), to show low levels of fearful inhibitions and anxiety (Frick, Cornell, Bodin, et al., 2003; Frick, Lilienfeld, et al., 1999; Lynam et al., 2005) and to show decreased sensitivity to punishment cues, especially when a reward-oriented response set is primed (Barry et al., 2000; Fisher & Blair, 1998).

These characteristics are all consistent with a temperamental style that has been variously labeled as low fearfulness (Rothbart & Bates, 1998) or low behavioral inhibition (Kagan & Snidman, 1991). This temperamental style could place a young child at risk for missing some of the early precursors to empathetic concern that involve emotional arousal evoked by the misfortune and distress of others (Blair, 1995), make the child less responsive than other youth to typical parental socialization practices (Oxford, Cavell, & Hughes, 2003; Wootton, Frick, Shelton, & Silverthorn, 1997), and lead to impairments in moral reasoning and empathic concern toward others (Blair, 1999; Pardini, Lochman, & Frick, 2003).

The few studies that have identified youth within the childhood-onset group who differ relative to the presence of CU traits also provide some clues as to the mechanisms that may be involved in the development of CPs in children and adolescents without these traits. These youth with CPs who do not have elevated CU traits are less likely to be aggressive than those who have elevated CU traits and who, when they do act aggressively, are more likely to be reactive (Frick, Cornell, Barry, Bodin, & Dane, 2003) in response to real or perceived provocation by others (Frick, Cornell, Bodin, et al., 2003). Also, CPs of antisocial youth who do not show CU traits are more strongly associated with dysfunctional parenting practices (Oxford et al., 2003; Wootton et

al., 1997) and with deficits in verbal intelligence (Loney et al., 1998). Finally, youth with CPs who do not show CU traits exhibit high levels of emotional distress (Frick, Cornell, Bodin, et al., 2003; Frick, Lilienfeld, et al., 1999), are more reactive to the distress of others in social situations (Pardini et al., 2003), and are highly reactive to negative emotional stimuli (Kimonis et al., 2006; Loney et al., 2003).

Overall, these findings suggest that a large number of children and adolescents with CPs but without CU traits have problems regulating their emotions (Frick & Morris, 2004). These problems in emotion regulation can lead to very impulsive, unplanned, aggressive and anti-social acts for which the child or adolescent may be remorseful afterwards but may still have difficulty controlling in the future (Pardini et al., 2003). The problems in emotion regulation can also make a youth particularly susceptible to becoming angry due to perceived provocations from peers, leading to violent and aggressive acts within the context of high emotional arousal (Hubbard et al., 2002; Loney et al., 2003).

CONDUCTING AN EVIDENCE-BASED ASSESSMENT OF CPs

Overview

Evidence-based assessment is necessarily evolving; as research accumulates to guide these assessments, these recommendations should change to incorporate new findings. Furthermore, in many areas of assessment, available measures with demonstrated adequate psychometric properties are quite limited, making the scientific basis stronger for some recommendations than for others. With these caveats in mind, we hope that the following guidelines (McMahon & Frick, 2005) are of practical use to practitioners and researchers as a way to translate the currently available research into practice recommendations and to stimulate further clinically based research in this area.

When a child or adolescent is referred for CP assessment, the first order of business is to ascertain whether the youth is in fact demonstrating significant CP levels. Most child referrals for mental health evaluation and services are initiated by individuals and entities other than the child, such as parents, teachers, and the juvenile justice system. This is especially true for

children with CPs, whose behavior is inherently distressing to others. Thus, it is important to rule out the possibility of the occasional inappropriate referral due, for example, to unrealistic parental or teacher expectations. After the appropriateness of the referral is determined, the primary tasks are to (1) identify the type and severity of the youth's CPs and determine the degree and types of impairment associated with them; (2) determine whether the youth is also experiencing significant levels of impairment related to other disorders and associated conditions; (3) determine what risk factors may have led to the development of the youth's CPs and/or more importantly, contribute to the continuation of these problems; and (4) determine which developmental pathway is most consistent with the youth's CP pattern, comorbid conditions, and risk factors.

As we detail below, knowledge concerning the particular developmental pathway that best fits the youth's clinical presentation is key to conducting an evidence-based assessment. It can provide a set of working hypotheses on the nature of the CP behavior, comorbid conditions, and salient risk factors. Determination of the likely developmental pathway guides the structure and focus of other areas of the assessment. For example, based on the available literature, one would hypothesize that a youth with adolescent-onset CPs would be less likely to be aggressive and to have intellectual deficits, temperamental vulnerabilities, and comorbid ADHD. However, association with a deviant peer group, and factors that may contribute to this deviant peer group affiliation (e.g., lack of parental monitoring and supervision), would be especially important to assess in youth on this pathway. In contrast, for a youth whose serious CPs began prior to adolescence, one would expect more cognitive and temperamental vulnerabilities, comorbid ADHD, and more serious problems in family functioning. For youth in this childhood-onset CP group who do not show CU traits, the cognitive deficits would more likely be verbal deficits, and the temperamental vulnerabilities would more likely be problems regulating emotions, leading to higher levels of anxiety, depression, and aggression involving anger. In contrast, for youth in the childhood-onset CP group who show high levels of CU traits, the cognitive deficits more likely involve a lack of sensitivity to punishment, and the temperamental vulnerabilities more likely involve a preference for dangerous

and novel activities, and a failure to experience many types of emotion (e.g., guilt and empathy). Furthermore, assessing the level and severity of aggressive behavior, especially the presence of instrumental aggression, would be critical for youth in this group.

As most clinicians recognize, people do not often fall neatly into the prototypes suggested by research. Therefore, these descriptions are meant to serve as hypotheses around which to organize an evidence-based assessment. Furthermore, to test these hypotheses adequately and determine how well a youth might fit into the prototypical descriptions of these developmental pathways, it is often necessary to conduct a comprehensive assessment. Finally, all of the constructs that are necessary to determine which of these developmental pathways might best describe the youth should be assessed by multiple assessment techniques and by measures that provide information on the youth in multiple contexts, further adding to the comprehensive nature of the assessment.

Therefore, a multistage assessment strategy is typically recommended (McMahon & Estes, 1997; McMahon & Frick, 2005; Nock & Kurtz, 2005). At the first stage, developmentally appropriate, broad-band screening instruments and unstructured clinical interviews should be employed initially to identify the relevant CP behaviors, as well as likely comorbid conditions. At the second stage, more focused and/or labor-intensive measures are administered to provide more detailed information concerning the youth's CP behavior, to assess factors that could help to identify the youth's most likely developmental trajectory (e.g., age of onset of the CPs, level of CU traits, problems in emotional regulation), and to assess associated conditions in multiple settings (e.g., home, school) based on the results of this initial assessment. Also, at this second stage, it is essential that the level of functional impairment or adaptive disability associated with the youth's CPs be determined. At the third stage, an array of risk factors needs to be assessed, guided by the information obtained at the first two stages of assessment as to the most likely developmental pathway that the youth may be following, and guided by the prototypical descriptions of these pathways provided earlier.

These recommendations are influenced by a number of issues related to the developmental level of the child. First, the issue of whether the youth's CPs represent a clinically significant

phenomenon or are a temporary developmental perturbation is especially salient for preschool-age children and for adolescents. Research suggests that some level of CP behavior in both of these developmental stages is normative (Keenan et al., 1998; Moffitt, 1993). Second, youth generally do not become reliable reporters of their CP behaviors until they are approximately 9 years of age (Kamphaus & Frick, 2005). Thus, reliance on self-report in the assessment battery may be more limited in the assessment of very young children. Third, with preschool-age children, assessment of language functioning and noncompliance is particularly important, and the use of structured laboratory observation analogues of parent-child interaction is important for the assessment of child noncompliance (McMahon & Forehand, 2003). Fourth, the number and breadth of salient domains of risk tend to increase with the youth's age, as a result of the broader social milieu in which he or she functions (Dodge & Pettit, 2003). Thus, whereas assessment of the youth's functioning in the family context is important across all ages, assessments of school and peer contexts become increasingly important in middle childhood and adolescence.

With respect to assessing CPs in girls, there is a relative dearth of information to guide clinicians in gender-specific issues, with two exceptions. A measure of relational aggression should be included in clinical or research settings that include girls with CPs. Also, because girls with CPs appear to be at increased risk for presenting with comorbid anxiety and depression, careful assessment of such conditions is especially warranted. Fortunately, a recent proliferation of research on CPs concerning girls (e.g., Moretti, Odgers, & Jackson, 2004; Pepler, Madsen, Webster, & Levene, 2005; Putallaz & Bierman, 2004; Silverthorn & Frick, 1999; Underwood, 2003) should in the near future facilitate the development of evidence-based guidelines that are applicable to girls with CPs.

These broad guidelines follow from the CP research. Importantly, there are many different ways to follow these recommendations in the various settings in which children with CPs may be assessed. Furthermore, given the length limitations of this chapter, it is impossible to provide an exhaustive discussion of all of the different measures that might be used to follow these recommendations. In the following sec-

tions, we provide examples of selected relevant measures that both have empirical support and are feasible for clinicians to implement in their practice.

Heterogeneity of CPs: Implications for Assessment

Based on the research showing the heterogeneity of CP behavior, a primary goal of assessment is to assess carefully and thoroughly the number, type, and severity of the CPs and the level of impairment they cause for the child or adolescent (e.g., school suspensions, police contacts, peer rejection). This is essential not only for diagnosis and screening but also to determine the validity of the initial referral, so that primary diagnoses of other disorders and the occasional referral due to inappropriate parent or teacher expectations can be identified (i.e., case conceptualization/planning). To obtain an accurate representation of the referred youth's CP behavior, it is important to use multiple assessment methods. Several methods are especially helpful in this respect, including interviews with the parents, youth, and other relevant parties (e.g., teachers); behavior rating scales; and behavioral observations in the clinic, home, and/or school settings. The first section of Table 3.1 lists instruments that may be used to assess CPs.

Interviews

Interviews may be divided into two general categories: clinical interviews and structured diagnostic interviews. The clinical interview with the parent is of major importance. Besides providing a method for assessing the type, severity, and impairment associated with the CPs, the clinical interview with the parent helps to assess typical parent-child interactions that may be contributing to the CPs, the antecedent stimulus conditions under which the CP behaviors occur, and the consequences that accompany such behaviors. A number of interview formats are available to aid the clinician in structuring the information from the parents about their child's behavior and about parent-child interactions (e.g., McMahon & Forehand, 2003; Patterson, Reid, Jones, & Conger, 1975; Wahler & Cormier, 1970). An individual interview with the child or adolescent may or may not provide useful, content-oriented information depending on the age and/or developmental level of the child and the nature of the spe-

cific behaviors. As noted earlier, it has been difficult to obtain reliable self-report information from interviews with children younger than age 9 (Kamphaus & Frick, 2005). However, even with younger children, informal interviews may be extremely useful, in that they can provide the therapist an opportunity to assess the child's perception of why he or she has been brought to the clinic, and a subjective evaluation of the child's cognitive, affective, and behavioral characteristics (e.g., Bierman, 1983). Furthermore, when assessing overt types of CPs, Loeber and Schmalting (1985) have suggested that maternal and teacher reports may be preferable to youth reports, because youth often underestimate or minimize their own aggressive behavior (see also David & Kistner, 2000; Edens, 1998). However, when assessing covert types of CPs, more valid reports are likely to be obtained from the child or adolescent.²

When the presenting problems include classroom behavior or academic underachievement, an interview with the youth's teachers is also appropriate. Breen and Altepeter (1990) have provided an outline for a brief interview with the teacher, which can be conducted at the school or by telephone. Situationally formatted interview guides based on Barkley's (1987, 1997) School Situations Questionnaire or Wahler and Cormier's (1970) preinterview checklists may be employed in conjunction with specific questions related to the child's problem behaviors. Contextual factors, such as classroom rules of conduct, teacher expectations, and the behavior of other children in the classroom, are important as well. (For additional discussions of teacher interviewing procedures, see McMahon & Forehand, 2003; Walker, 1995.)

Researchers and practitioners increasingly are using functional behavioral assessment (FBA) methods to assess children's needs in school and to match intervention strategies and behavioral functions to enhance treatment effectiveness (LaRue & Handleman, 2006; Walker, Ramsey, & Gresham, 2004). This is in part due to changes in the Individuals with Disabilities Education Act (IDEA; 1997), which now mandates an FBA for all students who have been suspended from school for at least

²However, given the strong positive correlations between stealing and lying, youth who steal may not be veridical in their self-reports.

TABLE 3.1. Implications of Research for the Assessment of Children and Adolescents with Conduct Problems

Assessment focus	Selected measures
	<u>Heterogeneity in types and severity of CPs</u>
Screen broadly for CP behaviors	ASEBA, BASC-2; DISC/DICA, CI
Focused assessments	
ODD/CD diagnosis	DISC/DICA, ASEBA (DSM scales); Child Symptom Inventories
Overt/covert CPs	ASEBA (Aggressive Behavior vs. Rule-Breaking Behavior); BASC-2 (Aggression vs. Conduct Problems); RBPC (Conduct Disorder vs. Social Aggression); ECBI/SESBI-R; SRD; Parent Daily Report; DISC/DICA, CI
Overt CPs only	Conner's Rating Scales; Problem-Solving Discussion
Covert CPs only	Firesetting History Screen/Firesetting Risk Interview/Children's Firesetting Interview; Lying Scale; Temptation provocation tasks (stealing/property destruction, firesetting); TIROSSA
Noncompliance	Child's Game/Parent's Game/Clean Up (BCS, DPICS); Compliance Test; REDSOCS
Reactive/proactive aggression	Parent Checklist; Teacher Checklist; Aggressive Behavior Rating Scale; Reactive-Proactive Aggression Questionnaire
Relational aggression	Ratings of Children's Social Behavior; peer nominations
Delinquency	SRD
Functional impairment/adaptive disability	C-GAS; CIS; CAFAS; NABC
	<u>Comorbid adjustment problems</u>
Screen broadly for comorbid disorders/conditions	ASEBA, BASC-2; DISC/DICA, CI
Focused assessments (as needed)	
ADHD ^a	
Depression ^a	
Anxiety ^a	
Substance use ^a	
Academic underachievement ^a	
Language impairment	CBCL/1½-5 Language Development Survey; BASC-2 Functional Communication

10 days for exhibiting CP types of behavior. FBA involves specification of problem behaviors in school in operational terms (e.g., what types of CPs are being exhibited in the classroom), as well as identification of events that reliably predict and control behavior through an examination of antecedents and consequences. For example, an FBA would determine whether the child’s CPs are occurring only in certain classes or situations (e.g., during class change, at lunch), and whether certain factors reliably lead to the CPs (e.g., teasing by peers, disciplinary confrontations with teachers). It would also determine the consequences associated with the CPs that may contribute to their likelihood of occurring in the future (e.g., getting sent home from school; preventing further teasing). Information relevant to an FBA is gathered through both interviews and direct observation of classroom behavior by teachers or school psychologists. Use of these methods has been shown to contribute to beneficial out-

comes for children and adolescents in school (Walker et al., 2004).

One criticism of the unstructured interview has been the difficulty in obtaining reliable information in this format. Structured interviews have been used in efforts to improve the reliability and validity of the information that is obtained. Two frequently used structured diagnostic interviews in the assessment of children with CPs are the Diagnostic Interview Schedule for Children (DISC; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) and the Diagnostic Interview for Children and Adolescents (DICA; Reich, 2000). For reviews of these and other structured diagnostic interviews, see Loney and Frick (2003) and McClellan and Werry (2000). Most of these interviews provide a structured format for obtaining parent and youth reports on symptoms that comprise the criteria for ODD and CD according to DSM-IV-TR (APA, 2000). Also, such interviews provide a structured method to assess how much

these symptoms impair a child's or adolescent's social and academic functioning.

There are a number of limitations in the information provided by structured interviews, however (see Loney & Frick, 2003). The interviews are time-consuming to administer (often taking over 2 hours for youth with many problems in adjustment) and often do not contain information that can be compared to a normative comparison group. Furthermore, most structured interviews do not have formats for obtaining teacher information, and obtaining reliable information from young children (below age 9) has been problematic. Thus, it is difficult to obtain multi-informant assessments for many youth using structured interviews. Perhaps one of the major limitations in the use of structured interviews, however, is the evidence that the number of reported symptoms declines within an interview schedule; that is, parents and youth tend to report more symptoms for diagnoses assessed early in the interview, regardless of which diagnoses are assessed first (Jensen, Watanabe, & Richters, 1999), calling into question the validity of diagnoses assessed later in the interview.

An alternative approach to interviewing youth, developed by McConaughy and Achenbach (2001), the Semistructured Clinical Interview for Children and Adolescents (SCICA) is a broad interview administered to youth (ages 6–18) that employs a protocol of open-ended questions to assess a variety of areas of youth functioning. Dimensional scores similar to those obtained from various instruments in the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2000, 2001; see below) can also be derived from these items. Kolko and colleagues have developed several semistructured interviews for parents and children that have been used to assess various aspects of firesetting and matchplay in inpatient, outpatient, and community samples of children, including the Firesetting History Screen, the Firesetting Risk Interview, and the Children's Firesetting Interview (Kolko, Nishi-Strattner, Wilcox, & Kopet, 2002; Wilcox & Kolko, 2002). Evidence for the reliability and validity of these interviews is encouraging. For example, there is relatively good agreement between parent and child reporters on the Firesetting History Screen, and it is related to other measures of firesetting involvement. Both the Firesetting Risk Interview

and the Children's Firesetting Interview have adequate internal consistency, differentiate between firesetters and nonfiresetters, and predict recidivism.

The interview as an assessment tool does not end with the first contact with the youth, but continues throughout treatment formulation and implementation. It is used to obtain information necessary for the development of interventions, to assess the effectiveness of the intervention and its implementation, and to alter the intervention, if necessary (Breen & Altepeter, 1990).

Behavior Rating Scales

Behavior rating scales completed by adults (i.e., parents, teachers) or by the youth him- or herself are very useful as screening devices that cover a broad range of CP behaviors and assess other problems in adjustment that may be used to evaluate the level of CP-associated impairment. For example, many rating scales contain items assessing the child's or adolescent's peer relations and academic performance, both of which are important areas of impairment experienced by many youth with CPs (e.g., Reynolds & Kamphaus, 2004). More importantly, these rating scales often provide the best norm-referenced assessment concerning the child's or adolescent's CPs. Specifically, these scales often have large normative bases from which the scores obtained (e.g., *T*-scores) compare the child's CP level to a reference group of youth of the same age and gender. Although there are many behavior rating scales, several have been used extensively in clinical practice and research with children and adolescents with CPs (Kamphaus & Frick, 2005; McMahon & Frick, 2005). These scales, which are summarized in Table 3.2, include the ASEBA (Achenbach & Rescorla, 2000, 2001), the Behavior Assessment System for Children—Second Edition (BASC-2; Reynolds & Kamphaus, 2004), the Conners Rating Scales (Conners, 1997), the Revised Behavior Problem Checklist (RBPC; Quay & Peterson, 1996), and the Child Symptom Inventories (e.g., Gadow & Sprafkin, 1998). See Kamphaus and Frick (2005) for a more comprehensive summary of the strengths and weaknesses of each of these scales.

Most of the scales listed in Table 3.2 cover the same age range and have parallel forms for

TABLE 3.2. Summary of Selected Comprehensive Behavior Rating Scales Used in the Assessment of Conduct Problems

Scale/authors	Publisher	Age range	CP assessed	Domains assessed	Informant
Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2000, 2001)	Author, University of Vermont	1.5–18	<p><i>Aggressive behavior</i>—overt conduct problems including arguing, bragging, and being mean.</p> <p><i>Rule-breaking behavior</i>—covert conduct problems such as lying, cheating, stealing, and truancy (6–18 only).</p>	6–18: withdrawn, somatic complaints, anxious/depressed, social problems, thought problems, attention problems (hyperactivity–impulsivity)—Teacher’s Report Form only), competence DSM scales: Affective Problems, Anxiety Problems, Somatic Problems, Attention Deficit/Hyperactivity Problems, Oppositional Defiant Problems, Conduct Problems	Parent, teacher, and child (ages 11–18)
Behavior Assessment System for Children, Second Edition (BASC-2; Reynolds & Kamphaus, 2004)	American Guidance Service	2–21	<p><i>Aggression</i>—overt conduct problems including oppositional behavior, arguing, and hitting.</p> <p><i>Conduct problems</i>—covert conduct problems, including lying and stealing.</p>	1.5–5: emotionally reactive, anxious/depressed, somatic complaints, withdrawn, sleep problems, attention problems, aggressive behavior, language development survey (1.5–5) DSM scales: Affective Problems, Anxiety Problems, Pervasive Developmental Problems, Attention Deficit/Hyperactivity Problems, Oppositional Defiant Problems	Parent, teacher, and child (ages 8–21)

interpersonal relations, locus of control, relations with parents, self-esteem, self-reliance, sensation seeking, sense of inadequacy, social stress							
Child Symptom Inventory (e.g., Gadow & Sprafkin, 1998).	Checkmate Plus	3–18	<i>Oppositional defiant disorder</i> —angry, hostile, and defiant behaviors <i>Conduct disorder</i> —violations of the rights of others or age-appropriate norms.	Attention-deficit/hyperactivity disorder, generalized anxiety disorder, social phobia, separation anxiety disorder, major depressive disorder, dysthymic disorder, pervasive developmental disorder, autistic disorder, schizophrenia, tic disorder	Parent, teacher, and child (ages 12–18)		
Conners Rating Scales (Conners, 1997)	Multi-Health Systems	3–17	<i>Oppositional</i> —overt behaviors such as being angry and hostile, losing temper, and arguing with adults.	Cognitive problems, hyperactivity, anxious-shy, perfectionism, social problems, psychosomatic, family problems, anger control problems	Parent, teacher, and child (ages 12–18)		
Revised Behavior Problem Checklist (Quay & Peterson, 1996)	PAR	5–18	<i>Conduct disorder</i> —overt behaviors such as anger, fighting, and disobedience. <i>Socialized aggression</i> —covert conduct problems such as stealing, substance use, lying, and truancy.	Attention problems, immaturity, anxiety—withdrawal, psychotic behavior, motor tension—excess	Parent and teacher

parent, teacher, and youth reports. The exception, the BASC-2 (Reynolds & Kamphaus, 2004), includes CPs only on their parent and teacher versions. Also, most of these scales divide CP assessment into scales that assess overt and covert CP. Exceptions are the Child Symptom Inventories (e.g., Gadow & Sprafkin, 1995), whose items correspond to the DSM-IV-TR symptom list for ODD and CD.

We provide an overview of the ASEBA family of instruments (Achenbach & Rescorla, 2000, 2001) because of their widespread adoption in both research and clinical settings. A number of instruments in the ASEBA are applicable for use with children and adolescents. There are parallel forms for parents (Child Behavior Checklist; CBCL/1½–5, CBCL/6–18), teachers (Caregiver-Teacher Report Form for Ages 1½–5, C-TRF; Teacher's Report Form, TRF/6–18), youth (Youth Self-Report; YSR/11–18), and observers (Direct Observation Form; DOF/5–14; described below). These instruments are similar in terms of structure, items, scoring, and interpretation. They are designed to be self-administered, and each can usually be completed in 10 to 20 minutes. The instruments include sections concerning Competence and Problem items (the CBCL/1½–5 includes Problem items and a Language Development Survey; the DOF includes only Problem items). Competence scales include items related to various activities, social relationships, and success in school. With respect to the Problem items, the various ASEBA instruments typically yield Total, Internalizing, and Externalizing broad-band scales, and a number of narrow-band scales. With respect to CPs, narrow-band scales comprising the Externalizing scale (e.g., Rule-Breaking Behavior and Aggressive Behavior on the CBCL/6–18) are of particular interest. The ASEBA now also includes DSM-oriented scales, such as Oppositional Defiant Problems and Conduct Problems on the CBCL/6–18 (Achenbach, Dumenci, & Rescorla, 2003), and parent ratings on a Dutch version of the CBCL have been shown to predict DSM-IV diagnoses (Krol, De Bruyn, Coolen, & van Aarle, 2006).

The normative samples collected for the components of the ASEBA are generally quite extensive and representative of the 48 contiguous United States for SES, ethnicity, region, and urban-suburban-rural residence (Achenbach & Rescorla, 2000, 2001). Importantly, the samples generally excluded children referred

for mental health or special education services within the past year, which makes them normal rather than normative samples. However, the large samples allow for norm-referenced scores that can be age- and gender-specific. These extensive normative samples also provided extensive factor support for the various ASEBA scales, and the factor structure has been replicated extensively not only in the United States but also in many other countries (Achenbach, Rescorla, & Ivanova, 2005). These studies have provided strong support for the reliability of both the global composites and, with only a few exceptions, the narrow-band scales (Achenbach & Rescorla, 2001). Finally, the extensive research on the rating scale component of the ASEBA has provided strong support for the validity of the scales in differentiating between children with CP and normally developing children, and in documenting the effects of treatment for children with CPs (e.g., DeGarmo, Patterson, & Forgatch, 2004; Eisenstadt, Eyberg, McNeil, Newcomb, & Funderburk, 1993; Kazdin, Bass, Siegel, & Thomas, 1989; Kendall, Reber, McLeer, Epps, & Ronan, 1990; Scott, Spender, Doolan, Jacobs, & Aspland, 2001). Thus, the ASEBA instruments may be used for both general and more specific purposes, including classification, screening, diagnosis, and treatment evaluation. With children with CPs, its comprehensive coverage can be useful in screening for some of the disorders that are often comorbid with CPs (see below).

The primary limitations in the ASEBA scales involve the narrow-band scales. The content, by being broad in coverage, sometimes does not allow for adequate assessment of specific domains that may be important for some evaluations. For example, there is no separate depression scale or a scale assessing hyperactivity. Furthermore, the sole reliance on factor analysis in developing scales led to some heterogeneity in the content of some of the narrow-band scales (Kamphaus & Frick, 2005). For example, the Attention Problems scales on the parent and teacher measures include items related to attention (e.g., “can’t concentrate,” “can’t pay attention for long”), as well as items such as “acts too young for his or her age” and “nervous or high strung” that are not specific to inattention. This scale heterogeneity needs to be considered when interpreting the narrow-band scales.

The scales summarized in Table 3.2 are broad rating scales that cover many dimensions

of child and adolescent adjustment, not just CPs. Also, due to the need to cover a large number of domains, they often include only a limited number of CP behaviors. Several rating scales, however, focus solely on CPs and provide a more comprehensive coverage of various CP types. Two examples of parent and teacher report measures are the Eyberg Child Behavior Inventory and the Sutter–Eyberg Student Behavior Inventory—Revised (ECBI and SESBI-R, respectively; Eyberg & Pincus, 1999). The ECBI is completed by parents and is intended for use with children ages 2–16. It takes approximately 10 minutes to administer and score. The 36 items describe specific CP behaviors (primarily overt) and are scored on both a frequency-of-occurrence (Intensity) scale and a yes–no problem identification (Problem) scale. Both scales have been shown to discriminate between children with CPs and other, clinic-referred children and nonreferred children (e.g., Burns & Patterson, 1990, 2001; Burns, Patterson, Nussbaum, & Parker, 1991; Eyberg, 1992; Eyberg & Colvin, 1994; Rich & Eyberg, 2001), and to be sensitive to treatment effects from parent management training interventions with young children (e.g., Eisenstadt et al., 1993; McNeil, Eyberg, Eisenstadt, Newcomb, & Funderburk, 1991; Nixon, Sweeney, Erickson, & Touyz, 2003; Webster-Stratton & Hammond, 1997).

The original normative data for the ECBI (Eyberg & Robinson, 1983; Robinson, Eyberg, & Ross, 1980) were limited in sample size and age range. Based on a larger and more demographically representative sample (Colvin, Eyberg, & Adams, 1999; Eyberg & Pincus, 1999), currently recommended cutoff points for the Intensity and Problem scales have been revised, resulting in improved sensitivity, specificity, and predictive power (Rich & Eyberg, 2001). There have not been meaningful gender or ethnic differences (Burns & Patterson, 2001; Eyberg & Colvin, 1994), although Burns and Patterson (2001) found that scores tended to decrease with children's age increases, especially for the Intensity score.

With respect to other psychometric considerations, adequate test–retest, split-half, and internal consistency reliabilities have been reported (e.g., Burns & Patterson, 1990; Burns et al., 1991; Eyberg, 1992; Eyberg & Colvin, 1994; Funderburk, Eyberg, Rich, & Behar, 2003). Mean levels of scores are stable across time as well (Eyberg, 1992; Funderburk et

al., 2003), and evidence for longer-term (10-month) test–retest reliability has also been obtained (Funderburk et al., 2003). Interparent agreement on the ECBI is moderate to strong for both Intensity ($r = .69$) and Problem ($r = .61$) scales (e.g., Eisenstadt, McElreath, Eyberg, & McNeil, 1994). The ECBI is significantly correlated with the Externalizing broad-band scale of the CBCL (Boggs, Eyberg, & Reynolds, 1990), with other rating scales (e.g., Funderburk et al., 2003), and with various clinic-based observational coding systems (e.g., Robinson & Eyberg, 1981; Webster-Stratton, 1985). Responses on the ECBI have been shown to be independent of social desirability factors (Robinson & Anderson, 1983).

The original SESBI is identical in format to the ECBI, with 36 items rated on both Intensity and Problem scales, although items on the ECBI that were not relevant to the school setting were replaced by 13 new items. Standardization studies have been done on the SESBI, with samples ranging from preschoolers through high school students (e.g., Burns & Patterson, 2001; Burns, Sosna, & Ladish, 1992; Floyd, Rayfield, Eyberg, & Riley, 2004; Funderburk et al., 2003). The SESBI has also been shown to be sensitive to the effects of a parent management training intervention (McNeil et al., 1991). Eyberg and colleagues have begun to evaluate a revised version of the SESBI (SESBI-R; Eyberg & Pincus, 1999) that includes additional items derived from the disruptive behavior categories of DSM-IV (APA, 1994) and deletion of infrequently occurring items. The SESBI-R, which comprises 38 items, appears to have adequate psychometric properties (Querido & Eyberg, 2003; Rayfield, Eyberg, & Foote, 1998) and discriminates between children referred for CPs and nonreferred children (Querido & Eyberg, 2003).

Children whose scores exceed the cutoff points on the ECBI or the SESBI-R are probably a heterogeneous group that may present with ADHD, as well as ODD or CD (McMahon & Estes, 1997), because the items that comprise the ECBI and SESBI-R are consistent with the DSM diagnostic categories of ODD, CD, and ADHD (Burns & Patterson, 1991). Given the increasing attention paid to comorbidity of ADHD and CPs, this represents a potentially serious limitation of these instruments. However, the ECBI and SESBI-R show promise as useful rating scales in clinical settings, where they can be employed as screening

instruments and as treatment outcome measures for disruptive behavior (broadly defined), as rated by parents and teachers.

To begin to address limitations resulting from the unidimensional nature of the ECBI and SESBI-R, researchers have conducted factor analyses, resulting in a three-factor solution for the ECBI (Oppositional Defiant Behavior toward Adults, Inattentive Behavior, and Conduct Problem Behavior) (Burns & Patterson, 2000; Weis, Lovejoy, & Lundahl, 2005) and a two-factor solution for the SESBI and SESBI-R (Oppositional Behavior and Attentional Difficulties) (Floyd et al., 2004; Rayfield, Eyberg, & Foote, 2003). This additional information on the factor structure of the ECBI and SESBI-R may increase their utility as screening instruments. However, for situations in which a broader screening is desired, or when information pertinent to differential diagnosis is sought, the CBCL, TRF, and related ASEBA instruments are recommended.

The Intensity and Problem scales on the ECBI and SESBI-R may also provide useful information concerning the role of parental perceptions of a child in the rating process (Robinson et al., 1980). Eyberg (1992) has suggested that a low Intensity score in conjunction with a high Problem score may indicate that the parent (or teacher) is intolerant or personally distressed. On the other hand, a high Intensity score and a low Problem score may occur when a parent (or teacher) has a very high tolerance level or is reluctant to admit that the child is a behavior problem.

Another rating scale that focuses specifically on CPs, the Self-Report Delinquency Scale (SRD; Elliott, Huizinga, & Ageton, 1985), is probably the most widely used self-report measure of CP behavior. It comprises 47 items derived from offenses listed in the *Uniform Crime Reports* (Federal Bureau of Investigation, 2004), and covers Property Offenses (e.g., "Have you ever purposely damaged or destroyed property belonging to school?"), Status Offenses (e.g., "Have you ever taken a vehicle for a ride without the owners' permission?"), Drug Offenses (e.g., "Have you ever sold hard drugs such as heroin, cocaine, and LSD?"), and Violent Offenses ("Have you ever been involved in gang fights?"). Importantly, the Violent Offenses scale includes threats of physical violence, as well as actual violence (e.g., "Have you ever hit [or threatened to hit] a teacher or other adult at school?"). The SRD is intended

for use by 11- to 19-year-olds, who report on the frequency of engagement in each behavior over the past year. It has been employed primarily in epidemiological and community samples to assess prevalence of delinquent behaviors (e.g., Elliott et al., 1985; Loeber, Stouthamer-Loeber, Van Kammen, & Farrington, 1989), as an outcome measure in longitudinal studies (Frick, Stickle, Dandreaux, Farrell, & Kimonis, 2005), and as a measure of intervention outcome (e.g., Kazdin, Mazurick, & Siegel, 1994; Kazdin, Siegel, & Bass, 1992; Scherer, Brondino, Henggeler, Melton, & Hanley, 1994).

The Parent Checklist and the Teacher Checklist (Conduct Problems Prevention Research Group, 1999; Dodge & Coie, 1987), the Reactive-Proactive Aggression Questionnaire (Brown, Atkins, Osborne, & Milnamow, 1996), and the Aggressive Behavior Rating Scale (Raine et al., 2006) were developed to distinguish between reactive and proactive forms of aggression. The Ratings of Children's Social Behavior (RCSB; Crick, 1996), a 17-item rating scale, assesses relational aggression, using item content analogous to the peer-nomination procedure used in past studies of relational aggression (Crick & Grotpeter, 1995). Little and colleagues (2003) recently developed a scale that is unique in assessing reactive and proactive forms of aggression for both relational and overt aggression. These authors reported that these different forms of aggression could be distinguished in a factor analysis, and that reactive forms of relational aggression (but not proactive forms) were positively associated with low frustration tolerance and a measure of hostility. The Lying Scale is a brief (12 items), parent-completed scale to assess parental perceptions of lying in their adolescent children (Engels, Finkenauer, & van Kooten, 2006). Psychometric analyses indicate that it taps into a single factor, and possesses adequate reliability and concurrent validity.

Behavioral Observations

Behavioral observations provide a third common way to assess CP behaviors. Behavioral observations in a child's or adolescent's natural setting (e.g., home, school, playground) can make a unique contribution by providing an assessment of the youth's behavior that is not filtered through the perceptions of an informant and an assessment of the immediate envi-

ronmental context of the youth's behavior that, as noted earlier, can be critical for conducting an FBA. In some cases, observational CP data have been stronger predictors of adolescent arrest rates and incarceration than were parent-reported data (Patterson & Forgatch, 1995). Because such naturalistic observations can be quite time-consuming and expensive, a variety of clinic- and laboratory-based analogues have been developed, many of which have evidence to support their clinical utility and sensitivity to intervention effects (for reviews, see Frick & Loney, 2000; Roberts, 2001).

Two widely used structured, microanalytic observation procedures available for assessing parental interactions with younger children (3–8 years) in the clinic and the home are the Behavioral Coding System (BCS; Forehand & McMahon, 1981) and the Dyadic Parent–Child Interaction Coding System (DPICS; Eyberg, Nelson, Duke, & Boggs, 2005). The BCS and the DPICS are modifications of the assessment procedure developed by Hanf (1970) for the observation of parent–child interactions in the clinic. As employed in clinic settings, both the BCS and DPICS place the parent–child dyad in standard situations that vary in the degree to which parental control is required, ranging from a free-play situation (i.e., Child's Game, Child-Directed Interaction) to one in which the parent directs the child's activity, either in the context of parent-directed play (i.e., Parent's Game, Parent-Directed Interaction) and/or in cleaning up the toys (i.e., Clean Up). Each task typically lasts 5 to 10 minutes. In the home setting, observations usually occur in a less structured manner (e.g., the parent and child are instructed to “do whatever you would normally do together”). In each coding system, a variety of parent and child behaviors are scored, many of which emphasize parental antecedents (e.g., commands) and consequences (e.g., praise, time out) for child compliance–noncompliance and other CP behaviors. The BCS comprises six parent behaviors and three child behaviors; the DPICS comprises 12 parent and 14 child behaviors. Interobserver agreement for both coding systems is adequate (e.g., Eyberg et al., 2005; Forehand & Peed, 1979); they discriminate between referred and nonreferred samples of parents and children (e.g., Eyberg et al., 2005; Griest, Forehand, Wells, & McMahon, 1980); and they have been employed successfully as intervention outcome measures for parent management train-

ing (e.g., Eisenstadt et al., 1993; McMahon, Forehand, & Griest, 1981; Peed, Roberts, & Forehand, 1977; Webster-Stratton & Hammond, 1997). In addition, both the BCS and the DPICS are used to determine movement from one set of parenting skills to the next in parent management training interventions (e.g., Herschell, Calzada, Eyberg, & McNeil, 2002; McMahon & Forehand, 2003). The BCS is available in Forehand and McMahon (1981) and the DPICS is available online at www.pcit.org. Simplified versions of both the DPICS and the BCS have been developed (Eyberg, Bessmer, Newcomb, Edwards, & Robinson, 1994; McMahon & Estes, 1994). These adaptations are designed to reduce training demands, and may ultimately prove to be more useful to clinicians.

A direct observational assessment of child compliance–noncompliance can also be obtained in the clinic with the Compliance Test (CT; Roberts & Powers, 1988), in which the parent issues a series of structured commands to the child. The parent is instructed to give a series of 30 standard commands without helping or following up on the commands with other verbalizations or nonverbal cues. In one version of the CT, two-part commands are given (e.g., “(Child's name), put the (toy) in the (container)”). In another version, the commands are separated into two codeable units (e.g., “(Child's name), pick up the (toy). Put it in the (container)”). The CT takes between 5 and 15 minutes to complete.

Roberts (2001; Roberts & Powers, 1988) presents evidence for the reliability and validity of the CT. For example, there is high interobserver agreement (97%), adequate test–retest reliability ($r = .73$ over 12 days), and convergent validity with other home and clinic observational measures. The CT appears to be a useful measure in identifying noncompliant children in research and clinical settings (Roberts & Powers, 1990), and there is preliminary evidence to support its discriminant, convergent, and divergent validity in a preschool setting (Filcheck, Berry, & McNeil, 2004). Because the CT does not measure parental instruction giving, Roberts (2001; Roberts & Powers, 1988) recommends that it be used in conjunction with a parent-directed chore analogue that allows coding of parental behavior, such as Clean Up (Eyberg et al., 2005).

For older children and adolescents, structured clinical observational paradigms have

been developed for the direct assessment of parent-child communication and problem solving (see Foster & Robin, 1997, for a review). For example, Martinez and Forgatch (2001) employed a series of tasks that included a parent-child problem-solving discussion and teaching tasks with elementary school-age children. They coded these tasks for various parenting practices, and child aversive behavior and noncompliance, using both microanalytic and global rating systems.

Many common CP behaviors are by nature covert (e.g., lying, stealing, firesetting), which makes them more difficult to capture through observational techniques. However, Hinshaw and colleagues have developed and evaluated an analogue observational procedure to assess stealing, property destruction, and cheating in children ages 6 to 12 years (Hinshaw, Heller, & McHale, 1992; Hinshaw, Simmel, & Heller, 1995; Hinshaw, Zupan, Simmel, Nigg, & Melnick, 1997). Samples of boys (ages 6–12) with ADHD (most of whom also had ODD or CD) and a comparison group were asked to complete an academic worksheet alone in a room that contained a completed answer sheet, money, and toys. Stealing was measured by counting objects in the room immediately following the work session, whereas property destruction and cheating were assessed by ratings derived from observing the child's behavior during the session. Each of these observational measures of child covert CPs was correlated with parental ratings of covert CPs. When the boys with ADHD were treated with methylphenidate, stealing and property destruction, which were also associated with staff ratings of potential for covert behavior, decreased to a level similar to that displayed by boys in the comparison condition. None of the three measures of covert CP correlated significantly with each other.

Kolko, Watson, and Faust (1991) employed a very brief (1-minute) observation to assess children's preference for fire-related stimuli (e.g., a simulated book of matches) over toys in a play setting. Interobserver agreement for percentage of time in contact with fire-related stimuli, picking up the matchbook, or attempting to strike a match, ranged from 93 to 100%. All three indices demonstrated significant decreases from pretreatment to posttreatment in an inpatient sample of children with disruptive behavior disorders who also engaged in match-play or firesetting.

In general, we recommend the use of structured clinical observations such as those described here to assess parent-child interactions. If there is a discrepancy between the clinic observations and the parent reports of interactions at home, then home observation may be necessary. The use of a coding system in the home setting instead of the clinic requires changes in the structure of the observation, transportation time, and scheduling flexibility (if home observations are planned to coincide with the times when the problem child behaviors are more likely to occur) (McMahon & Estes, 1997). Drotar and Crawford (1987) discuss many of the issues for clinicians involved in conducting home observations.

Although home observations are designed to record social interactions among family members in their "natural" environment (the home), the sessions are not completely unstructured. For example, prior to the observation, members of the family are typically given instructions such as the following: (1) Everyone in the family must be present; (2) no guests should be present during observations; (3) the family is limited to two rooms; (4) no telephone calls are to be made, and incoming calls must be answered briefly; (5) no television viewing is permitted; (6) no conversations may be held with observers while they are coding; and (7) therapy-related issues are not to be discussed with the observer (Reid, 1978).

The BCS (Forehand & McMahon, 1981) and DPICS (Eyberg et al., 2005) have been used in both the home and the clinic. For example, when employed in the home setting, the BCS is used to collect data in blocks of four 40-minute observations. The observations are conducted on different days and may be done at different times of the day. As noted earlier, McMahon and Estes (1994) developed a simplified version of the BCS that has been used in structured observations in the home. It has fewer codes to maximize reliability and to minimize training time, while retaining important treatment outcome information about parent-child interaction. Observers use a standardized set of toys and give standardized instructions to the parents before the interaction begins. The structure of the session includes Child's Game (5 minutes), Parent's Game (5 minutes), a Lego Task (in which the child is told to construct a developmentally challenging Lego figure and the parent is instructed to give only verbal aid; 5 minutes), and Clean Up (3 minutes).

Throughout each task, three parent and three child behaviors are recorded in 30-second intervals.

Behavioral observation systems designed specifically for assessing CP types of behavior in the school setting have received relatively less attention. Direct observations in the school have the same practical problems as those previously mentioned for home observations. The necessity of training reliable observers and the lengthy observation time are similar. Unfortunately, unlike the case with home observation, the clinician does not have the option of observing teacher–child interactions in the clinic. Therefore, if the presenting problems concern behavior at school (whether in the classroom or on the playground), observation in that setting may be necessary.

Nock and Kurtz (2005) have presented an excellent guide for clinicians on how to conduct direct observations in school settings. They provide information concerning formulation of the primary question(s) to be addressed in the observation, collaboration with school psychologists and teachers, description of the school/classroom context, and the selection and implementation of the actual observational procedures. Their recommendations about the key questions to be addressed by clinicians are presented in Table 3.3.

To aid in the observation of a child's behavior in the classroom, several of the rating scales systems reviewed previously include observational systems designed to be used in conjunction with parent-, teacher-, and self-report ratings. For example, the BASC-2 (Reynolds & Kamphaus, 2004) includes a Student Observation System (SOS), in which one can observe children's behavior in the classroom using a momentary time-sampling procedure. The SOS specifies 65 common behaviors in classrooms settings and includes both adaptive (e.g., "follows directions," "returns material used in class") and maladaptive (e.g., "fidgets in seat," "teases others") behaviors. The observation period in the classroom involves 15 minutes, divided into 30 intervals of 30 seconds each. The child's behavior is observed for 3 seconds at the end of each interval, and the observer codes all behaviors observed during this time window. Unfortunately, there has been minimal empirical testing of the BASC-SOS, although scores from this observation system did differentiate between students with and without disruptive

behavior disorders in one sample of school-children (Lett & Kamphaus, 1997).

A similar observational system can be used as part of the ASEBA assessment system. The DOF/5–14 (Achenbach & Rescorla, 2001) was designed to observe students, ages 5–14, for 10-minute periods in the classroom. Following this period, the observer writes a narrative of the child's behavior and rates 96 behaviors on a 4-point scale (0, *Behavior was not observed*, through 3, *Definite occurrence of behavior with severe intensity or for greater than 3 minutes duration*). Like the ASEBA rating scales, these ratings can be summed into Total Problem, Internalizing, and Externalizing behavior composites. The DOF has been shown to discriminate between referred and nonreferred children in the classroom (e.g., Reed & Edelbrock, 1983), as well as between children with externalizing and other behavior problems (e.g., McConaughy, Achenbach, & Gent, 1988).

The BCS (Forehand & McMahon, 1981) has been modified for use in the classroom to assess teacher–child interactions, both alone (e.g., Breiner & Forehand, 1981) and in combination with a measure of academic engaged time (AET) (McNeil et al., 1991). AET, the amount of time that a child or adolescent is appropriately engaged in on-task behavior during class time, is assessed with a simple stopwatch recording procedure (Walker, Colvin, & Ramsey, 1995). Walker and colleagues (1995) recommend observing children during two 15-minute periods. AET has been shown to correlate positively with academic performance and to discriminate between boys at risk for CPs and those not at risk (e.g., Walker, Shinn, O'Neill, & Ramsey, 1987). The Revised Edition of the School Observation Coding System (REDSOCS; Jacobs et al., 2000), which has been used with 3- to 6-year-old clinic-referred children with ODD and nonreferred children in preschool and kindergarten classrooms (e.g., Filcheck et al., 2004), may be particularly appropriate for classroom observations of young, noncompliant children.

There are surprisingly few data to guide pragmatic decisions concerning the number and length of observation sessions needed to obtain reliable and valid information. Although potentially very useful, as noted earlier, observational assessment methods may be expensive in terms of time and personnel, especially if multiple observation sessions are

TABLE 3.3. Major Questions Guiding the School Observation ReportDescriptive information

What is the child's name, date of birth, parents' names, and contact information?
 Who is the referring clinician?
 What is the location, date and time of the actual observation?
 What is the name of the teacher or any other staff involved with the child?

Reason for observation

Who requested the observation?
 What are the goals of the observation?
 What are the primary referral questions?
 What are the specific target behaviors (both adaptive and maladaptive)?
 Were any previous observations performed? What were the results?

Teacher interview

What problem behaviors are reported by teacher?
 What academic difficulties are reported by teacher?
 In what settings do the problem behaviors most frequently occur?
 What are the suspected triggers of the problem behaviors?
 What are the current consequences of the problem behaviors?
 What past or current interventions were implemented by the teacher or other professionals? How effective were they?

Classroom environment

What is the number of students and staff in the classroom?
 What is the size and shape of the classroom?
 What is the location of furniture/equipment, seating arrangements and placement of the child?
 Are there distracting stimuli, background noises, or outside-class interruptions?
 Are the traffic patterns well defined and safe?
 Are there established routines for toileting, drinks, snack time, etc.?
 Are the class rules and consequences posted in a visible location? Are the rules reinforced?

Child observation

What classes, lessons, or tasks occurred during the observation period?
 What evaluation procedures were used and are they described?
 What were the results of the observation?
 Describe the severity, frequency, and duration of the target behaviors
 Describe the antecedents and consequences of the observed behaviors
 Support all statements with data from the observation
 Are the results of the observation reliable and valid?
 Was the child's behavior during the observation representative of this child's behavior in this context more generally?

Recommendations

Based on the results, what should the teachers and school personnel do to effectively modify the child's behavior?
 Based on the results, what can the parents do to effectively modify the child's behavior?
 What implications do the results have for the therapist treating the child?
 Is a follow-up school observation warranted? If so, when?

Note. From Nock and Kurtz (2005). Copyright 2005 by the Association for Advancement of Behavior Therapy. Reprinted by permission.

conducted to enhance sensitivity to treatment effects (Aspland & Gardner, 2003). Reactivity to being observed does not appear to be a significant problem for most young children and their parents, especially if clinicians and researchers provide the opportunity for them to become familiar with the observation procedures, use the same observer across multiple sessions, and minimize the obtrusiveness of recording equipment (Aspland & Gardner, 2003).

An alternative to observations by independent observers in the natural setting is to train significant adults in the child's or adolescent's environment to observe and record certain types of behavior. The most widely used procedure of this type, the Parent Daily Report (PDR; Chamberlain & Reid, 1987), is a parent observation measure that is typically administered during brief (5- to 10-minute) telephone interviews. Parents are asked which of a number of overt and covert behaviors have occurred in the past 24 hours. The PDR can be employed on a pretreatment basis to assess the magnitude of behavior problems and as a check on information presented by the parents in the initial interview. It can also be used during intervention to monitor the progress of the family. Finally, the PDR has been employed extensively as a measure of parent management training outcome (e.g., Bank, Marlowe, Reid, Patterson, & Weinrott, 1991; Chamberlain & Reid, 1991; Webster-Stratton & Hammond, 1997). It has the added advantages of being brief and, because of the 24-hour reporting frame, of perhaps providing more objective data than that obtained from behavior rating scales or interviews.

Reviews of the psychometric characteristics of the PDR are presented by Patterson (1982) and Chamberlain and Reid (1987). The PDR possesses adequate intercaller and interparent reliability, as well as internal consistency and temporal stability. With respect to stability, Chamberlain and Reid noted that, at least with nonreferred families, PDR scores tend to be inflated on the first day but stable thereafter. It may be advisable to discard data from the first telephone interview with the PDR. Normative data are presented by Chamberlain and Reid for parents of children ages 4–10. The PDR has been shown to correlate significantly with direct observation measures in populations of socially aggressive, stealing, and normal children

(Patterson, 1982; Webster-Stratton & Spitzer, 1991). The PDR has shown moderate convergent validity with other parent report measures of child behavior and parental adjustment (Chamberlain & Reid, 1987; Webster-Stratton & Spitzer, 1991). Chamberlain and Reid reported that social desirability factors seem to exert minimal influence on PDR scores, at least with nonreferred families.

For the occurrence of certain low-rate covert behaviors, such as stealing, firesetting, and truancy, parent- and/or teacher-collected data may be the only sources of information. Patterson and his colleagues (1975) developed specific techniques for the assessment and treatment of children who steal. Because behaviors such as stealing are rarely observed, the target behavior is redefined as "the child's taking, or being in possession of, anything that does not clearly belong to him" or the parent's "receiving a report or complaint by a reliable informant" (Patterson et al., 1975, p. 137). Jones (1974) developed a brief daily interview similar to the PDR for collecting parent report data on stealing by children between ages 5 and 15. The parent is queried as to whether stealing took place, and, if so, the item(s) stolen and their value, the location and social context of the theft, how the parent learned of the theft, and the parent's response to the theft. The Telephone Interview Report on Stealing and Social Aggression (TIROSSA) has adequate test-retest reliability and is sensitive to the effects of treatment procedures designed to reduce stealing (Reid, Hinojosa Rivera, & Lorber, 1980).

Functional Impairment

It is increasingly being recognized that the child's or adolescent's level of functional impairment, over and above the level of CP symptomatology, is critical to determining whether the youth needs treatment and the intensity of treatment that may be required (Bird, 1999; Bloomquist & Schnell, 2002). Furthermore, degree of impairment may vary across domains of functioning, so it is important that multiple domains be assessed, and by multiple informants when possible. As noted earlier, structured interviews based on the DSM allow for the assessment of impairment. There are also a number of measures designed specifically to assess the youth's level of impairment, including the Children's Global Assessment Scale (C-GAS;

Shaffer et al., 1983), the Columbia Impairment Scale (CIS; Bird et al., 1993), and the Child and Adolescent Functional Assessment Scale (CAFAS; Hodges, 2000). Also, several of the broad rating scales summarized in Table 3.2 include subscales that assess important areas of potential impairment of children with CPs. For example, the BASC-2 (Reynolds & Kamphaus, 2004) contains scales that assess the child's academic adjustment (e.g., learning problems, attitude toward school and teacher, study skills), social adjustment (e.g., social stress, interpersonal relations), and self-concept (e.g., self-concept, sense of inadequacy).

Knowledge of impairment is important for a number of reasons. First, it can determine how intensive and restrictive an intervention may need to be (Frick, 2004), it can provide useful information to the clinician concerning possible intervention targets (Frick, 2006), and it may also serve as an important indicator of intervention outcome (Hodges, Xue, & Wotring, 2004). A related construct, adaptive disability, is based on the degree of discrepancy between the child's or adolescent's adaptive functioning and IQ level (Barkley et al., 2002). Using the parent-completed Normative Adaptive Behavior Checklist (NABC; Adams, 1984) to assess adaptive functioning in samples of normal and behaviorally disruptive preschool-age children, Barkley and colleagues (2002) found adaptive disability to be an independent predictor of negative outcomes, over and above initial levels of disruptive behavior.

Summary

Because of the heterogeneity in CP behaviors, it is essential to assess levels and types of these behaviors. Developmentally appropriate, broad-based behavior rating scales may be completed by multiple informants in relatively brief time periods and provide good, norm-referenced information on the child's or adolescent's behaviors. Structured diagnostic interviews may also be employed, although they are usually much more time-consuming. Noncompliance is best assessed through structured clinical interviews and observation of parent-child interaction (e.g., McMahon & Forehand, 2003). A number of clinic-based analogues to assess CPs (especially in the context of parent-child interaction) demonstrate sensitivity to treatment effects. Other forms of aggression (e.g., reactive, proactive, relational) may be as-

essed through youth, parent, and teacher rating scales. Covert CP behaviors, because of their clandestine nature, are extremely difficult to assess. At present, clinicians are forced to rely primarily on reports from multiple informants on behavior rating scales (or in the case of stealing, on brief phone interviews) as to whether, and to what extent, such behaviors are occurring. Innovative observational paradigms to assess covert behaviors such as stealing, property destruction, and firesetting behaviors (e.g., Hinshaw et al., 1992; Kolko et al., 1991) are promising, but their clinical utility has yet to be demonstrated. A major task for the field is to develop valid and clinically useful instruments for the assessment of covert CPs.

Comorbidity: Implications for Assessment

The large number of co-occurring conditions that are often present in youth with CPs suggest that assessment must be comprehensive and cover a large number of adjustment areas, and not focus solely on CPs (see Table 3.1). As illustrated in Table 3.2, many behavior rating scales provide information on a number of important areas of adjustment; thus, they have utility as screening instruments. As mentioned previously, these often include forms for parents, teachers, and the youth to complete, providing information from multiple informants in a time-efficient manner. Furthermore, most scales provide good, norm-referenced scores to compare the child's or adolescent's score to a reference group. However, to assess many of the comorbid conditions, more detailed information on the history of symptoms and the level of impairment they cause for the child or adolescent may be important. This typically requires a clinical and/or a structured interview, perhaps in conjunction with a rating scale designed to assess functional impairment or adaptive functioning, to make the diagnosis adequately. If CPs occur in the context of a language impairment, then a developmental assessment is warranted (Wakschlag & Danis, 2004). The CBCL/1½-5 (Achenbach & Rescorla, 2000) incorporates the Language Development Survey, and the BASC-2 (Reynolds & Kamphaus, 2004) includes a Functional Communication subscale, both of which assess risk factors for language delays and parental report of the young child's expressive vocabulary and word combinations.

Space limitations preclude discussion of the assessment of the various conditions that occur with CPs. Instead, we refer the reader to Chapters 2, 4, 5, 8, and 13, this volume, on ADHD, substance use, depression, anxiety, and learning disabilities, respectively.

Summary

Comorbid disorders that are most likely to be encountered in youth referred for CPs include ADHD, depressive and anxiety disorders, substance use problems, language impairment, and learning difficulties. As a result, most assessments of children and adolescents with CPs need to be comprehensive, covering many domains of psychological functioning. Most of the same broad-band measures recommended for initial use in identifying the range of CP behaviors may also be used as general screens for the identification of comorbid disorders and conditions. Disorder-specific behavior rating scales, interviews, and other, more intensive assessment procedures (e.g., intelligence and achievement testing) should then be conducted as needed for the comorbid disorders.

Multiple Risks: Implications for Assessment

Research clearly documents myriad factors in various domains, both internal and external to the child or adolescent, associated with CPs. The availability of instruments to assess these many factors is quite variable. In this section, we note those that seem most salient and potentially appropriate for use in applied settings, although the clinical utility of many of these instruments has yet to be adequately tested. (See Table 3.1 for a list of representative measures.)

One should obtain a brief developmental and medical history of the child or adolescent to determine whether any medical factors might be associated with the development or maintenance of the CP behaviors, and whether the youth's early temperament may have contributed to the development of a coercive style of parent-child interaction. A number of standardized ratings of temperament may have utility in assessing youth with CPs (Frick, 2004), such as the Children's Behavior Questionnaire (Rothbart & Jones, 1998).

One class of potentially important correlates to severe CPs is specific cognitive deficits and learning styles. As discussed earlier, because deficits in intelligence, especially verbal intelli-

gence, have been associated with CPs, a standard intellectual evaluation should be part of most assessment batteries for CPs. There are also computerized tasks that assess the characteristic learning style of many youth with CPs (e.g., heightened sensitivity to rewards compared to punishments). However, some major limitations in the development of these tasks make their usefulness in many clinical assessments somewhat limited at the present time (see Frick & Loney, 2000, for a review). There are also research-based measures, typically involving a child or adolescent being provided a hypothetical vignette of a social situation and asked to state how he or she would respond if the situation were real, that assess several deficits in social cognition associated with CPs, such as a hostile attributional bias. Examples include the Intention-Cue Detection Task, the Problem-Solving Measure for Conflict, and the Wally Child Social Problem-Solving Detective (WALLY) Game (Conduct Problems Prevention Research Group, 1999; Dodge & Coie, 1987; Webster-Stratton & Lindsay, 1999). Although these measures are also not without limitations in their clinical usefulness (Frick & Loney, 2000), interventions for the deficits assessed by these measures are part of many treatment programs for CPs; therefore, the information they provide may be useful in treatment planning (Lochman & Wells, 1996). The recently developed Social-Cognitive Assessment Profile (SCAP; Hughes, Meehan, & Cavell, 2004), which shows promise as a brief (15- to 20-minute), clinically useful interview with elementary school-age children, is designed to assess social-cognitive deficits associated with CPs.

As noted earlier, children and adolescents with CPs frequently have problems with peer interactions (e.g., peer rejection, association with a deviant peer group). If the information from behavioral interviews, behavior rating scales (e.g., the Social Competence scales of the CBCL/6-18; Achenbach & Rescorla, 2001), and/or observations indicate that this is a problem area for a particular youth, additional assessment of his or her social skills is necessary. The assessment should examine not only the behavioral aspects of the social skills difficulties but also cognitive and affective dimensions. Traditionally, assessment of social skills has involved behavioral observations, sociometric measures, and questionnaires. Bierman and Welsh (1997) provided strategies for the assess-

ment of social relationship problems, and Demaray and colleagues (1995) reviewed several behavior rating scales for the assessment of social competence. Although a number of strategies have been developed to assess social functioning, some of the measures (e.g., sociometrics) have minimal clinical utility, because these data are extremely time-consuming to collect (Kamphaus & Frick, 2005). However, a brief (5- to 10-minute) observation analogue procedure for assessing young children's CPs with peers in a rigged card game (SNAP!—Hughes, Cutting, & Dunn, 2001; Hughes et al., 2002) shows promise, because it differentiates between children with CP and control children, and is associated with parent and teacher CP ratings. Similarly, clinically useful measures to assess associations with a deviant peer group are limited currently to youth or parent reports, although a structured observational paradigm developed for research purposes may prove to be adaptable to the clinical setting (e.g., Dishion, Andrews, & Crosby, 1995).

McMahon and Estes (1997) delineated six areas that are relevant to the assessment of familial and extrafamilial factors in youth with CPs: parenting practices; parents' perceptions of the youth and social cognitions; parents' perceptions of their own personal and marital adjustment; parental stress; parental functioning in extrafamilial social contexts; and parental satisfaction with treatment. The first area, *parenting practices*, has been assessed through clinical interviews, behavioral observation of parent-child interactions, and parent and youth reports on behavior rating scales. As noted earlier, direct behavioral observation has long been a critical component of the assessment of youth with CPs and their families, both for delineating specific patterns of maladaptive parent-child interaction and for assessing change in those interactions as a function of treatment. Observational data can be compared with data gathered via other methods to assist the clinician in determining whether the focus of treatment should be on the parent-child interaction or on parental perceptual and/or personal adjustment issues. For example, congruence between observational data and a parent-completed behavior rating scale would be consistent with the former focus, whereas normal levels of youth behavior in the observed interaction might suggest that the focus of intervention be on parental perceptual issues. The observation procedures and coding sys-

tems described earlier for assessing CPs in the context of parent-child interactions (e.g., BCS, DPICS) also provide important information concerning parent behavior.

Several questionnaires designed specifically to assess parenting practices may potentially be quite useful as adjuncts to behavioral observations and/or to assess parental behaviors that either occur infrequently or are otherwise difficult to observe (e.g., physical discipline, parental monitoring practices), as screening instruments, and to measure the effects of parent management training interventions. Two examples that have significant psychometric support are the Parenting Scale (Arnold, O'Leary, Wolff, & Acker, 1993) and the Alabama Parenting Questionnaire (Shelton, Frick, & Wootton, 1996). (See Morsbach & Prinz, 2006, for a summary of parent report measures of parenting practices and suggestions for improving their validity.)

The Parenting Scale (Arnold et al., 1993) comprises 30 items that describe parental discipline practices in response to child misbehavior. Each item has a 7-point rating scale anchored by statements of the effective and ineffective forms of a particular parenting behavior (e.g., "I coax or beg my child to stop" and "I firmly tell my child to stop"). Items are worded at a sixth-grade level or below, and the measure takes 5–10 minutes to complete.

The original factor analysis of the Parenting Scale conducted with parents of 2- to 3-year-old children indicated that three factors accounted for 37% of the variance: Laxness, Overreactivity, and Verbosity (Arnold et al., 1993). However, subsequent research with more ethnically diverse samples and broader age ranges have generally found a two-factor solution, with factors that resemble the original Laxness and Overactivity factors. The Verbosity factor has not been replicated in these subsequent studies. The two-factor solution has been identified in samples of European American 2- to 12 year-old children (Collett, Gimpel, Greenon, & Gunderson, 2001) and middle school students (Irvine, Biglan, Smolkowski, & Ary, 1999), as well as in preschool-age (Reitman et al., 2001) and elementary school-age (Steele, Nesbitt-Daly, Daniel, & Forehand, 2005) African American samples. In addition, these studies have generally found that 5- to 6-item solutions for each factor are sufficient, thus suggesting that the original 30-item Parenting Scale can be shortened considerably.

These studies have documented that the Parenting Scale has reasonable properties with respect to reliability and validity, and that it is sensitive to intervention effects (e.g., Gardner, Burton, & Klimes, 2006; Irvine et al., 1999; Nixon et al., 2003; Sanders, Markie-Dadds, Tully, & Bor, 2000).

The Alabama Parenting Questionnaire (APQ; Frick, 1991) was developed for use with parents of elementary school-age children and adolescents (6–17 years old), although it has been used in samples as young as age 4 (e.g., Dadds, Maujean, & Fraser, 2003). It comprises 42 items that have been divided into five a priori constructs—Involvement, Positive Parenting, Poor Monitoring/Supervision, Inconsistent Discipline, and Corporal Punishment. It also includes several other items assessing “other discipline practices,” such as use of time out or taking away privileges. The items are presented in both global report (i.e., questionnaire) and telephone interview formats, and there are separate versions of each format for parents and children. Thus, there are currently four different versions of the APQ. The questionnaire format employs a 5-point Likert-type frequency scale and asks the informant how frequently each of the various parenting practices typically occurs. Four telephone interviews are conducted, and the informant is asked to report the frequency with which each parenting practice has occurred over the previous 3 days.

Most of the published research using the APQ to date has utilized the global report formats of the scale, with the exception of Shelton and colleagues (1996). Two studies now provide support for the five-factor structure of the parent global report format of the APQ, which corresponds to the five dimensions around which the scale was developed. The first study was conducted with 1,402 children, ages 4–9, in Australia (Elgar, Waschbusch, Dadds, & Sigvaldason, 2007), and the second study, with 1,219 German schoolchildren, ages 10–12 (Essau, Sasagawa, & Frick, 2006). Importantly, one study has also shown that parent ratings on the APQ are significantly associated with observations of parenting behavior in 4- to 8-year-old boys (Hawes & Dadds, 2006). A number of studies have shown that the APQ scales are associated with CPs in children in community (Dadds et al., 2003), clinic-referred (Frick, Christian, & Wootton, 1999; Hawes & Dadds, 2006), and inpatient samples (Blader, 2004), as well as in families with deaf children

(Brubaker & Szakowski, 2000) and with substance-abusing parents (Stanger, Dumenci, Kamon, & Burstein, 2004). Also, these studies have documented this relationship in samples as young as age 4 (Dadds et al., 2003; Hawes & Dadds, 2006) and as old as age 17 (Frick, Christian, & Wootton, 1999). However, Frick, Christian, and Wootton (1999) did demonstrate some differences in which dimensions of parenting were most strongly associated with CPs at different ages: Inconsistent Discipline was most strongly associated with CPs in young children (ages 6–8); Corporal Punishment was most strongly associated with CPs in older children (ages 9–12), and Involvement and Poor Monitoring/Supervision were most strongly related to CPs in adolescents (ages 13–17). Also, this study raised concerns about the reliability of the child report format in very young children (under age 9) (see also Shelton et al., 1996). Finally, several studies have used the APQ scales to test changes in parenting behaviors following interventions with children with CPs (e.g., August, Lee, Bloomquist, Realmuto, & Hektner, 2003; Feinfield & Baker, 2004; Hawes & Dadds, 2006).

Parental perceptions of the youth and social cognitions are a second important area to be assessed. Parental perception of a child is a strong predictor of referral for CP types of behavior, perhaps even more so than the child's behavior (e.g., Griest et al., 1980). In an analogue study, Johnston and Patenaude (1994) reported that parents of children with ADHD perceived children who displayed oppositional behavior as having more control over their behavior than did children who displayed inattentive/overactive behavior, and they reported more negative affective responses to the oppositional children. As noted earlier, studies with parents of clinic-referred children have shown that they are more likely to misperceive child behaviors than are parents of nonreferred children (e.g., Holleran et al., 1982; Wahler & Sansbury, 1990).

These findings suggest that some measure of significant adults' perceptions of the child is an essential component of the assessment process. The behavior rating scales described earlier are the most ready sources of such data. As noted, comparisons of the ECBI Problem and Intensity scores may be especially useful with respect to parent tolerance for child behavior. (This also applies to the SESBI-R with teachers.) When examined in the context of behavioral

observation data and the clinician's own impressions, these behavior rating scales can be important indicators of whether the informants (parents, teachers) appear to have a perceptual bias in their assessment of the referred child's behavior.

An alternative methodology for assessing potential perceptual biases in the parents of children with CPs is the use of brief written, audiotaped, or videotaped scenarios or vignettes describing parent-child interactions in which a child displays a variety of inappropriate, neutral, and positive behaviors (e.g., Holleran et al., 1982; Wahler & Sansbury, 1990). Although such methods have been employed on a limited basis in the research literature, their validity and utility in clinical settings have yet to be examined. A more clinically relevant method for assessing parent and child perceptions of self and each other was developed by Sanders and Dadds (1992). In their video-mediated recall procedure, the parent views a videotape of a previously recorded problem-solving discussion with his or her child. The videotape is stopped every 20 seconds, and the parent describes what he or she was thinking at that point in the interaction. Sanders and Dadds demonstrated that this procedure discriminated between clinic-referred families whose child has CPs and nonreferred families. The clinic-referred parents stated fewer self- and family-referent positive cognitions and more family-referent negative cognitions than did the nonreferred parents. Furthermore, the video-mediated recall procedure was superior to an alternative thought-listing procedure.

Two measures that assess aspects of parental self-esteem (e.g., satisfaction, self-efficacy, and locus of control with the parenting role) are the Parenting Sense of Competence Scale (PSOC; as adapted by Johnston & Mash, 1989) and the Parental Locus of Control Scale (PLOC; Campis, Lyman, & Prentice-Dunn, 1986). The PSOC comprises 16 items that typically load on two factors: Satisfaction, which refers to the extent to which the parent reports satisfaction with the parenting role, and Efficacy, which reflects the parent's self-report of skill and familiarity with the parenting role (Johnston & Mash, 1989; Ohan, Leung, & Johnston, 2000; Rogers & Matthews, 2004), although Rogers and Matthews also found support for a third factor of parental Interest. Adequate internal consistency reliabilities for the total, Satisfaction, and Efficacy scales have been reported

(e.g., r 's = .79, .75, and .76, respectively) by Johnston and Mash (1989). The Satisfaction score was consistently more highly correlated with measures of child behavior and parental adjustment than was the Efficacy score (Johnston & Mash, 1989; Ohan et al., 2000; Rogers & Matthews, 2004). The Efficacy score was positively correlated with social desirability in a nonreferred sample (Lovejoy, Verda, & Hays, 1997). There are minimal effects of child age or gender on PSOC scores.

The PSOC has been employed with several clinic-referred populations, including children with CPs (Gardner et al., 2006), physically abused children (Mash, Johnston, & Kovitz, 1983), and children with ADHD (e.g., Mash & Johnston, 1983) and ADHD plus CPs (Johnston, 1996b). Johnston reported that the total PSOC score distinguished among parents (mothers and fathers) of nonreferred children, children with ADHD plus low levels of oppositional behavior, and children with ADHD plus high levels of oppositional behavior. The PSOC has been shown to be sensitive to the effects of parent management training in samples of children with CPs (Gardner et al., 2006) and ADHD (Pisterman et al., 1992).

The PLOC comprises 47 items that load on five factors: Parental Efficacy, Parental Responsibility, Child Control of Parent's Life, Parental Belief in Fate/Chance, and Parental Control of Child's Behavior. Adequate internal consistency and test-retest reliabilities have been demonstrated (Campis et al., 1986; Roberts et al., 1992). Parents of clinic-referred children have a more external locus of control than do parents of nonreferred children (Campis et al., 1986; Mouton & Tuma, 1988; Roberts et al., 1992). Scores on the PLOC have been shown to be affected by social desirability (Campis et al., 1986; Lovejoy et al., 1997). The total score on the PLOC is correlated with the PSOC (Lovejoy et al., 1997) and the Parenting Stress Index (Mouton & Tuma, 1988), but not with observed parent behavior (Roberts et al., 1992). It is associated with observed severity of child oppositional behavior on the CT (Roberts et al., 1992). Parents who completed a parent management training program had a more internal locus of control by the end of treatment (e.g., Eyberg, Boggs, & Algina, 1995; Nixon et al., 2003; Roberts et al., 1992). Roberts and colleagues (1992) also reported that parental locus of control was not associated with treatment dropout.

To assess the extent to which *parents' personal and marital adjustment problems* may be playing a role in the youth's CPs, a set of screening procedures that includes brief questions in the initial interviews with the parents and certain parental self-report measures can be utilized. Exposition and discussion of a thorough assessment of various personal (e.g., depression, antisocial behavior, substance abuse) and marital adjustment problems that may occur in parents of children with CPs are beyond the scope of this chapter. Instead, a set of brief screening procedures is needed to ascertain whether a more complete and thorough assessment for a particular problem, or group of problems, is required. Questions related to these issues can best be incorporated into the initial interview with the parents. In some cases, the youth may also be asked for his or her perceptions (e.g., "Does your dad ever seem to have too much to drink?" "How do your mom and dad get along with each other?"). In conjunction with the judicious use of the various self-report measures described below, the clinician should be able to make a decision as to the necessity of pursuing any of these areas in greater detail. Should that be the case, then the Special Section, "Developing Guidelines for the Evidence-Based Assessment (EBA) of Adult Disorders" in the journal *Psychological Assessment* (2005, Volume 17) is a useful resource. Additional sources are cited in the relevant sections below.

The Beck Depression Inventory (BDI; Beck, Rush, Shaw, & Emery, 1979) (and its successor, the BDI-II [Beck, Steer, & Brown, 1996], which was modified to make it more consistent with the DSM-IV criteria) has been the most frequently employed measure of maternal depression with mothers of children with CPs. The BDI-II comprises 21 items that assess sadness, anhedonia, and suicidal ideation. Each item is scored on a 4-point scale, with higher scores indicating greater depression. It is typically self-administered and can be completed in 5–10 minutes. Psychometric data on the BDI and BDI-II with various populations are quite extensive and supportive of their validity for assessing clinically significant levels of distress (e.g., Beck et al., 1996; Beck, Steer, & Garbin, 1988). With respect to its use with parents of children with CPs, most of the extant research has used the BDI rather than the BDI-II. The BDI differentiates between mothers of non-referred children and mothers of clinic-referred

children with CPs (e.g., Griest et al., 1980), and relative to other types of measures (e.g., behavioral observations of child behavior), has been found to be the best predictor of maternal perceptions of clinic-referred children with CPs (Forehand, Wells, McMahon, Griest, & Rogers, 1982; Webster-Stratton, 1988). It has been shown to change in a positive direction following parents' completion of a parent management training program and/or a child's cognitive-behavioral therapy intervention (e.g., Forehand, Wells, & Griest, 1980; Kazdin et al., 1992; Webster-Stratton, 1994), and to predict dropout and response to treatment (e.g., Kazdin 1995; McMahon, Forehand, Griest, & Wells, 1981).

It should be noted that the BDI/BDI-II is not intended for diagnosing depression; rather, it is a measure of the severity of various depressive symptoms (which cluster into cognitive and somatic-affective dimensions of depression; e.g., Steer, Ball, Ranieri, & Beck, 1999). Thus, when used with parents of children with CPs, the BDI/BDI-II is probably best regarded as an indicator of parental personal distress and of the need for more in-depth assessment of depression, rather than of depression per se (McMahon & Estes, 1997).

Parental antisocial behavior can be assessed with structured diagnostic interviews or the Minnesota Multiphasic Personality Inventory (MMPI), although time considerations may make these options less feasible. The Antisocial Behavior Checklist (ASB Checklist; Zucker & Noll, 1980) is a self-report instrument that comprises 46 items describing a variety of overt and covert antisocial activities that may have occurred from adolescence through adulthood. Each item is rated on a 4-point scale for frequency of occurrence. A cutoff score of 24 or higher is considered indicative of antisocial behavior and is consistent with DSM-III-R criteria for APD (with a sensitivity of .85 and specificity of .83). The ASB Checklist has reasonable psychometric properties when assessed in samples from prison populations, court offenders, community-based alcoholics, court-referred alcoholics, university students, and community dwellers (Ham, Zucker, & Fitzgerald, 1993). Scores on the ASB Checklist were negatively correlated with SES and education, and positively correlated with measures of hostility, depression, family conflict, and alcohol-related problems (e.g., Ham et al., 1993; Loukas, Fitzgerald, Zucker, & von Eye, 2001).

In a sample of families with alcoholic fathers, scores on the ASB Checklist were significantly higher for both the alcoholic fathers and their spouses than for fathers and mothers in comparison families (Fitzgerald et al., 1993). However, neither paternal nor maternal ASB Checklist scores were significant predictors of child behavior problems (externalizing or internalizing) in 3-year-old sons. In a subsequent report, both the alcoholic fathers and the mothers of 3- to 5-year-old boys who scored above the clinical cutoff on the CBCL Total Behavior Problems scale had higher scores on the ASB Checklist than the parents of boys who scored below the CBCL cutoff (Jansen, Fitzgerald, Ham, & Zucker, 1995). Both maternal and paternal scores on the ASB Checklist contributed to the prediction of CBCL scores for the total sample. To our knowledge, this measure has not been used with samples of parents whose children have CPs. However, given the findings we described with alcoholic families, its use as a measure of parental ASB appears promising.

Because antisocial fathers are often absent or uninvolved, clinicians are often forced to rely on these men's female partners for reports about the fathers' antisocial behavior, and this seems especially to be the case in families of children with CPs (Tapscott, Frick, Wootton, & Kruh, 1996). Tapscott and colleagues (1996) reported significant correlations between mothers' and fathers' report of fathers' history of antisocial behavior in a clinical referred sample of children. Similarly, Caspi and colleagues (2001) demonstrated that women's and men's reports about the men's antisocial behavior were highly correlated. However, in this latter study, the women's reports underestimated the absolute level of the antisocial behavior. Thus, whereas a mother's report may be a reasonably accurate proxy of a father's relative level of antisocial behavior, reliance on this information is not sufficient to determine the true frequency of antisocial behavior in fathers.

With respect to substance use, some of the more frequently employed screening instruments that may prove useful in working with parents of youth with CPs include the Short Michigan Alcoholism Screening Test (SMAST; Selzer, Vinokur, & van Rooijen, 1975), the Drug Abuse Screening Test (DAST; Skinner, 1982), and the Alcohol Use Disorders Identification Test (AUDIT; Saunders, Aasland, Babor, de la Fuente, & Grant, 1993).

Parents also should be screened for both lifetime and current ADHD if the youth presents with comorbid CP and ADHD. The DSM-IV ADHD Rating Scale is a screening device that can be used for this purpose (Murphy & Gordon, 1998).

With respect to marital discord, the Marital Adjustment Test (MAT; Locke & Wallace, 1959) and the Dyadic Adjustment Scale (DAS; Spanier, 1976) have been the most widely used instruments with parents of children with CPs. The MAT has been shown to discriminate between distressed and nondistressed couples (Locke & Wallace, 1959) and to correlate with children's CPs (e.g., Forehand & Brody, 1985; Frick et al., 1989). The MAT has shown high levels of reliability, stability (i.e., 2 years; Kimmel & van der Veen, 1974), and validity (Burgess, Locke, & Thomes, 1971). It has shown convergent validity with independent observations of marital interaction (Julien, Markman, & Lindahl, 1989) and with scores on the DAS (Busby, Christensen, Crane, & Larson, 1995). Webster-Stratton (1988) found that marital distress measured by the MAT contributed to negative perceptions of child behavior and to increased negative maternal behavior.

The DAS (Spanier, 1976), a 32-item self-report inventory, contains four subscales of marital adjustment: Dyadic Consensus (spouses' agreement regarding various marital issues), Dyadic Cohesion (extent to which partners involve themselves in joint activities), Dyadic Satisfaction (overall evaluation of the marital relationship and level of commitment to the relationship), and Affectional Expression (degree of affection and sexual involvement in the relationship). The DAS has been found to possess adequate reliability (e.g., Carey, Spector, Lantinga, & Krauss, 1993; Spanier, 1976) and validity (e.g., Crane, Allgood, Larson, & Griffin, 1990). Marital dissatisfaction, as measured by the DAS, has been shown to relate to greater oppositional behavior in elementary school-age boys through the indirect pathway of rejection by fathers (Mann & MacKenzie, 1996).

Two questionnaires are often used to assess general marital conflict: the O'Leary-Porter Scale (OPS; Porter & O'Leary, 1980), and the Conflict Tactics Scales—Partner (CTS-Partner; Straus, 1979, 1990). The OPS, a 10-item parent-completed questionnaire, is designed to

assess the frequency of various forms of overt marital hostility (e.g., quarrels, sarcasm, and physical abuse) that are witnessed by the child. There is some evidence that this scale is more strongly associated than the MAT with parental ratings of CP behavior (Porter & O'Leary, 1980). Conflict, as measured by the OPS, is related to increased oppositional behavior in boys through disruptions in maternal discipline (Mann & MacKenzie, 1996) and to adolescent overt and covert CP behavior (Forehand, Long, & Hedrick, 1987).

The CTS-Partner, a 38-item parent-report questionnaire, assesses the strategies couples use to resolve conflict. It includes a range of strategies, from discussion to yelling, pushing, threatening or beating up the partner. Straus (1979, 1990) reported adequate reliability, validity, and norms to use in interpreting scores on the CTS-Partner. O'Leary, Vivian and Malone (1992) suggest that the CTS-Partner may be a particularly accurate method for obtaining reports of physical aggression, because wives tend to underreport aggression in written self-reports and interviews. Marital physical and nonphysical aggression as measured by the CTS-Partner, has been shown to be positively correlated with children's CPs (Jouriles, Norwood, McDonald, Vincent, & Mahoney, 1996). The CTS-Partner has been revised extensively. Psychometric properties of the CTS2 are presented in Straus, Hamby, Boney-McCoy, and Sugarman (1996).

In addition, instruments that have been designed to measure parenting-related conflict include the Parenting Alliance Inventory (Abidin & Brunner, 1995) (now called the Parenting Alliance Measure; Abidin & Konold, 1999), Child-Rearing Disagreements (Jouriles et al., 1991), and the Parent Problem Checklist (Dadds & Powell, 1991). There is some evidence to suggest that these more specific measures may account for additional explanatory variance over measures of marital satisfaction. For example, Jouriles and colleagues (1991) reported that Child-Rearing Disagreements significantly predicted CPs even after general marital dissatisfaction, as measured by the MAT, was controlled.

The fourth area, *parenting stress*, includes both general measures of stress (e.g., life event scales) and specific measures of parenting-related stress. Examples of the former include the Life Experiences Survey (Sarason, Johnson,

& Siegel, 1978) and the Family Events List (Patterson, 1982). The Life Experiences Survey, a 47-item, self-report measure, has been shown to be a moderately reliable instrument. Parents of children with ADHD and CPs have been shown to have higher scores on the Life Experiences Survey (Johnston, 1996b), and in families whose children have CPs, the measure has discriminated between abusive and nonabusive parents (Whipple & Webster-Stratton, 1991). The Family Events List (Patterson, 1982) is a self-report measure with 46 minor but "hassling" events that may occur in daily living (e.g., child care problems, car problems, work-related problems). Snyder (1991) reported that when mothers of children with CPs experienced frequent hassles and negative mood, they tend to respond to their children's negative behavior in a more coercive manner. The types of stressors and the time frame for reporting on these life event scales vary. This is important, because it may be that proximal "hassle" stressors, such as those on the Family Events List, have a different relationship to family functioning, parenting behavior, and CPs than the distal stressors on the Life Experiences Survey.

Measures specific to parenting-related stress include Parenting Daily Hassles (Crnic & Greenberg, 1990) and the Parenting Stress Index (PSI; Abidin, 1995). Parenting Daily Hassles, a 20-item self-report questionnaire, measures events in parenting and parent-child interactions (Crnic & Greenberg, 1990). Parents rate the frequency, the degree of hassle, and the intensity of each hassle. In a non-referred sample, Crnic and Greenberg found that the cumulative effects of relatively minor stresses related to parenting are important predictors of parent and child behaviors, and that daily hassles are more predictive of children's CPs than scores on the Life Experiences Survey. Greater mother-reported daily hassles are positively correlated with CBCL/1½-5 Externalizing scores in 1-, 2-, and 3-year-olds (van Zeijl et al., 2006) and greater trouble managing toddlers' behavior (Belsky, Woodworth, & Crnic, 1996).

The PSI (Abidin, 1995) was designed as a screening instrument for assessing relative levels of stress in the early parent-child system (0-3 years), although it has been used with children up to 12 years of age. There is also a version for parents of youth ages 11-19—the

Stress Index for Parents of Adolescents (Sheras, Abidin, & Konold, 1998). The design of the PSI was theoretically derived and includes domains related to stress and coping in parent and child temperament. The PSI comprises 120 items, requires approximately 20 minutes to complete, and yields a total score and two scale scores: Child and Parent. The Child domain includes six subscales concerning the child's Adaptability, Reinforcing Qualities, Demandingness, Distractibility/Hyperactivity, Mood, and Acceptability to the parent. The Parent domain includes subscales related to Depression, Attachment to the Child, Spousal and Social System Support, Parental Health, Perceived Restrictions of Role, and Parent's Sense of Competence. High total scores may indicate risk for problems in development; low scores may also be a reason for concern, either because of a "fake good" response set or indications of lack of parental involvement with the child. A high score in the Parent domain may indicate difficulty with parental functioning. High scores in the Child domain may indicate that a child has difficult characteristics (i.e., "temperamentally difficult"). Webster-Stratton (1990) reported that the mean Child domain score in a sample of 120 children with CPs was above the 95th percentile. (See Abidin, Flens, & Austin [2006] for a summary of research on the PSI.)

The PSI has been used extensively with parents of children with CPs. Scores on the PSI obtained in infancy have been used to predict child CPs 4½ years later in nonclinical samples (Abidin, Jenkins, & McGaughey, 1992). Higher PSI scores have been related to CPs in several samples (e.g., Cuccaro, Holmes, & Wright, 1993; Eyberg, Boggs, & Rodriguez, 1992; Webster-Stratton, 1990). Webster-Stratton and Hammond (1988) found that the Parent domain score on the PSI, in combination with the Life Experiences Survey Negative Change score, discriminated between depressed and nondepressed mothers in families with children with CPs. Parent management training outcome in families with children with CPs has been evaluated with the PSI (e.g., Eisenstadt et al., 1993; Nixon et al., 2003; Webster-Stratton & Hammond, 1997), and higher scores on the Child and Parent domains of the PSI have been linked with premature termination of treatment for CPs (e.g., Kazdin, 1990).

The PSI Short Form (PSI/SF; Abidin, 1995) comprises 36 items from the PSI and can be ad-

ministered in less than 10 minutes. In addition to a total score, there are three factor-analytically derived subscales (Parental Distress, Parent-Child Dysfunctional Interaction, Difficult Child). The PSI/SF subscales correlate with the full-length PSI in the expected pattern, and have shown adequate internal consistency and test-retest (6 month) reliability. However, other researchers (e.g., Haskett, Ahern, Ward, & Allaire, 2006) have identified a two-factor solution that appears similar to the two conceptually derived scales in the original PSI.

The youth's broader social ecology (i.e., extrafamilial functioning) is often crucial for understanding the development of CPs in many cases. Therefore, it is important to assess variables such as the economic situation of the family, the level of social and community support provided to the youth and his or her family, and other aspects of the youth's social climate (e.g., neighborhood, quality of school, and degree of exposure to violence). The Neighborhood Questionnaire (Greenberg, Lengua, Coie, Pinderhughes, & the Conduct Problems Prevention Research Group, 1999), a brief parent report measure, assesses the parent's perception of the family's neighborhood in terms of safety, violence, drug traffic, satisfaction, and stability. Things That I Have Seen and Heard (Richters & Martinez, 1990) is an example of an interview that focuses on the youth's exposure to violence.

The Community Interaction Checklist (CIC; Wahler, Leske, & Rogers, 1979), a brief interview that is usually administered on multiple occasions, has been used extensively in research with children with CPs and their families to assess maternal insularity. On the basis of maternal reports of extrafamily contacts over several previous 24-hour periods, mothers are categorized as insular if they report at least twice as many daily contacts with relatives and/or helping agency representatives as with friends, and if at least one-third of the daily contacts are reported as neutral or aversive (Dumas & Wahler, 1983, 1985). These mothers are more aversive and indiscriminate than noninsular mothers in the use of aversive consequences with their children, their children are more aversive, and coercive exchanges between insular mothers and their children are of longer duration than those involving noninsular mother-child dyads (Dumas & Wahler, 1985; Wahler, Hughey, & Gordon, 1981). Aversive maternal contacts with adults, as measured on

the CIC, are associated with mothers' aversive behavior toward their children on the same day (Wahler, 1980; Wahler & Graves, 1983). Finally, classification as insular on the CIC is a strong predictor of poor maintenance of the effects of parent management training interventions for children with CPs (e.g., Dumas & Wahler, 1983; Wahler, 1980). None of the mothers who were both insular and socioeconomically disadvantaged had a favorable outcome over the 1-year period.

Finally, it is important to evaluate *parental satisfaction with treatment*, which is a form of social validity that may be assessed in terms of satisfaction with the outcome of treatment, therapists, treatment procedures, and teaching format (McMahon & Forehand, 1983). At present, no single consumer satisfaction measure is appropriate for use with all types of interventions for youth with CPs and their families. In fact, most assessments of treatment satisfaction have focused on parents involved in parent management training interventions, although teachers have occasionally been assessed. The children and adolescents themselves have rarely been asked about their satisfaction with treatment, with the exception of some evaluations of multisystemic therapy with adolescents (e.g., Henggeler et al., 1999). The Therapy Attitude Inventory (TAI—Brestan, Jacobs, Rayfield, & Eyberg, 1999; Eyberg, 1993) and the Parent's Consumer Satisfaction Questionnaire (PCSQ—McMahon & Forehand, 2003; McMahon, Tiedemann, Forehand, & Griest, 1984) are examples of measures designed to evaluate parental satisfaction with parent management training programs (e.g., Brinkmeyer & Eyberg, 2003; McMahon & Forehand, 2003). Both the TAI and the PCSQ have data supporting their reliability and validity (e.g., Baum & Forehand, 1981; Eisenstadt et al., 1993; McMahon et al., 1981, 1984; Webster-Stratton, 1989; Webster-Stratton & Hammond, 1997).

Summary

CPs are associated with a wide variety of risk factors, both internal and external to the child. A correspondingly large array of measures have been developed to measure these various factors, although the clinical utility of many of the measures requires further testing. Assessment of youth social-cognitive processing difficulties is beginning to make its way into more

applied settings, but assessments of peer rejection processes and associations with deviant peer groups that are appropriate for the clinical setting are less well developed. Assessment of family-related factors is essential, and includes, at a minimum, measurement of parenting practices, parents' cognitions about their children and about their parenting, parental personal and marital adjustment, parental stress, parental functioning in extrafamilial contexts, and parental satisfaction with treatment. Although these constructs have most typically been assessed by behavior rating scales, it is imperative to assess parent-child interaction via observational methods whenever possible. A number of structured observational analogue tasks have a successful history of clinical utility and have been shown to be sensitive to treatment effects (e.g., McMahon & Estes, 1997; Roberts, 2001).

Multiple Developmental Pathways: Implications for Assessment

The key implication of the research base for the assessment of youth with CPs is that it is imperative for the clinician to be aware of the various potential developmental pathways to CPs. Knowledge of the different pathways can serve as a guide for structuring and conducting the assessment with respect to the CP behaviors themselves, the most likely candidates for comorbid disorders and conditions, and the most clinically salient risk factors (McMahon & Frick, 2005). Also, different intervention strategies can be designed for youth in these different developmental pathways (Frick, 1998, 2006).

One of the most critical pieces of information in guiding assessment, and perhaps ultimately intervention, is the age at which various CP behaviors began, which provides some indication of whether the youth may be on the childhood-onset pathway. An important advantage of many structured interviews over behavior rating scales (and behavioral observations) is that they provide a structured method for assessing when a youth first began showing serious CP behaviors, thereby providing an important source of information about the developmental trajectory. For example, in the DISC-IV (Shaffer et al., 2000), following any question related to the presence of a CD symptom that is answered affirmatively, the parent or youth is asked to estimate at what age the first

occurrence of the behavior took place. Obviously, such questions can also be integrated into an unstructured interview format.

In either case, however, there is always some concern about how accurately the parent or youth reports the timing of specific behaviors. Three findings from research can help in interpreting such reports. First, the longer the time frame involved in the retrospective report (e.g., a parent of a 17-year-old vs. a parent of a 6-year-old reporting on preschool behavior), the less accurate the report is likely to be (Green, Loeber, & Lahey, 1991). Second, although a parental report of the exact age of onset may not be very reliable over time, typical variations in years are usually small, and the relative rankings within symptoms (e.g., which symptom began first) and within a sample (e.g., which children exhibited the earliest onset of behavior) seem to be fairly stable (Green et al., 1991). As a result, these reports should be viewed as rough estimates of the timing of onset and not as exact dating procedures. Third, there is evidence that combining informants (e.g., such as a parent or youth) or combining sources of information (e.g., self-report and record of police contact), and taking the earliest reported onset from any source, provides an estimate that shows somewhat greater validity than any single source of information alone (Lahey et al., 1999).

If the youth's history of CPs is consistent with the childhood-onset pathway, then additional assessment to examine the extent to which CU traits may also be present is important. The Antisocial Process Screening Device (Frick & Hare, 2001), a behavior rating scale completed by parents and teachers, can be used to identify children with CPs who also exhibit CU traits (Christian et al., 1997; Frick, Bodin, & Barry, 2000; Frick, O'Brien, Wootton, & McBurnett, 1994). A self-report version of this scale is also available for older children and adolescents, and although it has been validated in a number of studies (Munoz & Frick, *in press*), it lacks normative data from which to make interpretations. If the presenting child is preschool age, then one assessment goal is to attempt to determine whether the child's behavior is indicative of the childhood-onset pathway or a less serious manifestation of CP. Although there are no clear-cut algorithms for making this determination, a broad assessment of overall risk is called for (see Wakschlag & Danis, 2004). Also, with preschool-age chil-

dren, a more extensive assessment of noncompliance is warranted given its centrality to early CPs and its amenability to intervention at that age (McMahon & Forehand, 2003).

Finally, because much of the current knowledge about developmental pathways to CPs has been based on longitudinal samples of boys, many questions about onset and development of CP behavior in girls remain unanswered (Silverthorn & Frick, 1999). At present, with few exceptions (e.g., relational aggression), there is a paucity of information to guide the development of evidence-based assessment of CPs in girls. There is even less information with respect to evidence-based assessment of CPs with ethnically diverse youth. Prinz and Miller (1991) noted that, in general, the validity of various methods to assess CPs has not been examined in specific cultural groups. They stressed the importance of ensuring that assessment methods are interpreted within the cultural context of the child with a CP. Others have noted the importance of assessing the acceptability of various intervention procedures (e.g., parenting skills taught in parent management training interventions) across different ethnic groups (Forehand & Kotchick, 1996). Based on accumulating evidence, we recommend that clinicians use these developmental pathways constructs (albeit cautiously) to guide their assessments of girls and ethnically diverse youth with CPs until research suggests otherwise.

Summary

Knowledge about the multiple developmental pathways of CPs is extremely important for assessment practice, in that it can guide the structure and focus of clinicians' assessment. At present, the most well-established pathways are the childhood- and adolescent-onset pathways, although others will likely be identified by future research. Thus, establishing age of onset of CPs is a critical and relatively straightforward step in the assessment of youth. Furthermore, given the growing body of evidence that youth with high levels of both CP and CU traits show many distinct risk factors compared to youth with CP who do not also display elevated levels of CU traits, determination of the extent to which the child or adolescent also displays CU traits is indicated. With preschool-age children who display CPs, the most critical issue is to determine whether

their behavior indicates the early stages of the childhood-onset pathway of CPs or a more temporary developmental perturbation. Finally, the applicability of these pathways to girls and ethnically diverse youth is less well established.

CONCLUSIONS

In this chapter, we have summarized four areas of research that we feel have direct and important implications for assessing youth with CPs: (1) the heterogeneity in the types and severity of CPs, (2) the presence of multiple comorbid conditions, (3) the multiple risk factors associated with CPs, and (4) the multiple developmental pathways to CPs. For each of these domains, we discussed the implications for assessment and presented examples of specific measures that can aid in assessments. We also provided recommendations for evidence-based assessment of CPs based on this research. In this final section of the chapter, we identify (1) some overarching issues in applying this knowledge to clinical assessments and (2) areas that we believe are in greatest need of attention for advancing evidence-based assessments of CPs.

The first overarching issue in most cases of youth with CPs is the need for a comprehensive assessment. We have emphasized throughout this chapter that adequate assessment of a youth with CPs must make use of multiple methods (e.g., interviews, behavior rating scales, observation) completed by multiple informants (parents, teacher, youth) and concern multiple aspects of the child's or adolescent's adjustment (e.g., CPs, anxiety, learning problems) in multiple settings (e.g., home, school) (Kamphaus & Frick, 2005; McMahon & Estes, 1997; McMahon & Frick, 2005). However, because of issues of time, expense, and practicality, how best to acquire and interpret this large array of information become important issues. As described earlier, a multistage approach may prove to be cost-effective in conducting such comprehensive assessments, which start with more time-efficient measures (e.g., broad-band behavior rating scales, unstructured clinical interviews) and are then followed by more time-intensive measures (e.g., structured interviews, behavioral observations) when indicated (McMahon & Estes, 1997; McMahon & Frick, 2005; Nock & Kurtz, 2005).

However, once these assessment data are collected, few guidelines are available to guide clinicians in integrating and synthesizing the multiple pieces of information to make important clinical decisions at each stage of the assessment process. This endeavor is complicated by the fact that data from different informants (Achenbach, McConaughy, & Howell, 1987; De Los Reyes & Kazdin, 2005) and different methods (Barkley, 1991) often show only modest correlations with each other. As a result, after collecting multiple sources of information on a youth's adjustment, the assessor often must make sense of an array of often conflicting information.

Several clinically oriented strategies for integrating and interpreting information from comprehensive assessments have been proposed elsewhere (Breen & Altepeter, 1990; Kamphaus & Frick, 2005; McMahon & Forehand, 2003; Sanders & Lawton, 1993; Wakschlag & Danis, 2004). The continued development and refinement of the ASEBA (Achenbach & Rescorla, 2000, 2001) have been particularly noteworthy for their emphases on integrating and interpreting data from parents, teachers, youth, direct observations, and clinical interviews from this family of instruments. Others have suggested that incorporation of a functional-analytic approach into more traditional assessment practices will facilitate integration of information from multiple sources and the selection of appropriate treatments (e.g., Reitman, 2006; Scotti, Morris, McNeil, & Hawkins, 1996). Such functional-analytic approaches are quite compatible with research on the different developmental pathways to CPs and emphasize the need to understand the specific causal processes that lead to or maintain each child's or adolescent's CPs, in order to guide more individualized interventions. Regardless of the approach, much more research is needed to guide this process of integrating data from comprehensive assessments.

Another issue that requires further attention is the great need to enhance the clinical utility of evidence-based assessment tools (Frick, 2000; Hodges, 2004). As noted throughout this chapter, many of the recommended assessment measures have been developed and employed in research as opposed to applied settings. Progress toward the development of brief, clinically useful assessment methods has occurred, but in a limited way. On one front, there have been attempts to simplify well

validated but complex observational systems such as the DPICS and the BCS. On another front has been the development of structured laboratory analogue tasks to assess the child's or adolescent's behavior under standardized conditions (Frick & Loney, 2000; Roberts, 2001). Especially encouraging have been the attempts to develop methods for assessing covert types of CP behavior (e.g., Hinshaw et al., 1992; Kolko et al., 1991). Although the clinical utility of these methods has yet to be demonstrated, clinicians at least now have a number of brief assessment methods with some empirical support from which to choose.

There is still somewhat of a disconnect between assessment concerning case conceptualization and treatment planning on the one hand, and the availability of evidence-based interventions that map onto those assessment findings. For example, interventions are much less developed for youth engaging primarily in covert forms of CPs (e.g., stealing, firesetting) than for youth involved in more overt CP behaviors such as noncompliance and aggression (McMahon et al., 2006). Similarly, subtype-specific interventions for reactive and proactive aggression, for relational aggression (e.g., Leff, Angelucci, Grabowski, & Weil, 2004; Levene, Walsh, Augimeri, & Pepler, 2004) and for the treatment of youth with and without CU traits (e.g., Frick, 1998, 2001, 2006) are in relatively early stages of development. On the other hand, high levels of noncompliance in a preschool-age child suggest selection of one of several well-validated parent management training interventions (McMahon et al., 2006).

Another area that requires additional investigation is testing the sensitivity of measures to change. Many of the applications of research to the assessment process have focused on making diagnostic decisions (e.g., determining whether CPs should be the primary source of concern, and whether they are severe and impairing enough to warrant treatment) and on treatment planning (e.g., determine what types of treatment the child may need). However, an important third goal of the assessment process is intervention monitoring and evaluating treatment outcome. Evidence-based assessments should provide a means for testing whether interventions have brought about meaningful changes in the child's or adolescent's adjustment for better or worse (i.e., an iatrogenic effect). As noted throughout this

chapter, many behavior rating scales and observational measures have demonstrated sensitivity to intervention outcomes. Unfortunately, there is very little evidence to date of the successful use of assessment measures to monitor the effects of *ongoing* intervention for CPs. Exceptions to this are the structured observational analogues employed in some parent management training programs for young oppositional children (Herschell et al., 2002; McMahon & Forehand, 2003). These analogues (e.g., Child's Game, Parent's Game, Clean Up) are employed repeatedly throughout the course of treatment not only to monitor progress but also to determine whether the parent has met specific behavioral performance criteria necessary for progression to the next step of the parent management training program.

An assessment domain that is related to outcome evaluation is satisfaction with treatment. As noted earlier, assessment of this domain has been limited largely to parental satisfaction with parent management training (and, in the case of multisystemic therapy, youth satisfaction also). Areas for future research include the development and evaluation of similar satisfaction measures for other interventions employed with youth with CPs, and the development of such measures to assess youth satisfaction. Similarly, there is a need for research examining the treatment acceptability of, and satisfaction with, assessment procedures and measures themselves (e.g., Kazdin, 2005; Rhule, McMahon, & Vando, 2005).

Several important issues are involved in developing measures suitable for treatment monitoring and outcome evaluation (McMahon & Metzler, 1998). First, the way questions on an interview or rating scale are framed may affect its sensitivity to change. For example, the response scale on a parent report behavior rating scale may be too general (e.g., *Never* vs. *Sometimes* vs. *Always*) or the time interval for reporting the frequency of a parent behavior (e.g., the past 6 months) may not be discrete enough to detect changes brought about by treatment. Second, the degree to which the behaviors measured in assessment match the behaviors targeted in intervention can greatly affect sensitivity to change. For example, if major parenting constructs addressed by an intervention (e.g., limit setting, positive reinforcement, monitoring) are measured weakly or not at all

in the assessment, then changes in these constructs as a function of intervention are not likely to be captured. Finally, assessment \times intervention interactions may occur. For example, as a function of intervention, parents may learn to become more effective monitors of their youths' behavior. As a consequence, they may become more aware of their children's CP behaviors. Comparison of parent reports of their children's behavior prior to and after the intervention may actually suggest that parents perceive deterioration in their children's behavior (i.e., a false iatrogenic effect), when in reality the parents have simply become more accurate reporters of such behavior (Dishion & McMahon, 1998).

Perhaps the most central issue for advancing evidence-based assessment is the need to focus assessment around the emerging research on the different developmental pathways to CPs. As noted previously, this research may be the most important area for understanding youth with CPs, because it might explain many of the variations in severity, the multiple co-occurring conditions, and the many different risk factors associated with CPs. This research may also be very important for designing more individualized treatments for youth with CPs, especially older children and adolescents with more severe antisocial behaviors (Frick, 1998, 2001, 2006). However, for research on developmental pathways to be translated into practice, it is critical that better assessment methods for reliably and validly designating youth in these pathways be developed. This is especially the case for girls and for ethnically diverse youth. Furthermore, the different causal processes and developmental mechanisms (e.g., lack of empathy and guilt, poor emotion regulation) that may be involved in the different pathways need to be assessed, and this typically involves translating measures that have been used in developmental research into forms that are appropriate for clinical practice (Frick & Morris, 2004; Lahey, 2004). This is perhaps the best illustration of the role that evidence-based assessment can play in translating research into practice.

Adolescent Substance Use and Abuse

Ken C. Winters
 Tamara Fahnhorst
 Andria Botzet

The use of alcohol and other drugs (hereafter referred to simply as “drugs”) among adolescents remains a public health threat within U.S. society. From an epidemiological standpoint, drug use by teenagers is relatively common. According to a recent nationwide survey, Monitoring the Future (Johnston, O’Malley, Bachman, & Schulenberg, 2005), over half (51%) of 12th graders have used an illicit drug in their lifetime, and nearly one-fourth (23.4%) reported use of an illicit drug within the prior month. Lifetime alcohol use was reported by 12th-grade students as over three-fourths (76.8%), and nearly half (48.0%) of the senior class had used alcohol within the past month. Thirty percent of eighth graders have used illicit drugs (including inhalants) in their lifetime, and almost half (44%) have used alcohol in their lifetime. In the prior month, usage of any illicit drug was reported at 8%, and alcohol was used by approximately 19% of eighth graders.

Certainly, not all adolescents who use drugs become dependent. Drug use is often best conceptualized along a continuum that starts with *abstinence* and is followed by several stages (see Figure 4.1): *experimental use*, which reflects minimal use (typically limited to alcohol) in social settings; *early abuse*, in which individuals often use more than one drug, use relatively frequently, and begin to face negative consequences; *abuse*, which reflects more regular and frequent drug use in the presence of social and personal negative consequences; and *dependence*, which marks the most severe end of the continuum and is characterized by signs of tolerance to the drug, continued use despite adverse consequences, and frequent failed attempts to reduce or quit using.

Though there is controversy about the applicability of abuse and dependence diagnostic criteria among adolescents (see “Developmental Considerations in Drug Use Assessment”),

FIGURE 4.1. Continuum of alcohol and drug use.

youth who display abuse and dependence symptoms are still a cause for concern within the public health area. According to a national survey of representative youth in 2004 in the United States (Substance Abuse and Mental Health Services Administration [SAMHSA], 2005), 5.2% of 12- to 18-year-olds met current (prior year) criteria of a substance dependence disorder for at least one drug, and an additional 5.8% met current criteria for an abuse disorder for at least one drug (excluding those that met criteria for a dependence disorder; Winters, Leitten, Wagner, & O'Leary Tevyaw, 2007). In other words, approximately 11% of U.S. adolescents likely fall in the severe end of the drug use continuum.

With such a large base of the adolescent population using substances, and an appreciable percent that may meet abuse or dependence criteria, there are several health and societal implications to consider, including school failure, risky sexual behavior (Jainchill, Yagelka, Hawke, & DeLeon, 1999; MacKenzie, 1993), delinquency, incarceration, suicidality (Bolognini, Plancherel, Laget, & Halfon, 2003; Kaminer, 1994), motor vehicle injuries—fatalities (Kokotailo, 1995), and significant medical health care costs (Drug Abuse Warning Network [DAWN], 1996; King, Gaines, Lambert, Summerfelt, & Bickman, 2000).

Thus, precise assessment of adolescent drug use is essential if we are to gain an accurate understanding of the prevalence and health significance of adolescent drug use. We discuss several issues surrounding assessment in this chapter, including the clinical content, developmental considerations, types of instruments used to assess drug use, and other issues related to methods and sources for assessment of adolescent drug use.

CLINICAL CONTENT

Substance Use Disorders

Drug use that goes beyond experimentation and progresses into problematic involvement is formally delineated by various classification systems: Primary systems include the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; American Psychiatric Association [APA], 1994) and the 10th revision of *International Classification of Diseases* (ICD-10; World Health Organization [WHO], 1992).

In the DSM-IV diagnostic system, problematic drug use is separated into categories of *abuse* or *dependence*, as shown in Table 4.1. Abuse symptoms reflect drug involvement that increases risk for or results in negative health and social consequences. Indicators of abuse include role impairment, physically hazardous use, recurrent substance-related legal problems, and *drug*-related social and interpersonal difficulties. Abuse symptoms, although associated with clinically significant impairment or distress, are expected to fall short of dependence symptoms on a severity spectrum. Accordingly, an individual must have met at least one of the abuse criteria within the prior 12 months, without obtaining a dependence diagnosis, to receive an abuse diagnosis. DSM-based dependence, on the other hand, requires the positive endorsement of at least three out of seven symptoms defined by psychological and physiological dimensions. Items indicating psychological dependence refer to continued and compulsive use in the face of negative consequences, such as continuing drug use despite recognition of drug-induced depression or quitting important social or occupational activities because of drug use. Items indicating physiological dependence refer to tolerance (i.e., the need for increased drug amounts to achieve intoxication) and withdrawal (i.e., the development of symptoms such as nausea, anxiety, increased pulse rate, or insomnia due to the cessation of heavy or prolonged drug use). In DSM-IV, substance abuse and dependence criteria are the same for all substances, are mutually exclusive, and the diagnoses of abuse and dependence are hierarchically arranged (i.e., a dependence diagnosis precludes an abuse diagnosis). One or two dependence symptoms without abuse symptoms results in the individual not meeting any diagnostic criteria for a substance use disorder (SUD); individuals falling into this category have been described as “diagnostic orphans” (Pollock & Martin, 1999) and are further discussed in the “Applicability of SUD Criteria” section.

It is noteworthy that ICD-10 (WHO, 1992) also identifies two subgroups of problematic drug use: harmful use and dependence. These two ICD-10 groups are defined similarly to the abuse and dependence groups of DSM-IV, and their applicability to youth has been supported (Pollock, Martin, & Langenbucher, 2000). However, most research on adolescent SUDs has focused almost exclusively on the applica-

TABLE 4.1. DSM-IV-TR Criteria for Substance Abuse and Dependence Disorders

Abuse criteria (must endorse at least one item in past 12 months and have no dependence diagnosis)	Dependence criteria (must endorse at least three items in past 12 months)
<ol style="list-style-type: none"> 1. Failure to fulfill role obligations at work, school, or home, such as: <ul style="list-style-type: none"> • Absences from work/school due to use • Avoiding family activities due to use 2. Use in physically hazardous situations, such as: <ul style="list-style-type: none"> • Driving • Operating a machine • Participating in dangerous activities 3. Substance-related legal problems, such as: <ul style="list-style-type: none"> • Possession of an illegal substance • Selling or distribution of an illegal substance • Minor consumption 4. Continued use despite social or interpersonal problems, such as: <ul style="list-style-type: none"> • Physical fights • Arguments with loved ones regarding consequences of drug use 	<ol style="list-style-type: none"> 1. Tolerance, defined by: <ul style="list-style-type: none"> • Need for larger amounts of the drug to achieve intoxication • Current effect of drug is diminished compared to previous use of same drug 2. tion of DSM-based criteria, making DSM-IV diagnosis more readily recognized in the field; therefore, it is the only classification system discussed in this chapter.

Diagnostic categories are intended to capture and describe a cluster of associated behaviors and symptoms, thus complementing dimensional approaches by providing categorical groupings. Theoretically, these features should represent core pathological processes and follow a distinctive course (Millon, 1991). Functions of a diagnosis include the ability to identify cases for clinical intervention, convey information about prognosis, facilitate communication among clinicians and researchers, increase the homogeneity of research samples, and provide phenotypes for genetic research (McGue, 1999).

To achieve an accurate diagnosis, a thorough assessment of SUDs should include reliable precursors of the SUD, such as onset prior to age 12 (Henly & Winters, 1988), preadolescent tobacco use (Clark, Kirisci, & Moss, 1998), and polydrug use (Winters, 1994). All of these drug use behaviors have been associated with an increased likelihood of developing an SUD. Though reported levels of substance use are not significantly correlated with the presence of an SUD, especially in the case of alcohol (Pollock & Martin, 1999), quantity and frequency variables can produce important information, particularly when data are compared with regularly updated norms of use; thus, they should also be considered during an assessment of SUDs.

Course of SUDs

The clinical course of an SUD indicates both the changes and expression of an SUD, and the associated functioning over time (Brown, 1993). Understanding the course of adolescent SUDs is essential in determining the etiology and prognosis; as previously mentioned, some adolescent drug use occurs within an experimentation phase that is quite normal within adolescent development (Kandel, 1975), whereas other adolescent drug use is at a level more indicative of abuse or dependence. Multiple studies that have examined developmental trajectories of adolescent drug use (Lewinsohn, Rohde, & Seeley, 1996; Schulenberg, O'Malley, Bachman, Wadsworth, & Johnson, 1996) have found results that support the notion of separate experimental and SUD paths. Devel-

opmental trajectories have been characterized as *developmentally limited* or *intermittent*, as would be expected in an experimental case, as well as *persistent* or *relatively continuous*, suggestive of an SUD. One such trajectory by Lewinsohn and colleagues found gender differences in alcohol use within a community sample; females had an earlier age of onset for an alcohol use disorder (AUD) compared to males (14.6 vs. 16.1 years old, respectively), though males developed alcohol-related problems at a faster rate between ages 18 and 19. The same sample provided evidence that the average duration of an AUD was about 52 weeks for the community sample of adolescents (Lewinsohn et al., 1996).

Certain populations of adolescents tend to have higher rates of SUDs, such as homeless youth, those in the juvenile justice system, and those in psychiatric settings. In one study of homeless youth, nearly half met criteria for alcohol dependence (45%; Baer, Ginzler, & Peterson, 2003), and almost one-third (32%) of youth in the juvenile justice system are estimated to have an SUD (Bilchik, 1998). In addition, approximately 41% of teenagers in a study of adolescent psychiatric inpatients met DSM criteria for an AUD (Grilo, Fehon, Walker, & Martino, 1996). These data suggest that the course of SUDs among certain populations of youth is more acute and calls for a heightened awareness of SUD assessment by treatment providers within these settings.

Some variables have been found to predict the course of SUDs among adolescents in a chemical dependence treatment setting. Pre-treatment characteristics associated with more favorable substance use outcomes include a lower severity level of substance use at admission (Maisto, Pollock, Lynch, Martin, & Ammerman, 2001), greater readiness to change (Kelly, Myers, & Brown, 2000), and fewer conduct problems or other co-occurring psychopathology (Grella, Hser, Joshi, & Rounds-Bryant, 2001; Winters, Stinchfield, Opland, Weller, & Latimer, 2000). Factors influencing better outcomes during treatment include a longer length of treatment (Hser et al., 2001) and family involvement in treatment (Liddle & Dakof, 1995). Posttreatment predictors of better outcome include participation in after-care (Winters, Stinchfield, et al., 2000), low levels of peer substance use (Winters, Stinchfield, et al., 2000), ability to use coping skills (Myers, Brown, & Mott, 1993), and continued

commitment to abstain (Kelly et al., 2000). Of all these factors, the posttreatment predictors accounted for more variance in the teenagers' outcomes 1 year after treatment than did the pretreatment and during-treatment variables. However, it is important to recognize that the predictors may change over time, just as the impact of the predictor on the course of SUD may change. For example, sibling drug use is associated with more frequent drug use during the first 6 months posttreatment, but as time passes, peer drug use becomes a stronger predictor of SUD course than does family environment, including sibling drug use (Latimer, Winters, Stinchfield, & Traver, 2000).

Psychosocial Factors

An accurate and detailed assessment of the adolescent's psychosocial functioning is additionally important. Measurement of the various psychosocial dimensions provides beneficial information regarding the extent of the drug use, aids in treatment planning, and yields data to monitor treatment efficacy. Dimensions that should be included in the assessment protocol include the deterioration of interpersonal relationships, school and employment problems, history of legal problems, the discontinuation (or significant change) of recreational activities, and the extent of sexual promiscuity. Two salient psychosocial factors merit additional discussion and are addressed in the following paragraphs: peer factors and family environment.

Peer Factors

The assessment protocol needs to examine the role of peer influence within the adolescent's drug use behaviors. Multiple research studies have found evidence that peer issues comprise one of the most prominent factors contributing to the onset and maintenance of drug use. For example, Chilcoat and Breslau (1999) found that youth who associate with peers who use drugs were six times as likely to use drugs as those who did not associate with drug-using peers. Similar results were found by Farrell and Danish (1993) and Winters, Latimer, Stinchfield, and Henly (1999). A parallel finding by Guo, Hill, Hawkins, Catalano, and Abbott (2002) revealed that adolescents involved with peers exhibiting antisocial behaviors were at a higher risk of initiating illicit

drug use. Understanding the intricacies of peer relationships is complex, to say the least. The nature of this association between drug use and peers may be due to pressure to use drugs exerted by drug-using friends, or to the increased likelihood that drug-using individuals seek out other drug-using peers. Peer influences may also impact a youth's attitudes and expectancies regarding drug use, as well as his or her access to drugs (Dishion, Capaldi, Spracklen, & Fuzhong, 1995; Hawkins, Catalano, & Miller, 1992; Patterson, Forgatch, Yoerger & Stoolmiller, 1998).

Family Factors

Family influences encompass several variables, including familial genetic risk and parenting practices. Children with parents who have an SUD have been shown to be at increased risk for the development of a SUD (McGue, 1999). Parent SUDs constitute both genetic liability and environmental influences for drug involvement and SUDs in the child. Also, other psychopathology in family members, particularly a history of parental antisocial behavior, is relevant in offspring SUD liability (Clark, Moss, et al., 1997; Earls, Reich, Jung, & Cloninger, 1988; Hill & Muka, 1996; Zucker, Fitzgerald, & Moses, 1995). Results from twin and family studies provide additional insight into the role of family genetics and home environment on youth drug use. There is converging evidence that the initiation of alcohol use in midadolescence is predominantly influenced by factors such as parental monitoring and the father's drinking level rather than genetic factors (e.g., Heath & Martin, 1988; Iacono, Carlson, Taylor, Elkins, & McGue, 1999; Koopmans & Boomsma, 1996), but once drinking is initiated, it appears that genetic factors increasingly influence the frequency of alcohol and other drug use, as well as the prevalence of SUDs (e.g., Rose, Dick, Viken, Pulkkinen, & Kaprio, 2001). Of course, it is important to keep in mind that normative developmental outcomes are more common among youth than a disordered developmental course in the face of presumed SUD heritable liability (Clark & Winters, 2002).

Parenting factors are strongly associated with adolescent risk for drug involvement, especially factors such as closeness or warmth and control or monitoring. These aspects of parenting reflect characteristics of affection,

nurturance, and acceptance of the child by the parent, and of supervision of the child's activities and firmness in setting limits (Clark, Thatcher, & Maisto, 2005; Kandel, 1990). Several researchers have found increased drug use among adolescents in families that lack closeness or affection, effective discipline, and supervision; that have excessive or weak parental control and inconsistent parenting (Cleveland, Gibbons, Gerrard, Pomery, & Brody, 2005; Dishion, Patterson, & Reid, 1988; Kandel, 1990; Kosterman, Hawkins, Guo, Catalano, & Abbott, 2000; Patock-Peckham, Cheong, Balhorn, & Nagoshi, 2001; Zucker & Noll, 1987).

Psychological Benefits

In spite of the detrimental effects incurred by drug use, many adolescents are driven by psychological benefits from such use (Shaffer, 1997). Psychological advantages of adolescent drug use include mood enhancement, stress reduction, and relief from boredom (Petraitis, Flay, & Miller, 1995). In one study, mood enhancement played a more central role in drug use among youth with an SUD, whereas these psychological benefits were not as important to youth who use drugs infrequently (Henly & Winters, 1988). Because these psychological benefits play such an important role in the attraction and exacerbation of drug use among adolescents, prevention and early intervention efforts must underscore the harmful implications to outweigh the perceived benefits.

Coexisting Mental Health Disorders

Numerous clinical and epidemiological studies have demonstrated that adolescents who are involved with drugs often have coexisting psychological disorders (Boys et al., 2003; Clark & Bukstein, 1998; Kandel et al., 1999). Rohde, Lewinsohn, and Sealy (1996) reported that among adolescents who either abused or were dependent on alcohol, 80% also had some other form of psychopathology. The most common types of comorbid psychiatric conditions include externalizing disorders (i.e., conduct disorder [CD], oppositional defiant disorder [ODD], and attention-deficit/hyperactivity disorder [ADHD]) and internalizing disorders (i.e., depression and anxiety disorders—primarily posttraumatic stress disorder [PTSD]). Comprehensive drug use assessment should

therefore not only ascertain information regarding problems the adolescent is experiencing with alcohol and other drugs but also thoroughly identify comorbid psychiatric symptomatology. Doing so may be a key element in the projected success of an SUD intervention and subsequent relapse prevention. In addition, the knowledge obtained from these comprehensive assessments may facilitate more effective drug abuse prevention initiatives.

Comorbid Externalizing Disorders

Childhood aggression, rebelliousness, theft, and destructiveness, along with related externalizing disorders such as CD and ODD, are common among youth with SUDs, as well as among children of parents with SUDs (Clark, Moss, et al., 1997; Earls et al., 1988; Zucker et al., 1995). Prospective research reveals that antisocial behaviors in late childhood and the initiation of drug use in early adolescence predict later drug involvement (Boyle et al., 1992; Clark, Parker, & Lynch, 1999). The exact relationship between externalizing behavior and SUDs is complex. Three theories have been outlined regarding their potential association (Clark & Bukstein, 1998). First, CD has been found to predate or contribute to the development of an SUD (Clark et al., 1998), whereby poor behavioral inhibition or increased novelty seeking may lead to increased substance use. Second, other researchers have found that SUDs precede CD. For example, Clark and Bukstein (1998) reported that factors coinciding with an SUD, such as poor judgment and association with delinquent peers, may act as a catalyst for antisocial behavior and subsequent ODD or CD. Finally, in a third perspective, CD and substance use may occur concurrently, for they may share common environmental and personal risk factors (e.g., socioeconomic status, family problems, low academic achievement, association with deviant peer group). These risk factors may act independently or synergistically to impact the severity of the substance use and antisocial behavior (Clark & Bukstein, 1998; Donovan & Jessor, 1985). Barkley, Fischer, Smallish, and Fletcher (2004) showed that both CD and drug use interact over time to escalate the severity of the other set of symptoms.

The relationship between ADHD and SUDs is equally complex despite the significant literature that has explored the association. Some

studies have found that individuals with a history of ADHD, compared with controls, are more likely to develop substance use and substance-related problems (Barkley et al., 2004; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1993; Milberger, Biederman, Faraone, Chen, & Jones, 1997). Other studies have not found similar relationships (Biederman et al., 1997; Hechtman & Weiss, 1986). Some researchers have found that the association between ADHD and drug use problems is mediated by CD (August et al., 2006; Biederman et al., 1997; Clark et al., 1999; Lynskey & Fergusson, 1995), whereas others have revealed an independent association beyond that explained by CD (Thompson, Riggs, Mikulich, & Crowley, 1996). For example, Barkley and colleagues (2004) found that ADHD is related to some forms of drug use and nonviolent, drug-related illegal activities, independent of CD. Another study found that by examining ADHD symptomatology dimensionally rather than categorically, level of attention predicted subsequent substance use beyond that of CD symptomatology (Tapert, Baratta, Abrantes, & Brown, 2002). With regard to tobacco, a commonly cited gateway drug, ADHD has also been linked to its early initiation and increased use (Milberger et al., 1997). Other researchers who have studied specific ADHD symptomatology found that inattention (Burke, Loeber, & Lahey, 2001) or impulsivity-hyperactivity (Molina, Smith, & Pelham, 1999) accounts for an association between tobacco use and ADHD, even after they controlled for CD.

Comorbid Internalizing Disorders

Internalizing disorders such as anxiety disorders (e.g., PTSD) and mood disorders (e.g., major depression) may be another pathway associated with SUDs (Clark & Miller, 1998; Clark & Sayette, 1993). Children of parents with SUDs have been found to have increased rates of internalizing disorders and related symptoms (Clark, Moss, et al., 1997; Earls et al., 1988; Hill & Muka, 1996). Among adolescents with SUDs, elevated rates of internalizing disorders and related symptoms have been reported, especially among female compared to male adolescents with SUDs (Deykin, Levy, & Wells, 1987; Martin, Lynch, Pollock, & Clark, 2000). Childhood major depression was more common in individuals with adolescent-onset

rather than adult-onset SUDs (Clark & Bukstein, 1998). These associations do not, however, establish a causal pathway between childhood internalizing disorders and later SUDs. Similar to the “chicken and egg” conundrum that exists with SUDs and externalizing disorders, the specific association between internalizing disorders and SUDs remains indistinct. Some researchers have found that symptoms of anxiety and depression may be produced by alcohol or other substances (Clark & Sayette, 1993; Schuckit & Hesselbrock, 1994), whereas others have demonstrated that an AUD may exacerbate symptoms of PTSD (Stewart, 1996).

Another complicating feature is that data from adolescents with SUDs indicate that both CDs and major depression may coexist in some individuals (Clark, Pollock, et al., 1997). Prospective longitudinal research that integrates findings for antisocial disorders and those for internalizing disorders that begin in preadolescence, and assesses the sequencing of these characteristics for specific developmental periods (i.e., early adolescence, middle adolescence) is needed to clarify these relationships (Clark et al., 1999).

Other psychiatric disturbances have also been shown to correlate with SUDs in adolescents though at a lower rate. A number of individuals with eating disorders such as bulimia nervosa also have been shown to abuse substances or to have an SUD (Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993). In addition, adverse life events, including childhood maltreatment (i.e., physical abuse, sexual abuse, neglect), are also associated with the development of an SUD (Stewart, 1996). Finally, some researchers have suggested that efforts be extended to study the possible co-occurrence of learning and language disabilities, and SUDs in adolescents (Weinberg, Rahdert, Colliver, & Glantz, 1998).

DEVELOPMENTAL CONSIDERATIONS IN DRUG USE ASSESSMENT

Categories Reflecting Use

Of great importance in assessing adolescent drug use is differentiation among normative use, abuse, and dependence. It can be difficult to determine when adolescent drug use will have short-term, minimal health effects, and when it may escalate, with negative, long-term

repercussions. As previously noted, its popularity among youth places drug use within a normative developmental phase for adolescents. Most often, drug use among youth occurs within a social context of legal drug use, namely, alcohol or tobacco (Kandel, 1975; SAMHSA, 2005). These so-called *gateway drugs* are readily accessible to minors due to their legality and general availability. Though the large majority of youth do not progress beyond the use of these gateway drugs, some progress to more serious levels of drug use that result in abuse or dependence. As already noted, national estimates indicate that about 11% of youth use drugs to the point of meeting criteria for either a substance abuse or substance dependence disorder during the teenage years (Winters et al., 2007).

Applicability of SUD Criteria

The applicability of DSM criteria to adolescents' use of alcohol and other drugs (AOD) has aroused researchers' reservations for several reasons (Martin & Winters, 1998). The first such reason, previously mentioned in the "Substance Use Disorders" section, concerns the distinction between abuse and dependence criterion sets, which are not well supported by research. The abuse diagnosis has low concordance across different classification systems (Pollock et al., 2000), and abuse criteria cover symptoms that are conceptually less severe than some dependence criteria (Pollock & Martin, 1999). Similarly, some studies have found a higher prevalence of the more severe dependence diagnosis in relation to the more moderate abuse diagnosis (Chung, Martin, Armstrong, & Labouvie, 2002).

Second, other reservations exist at the criterion level; certain criteria have limited utility among adolescents. For example, tolerance, an important criterion for dependence, has low diagnostic specificity among adolescents, because tolerance for drugs is likely a normal physiological phenomenon that can take extended lengths of time to develop; most adolescents have not been using drugs for a long enough period for this criterion to develop. This is particularly the case for alcohol (Chung, Martin, Winters, & Langenbucher, 2001). The definition of "tolerance" also imparts concern, because it is characterized as a marked increase in quantity used, so a tolerance symptom may be overassigned to those who report low initial

quantities, and underassigned to those who report high initial quantities, regardless of the physical effect on the individual. Another important diagnostic criterion, withdrawal, has limited utility for adolescents because it occurs at very low base rates even in clinical samples (Martin, Kaczynski, Maisto, Bukstein, & Moss, 1995; Winters, Latimer, & Stinchfield, 1999).

A third criterion issue concerns the interpretation or meaning of the symptom for adolescents. For example, "drinking more than intended" may be endorsed more frequently among teenagers not because of a compulsive pattern of use, but rather because of poor judgment, inexperience with the effects of the drug, or social pressures to use. Specific interview probes, such as motivation to use, perceived ability to control use, and reasons for limiting use, are more beneficial in discerning a clinical phenomenon of impaired control in adolescents.

A final word regarding the applicability of SUD criteria for adolescents pertains to the heterogeneity of the DSM-IV substance abuse criteria. The abuse symptoms cover a broad range of problems, yet only one symptom is required to meet the criteria. In addition, symptoms of abuse do not always precede symptoms of dependence, contrary to the notion that abuse should be a precursory condition to dependence (Martin, Kaczynski, Maisto, & Tarter, 1996). For these reasons, adolescents can more easily "fall through the cracks" of the DSM-IV system; that is, individuals who meet criteria only for one or two dependence symptoms, and no abuse symptoms, therefore do not qualify for any diagnosis (Hasin & Paykin, 1998; Pollock & Martin, 1999). Approximately 10–30% of adolescents in clinical settings fall into this "crack" of the diagnostic system (Harrison, Fulkerson, & Beebe, 1998; Lewinsohn et al., 1996; Pollock & Martin, 1999).

Differences with Adults

The groundwork for adolescent drug assessment and treatment procedures is largely based on theory and experience with adult drug use, with little or no modification of the criteria or diagnostic thresholds. Thus, the applicability of current assessment procedures to adolescents is uncertain (Martin & Winters, 1998; Tarter, 1990). Research has shown that adolescents exhibit behavioral, psychological, and

physiological characteristics differently than do adults (Kaminer, 1991). For example, alcohol is rarely the sole substance abused among adolescents; rather, they are likely also to abuse marijuana and other drugs concurrently with alcohol (SAMHSA, 1999). However, adults in treatment for substance problems frequently report alcohol as the primary substance abused. These drug use patterns in the two age groups probably reflect differences between generations, as well as the effects of age and age-related responsibility.

Another example illustrating the differences between adult and adolescent drug assessment pertains to the rate at which SUDs progress. Martin and colleagues (1995) found that drug use can progress from experimentation to abuse or dependence much more rapidly for adolescents than it can for adults. Adolescents are often diagnosed with SUDs within a year of their initial use, whereas adults generally use drugs for several years before progressing to dependence.

Neurobiology

Recent research has indicated that the brain does not fully develop until early adulthood (Giedd, 2004). In some regions of the brain, particularly the prefrontal cortical region associated with judgment (resisting impulses and other executive functioning), nearly 50% of the neurons undergo “pruning” and transformation during adolescence. Because of this immaturity, there is speculation that the developing adolescent brain may be highly vulnerable to the effects of drug use. Studies with laboratory animals have provided evidence that adolescents differ significantly from adults in their receptivity to the effects of alcohol (Spear, 2000). Adolescent rats show decreased sensitivity to the unpleasant effects of alcohol (i.e., vomiting, hangovers) and increased sensitivity to the social benefits of alcohol compared to older rats. Adolescent rats also require a larger amount of alcohol to reduce anxiety than do older rats (Varlinskaya & Spear, 2002). These findings suggest that adolescents may be less capable than adults of moderating their alcohol intake.

Laboratory animals also provide evidence that exposure to drugs during adolescence influences later neural functioning. Rats that were chronically exposed to alcohol during adolescence exhibited greater cognitive difficulties than rats exposed to the same amount of

alcohol in adulthood (Markwiese, Acheson, Levin, Wilson, & Swartzwelder, 1998). In regards to human subjects, Tapert and Schweinsburg (2005) reported that adolescents with a history of heavy alcohol use had smaller hippocampi compared to those of a matched control sample; the hippocampus is the area of the brain responsible for creating memories. The same adolescents revealed memory and other neuropsychological impairment during recall tasks, due to reduced brain activation. These findings are only suggestive because brain functioning prior to alcohol use was not measured, but they emphasize the importance of further study on the possible deleterious effects of alcohol use on the developing brain.

Gender

Although some exceptions exist, prevalence studies generally indicate that boys are at a greater risk than girls for drug use and drug problems (Kahler, Read, Wood, & Palfai, 2003). This pattern was emphasized in a recent national report of drug use among Americans. Adolescent boys reported higher rates on nearly every drug use variable, including early (prior to age 12) onset of drug use, binge drinking, illicit drug use, and SUDs (SAMHSA, 2005). Cigarette use is roughly the same across genders, however (Johnston et al., 2005).

Clinical studies have revealed both gender differences and similarities with regard to possible psychosocial determinants of drug use. Opland, Winters, and Stinchfield (1995) found that girls' drug use is a coping mechanism in response to stress, whereas boys tend to use drugs for the pleasurable effects. In a cross-sectional study of drug-abusing youth assessed in clinical settings, Winters, Latimer, Stinchfield, and Henly (1999) found that scales measuring delinquency and peer drug involvement were most highly correlated with overall drug use in both girls and boys. However, girls, compared to boys, tended to have higher associations between drug involvement and psychological distress. A related question is the relative severity of reported psychosocial problems. Hsieh and Hollister (2004) found that female subjects who were entering a substance abuse treatment program exhibited more severe psychological difficulties, poorer self-image, increased family problems, and more exposure to sexual abuse than did their male counterparts. However, boys, compared to

girls, in the same study exhibited higher rates of conduct problems related to school difficulties and legal problems. Dakof, Tejada, and Liddle (2000) found similar results in their clinical sample, namely, that drug-abusing girls exhibited much higher levels of internalizing symptoms and higher levels of family dysfunction, even though they used drugs just as extensively as the boys.

Other Factors

Other developmental issues are relevant with respect to assessing adolescent drug use. Delays in social and emotional functioning (Noam & Houlihan, 1990), diminished respect toward authority, and the tendency to be egocentric (Erikson, 1968) and to minimize negative consequences (Lewinsohn et al., 1996) may contribute to inaccurate reporting of personal drug use behaviors and to poor motivation to change (Cady, Winters, Jordan, Solberg, & Stinchfield, 1996).

THE ASSESSMENT PROCESS

When an adolescent is suspected of using drugs, the assessment process should begin with screening questions about recent drug use quantity and frequency (e.g., “How often did you use drugs in the past 6 months?”), the presence of adverse consequences of use (e.g., “Has your drug use led to problems with your parents?”), and situations in which drug use is common (e.g., “Do you use drugs before or during school?”). Several psychometrically sound screening instruments help to guide the screening process (a summary of screeners is provided in the next section).

If the screening suggests a possible drug use problem, the clinician should conduct a more comprehensive assessment to determine details of drug use quantity and frequency, consequences of such use, whether the teenager meets criteria for an SUD, and what other behavioral and mental comorbid problems may exist. Numerous examples of comprehensive instruments with established psychometric properties, including interviews and paper-and-pencil questionnaires, are available in the literature (these tools are summarized in the next section).

A thorough assessment of the adolescent’s drug use should include detailed inquiry into the age of onset and progression of use for spe-

cific substances, circumstances, frequency and variability of use, and types of drugs used. The assessor should also inquire about the context of use, which should include the usual times and places of drug use, the attitudes and use patterns of the adolescent’s peers, and typical behavioral and social triggers, and antecedents associated with drug use. The clinician should also ask about direct and indirect consequences of use in the domains of school, social, family, psychological functioning, and physical/medical problems. Finally, the assessor should evaluate the adolescent’s problem recognition and readiness for treatment. These questions may help to determine the initial treatment goals.

The determination of an SUD requires that the assessor review the criteria for substance abuse and dependence for specific substances. As previously mentioned, abuse criteria focus on negative social and personal consequences as a result of repetitive use; dependence criteria address symptoms associated with the continued use of drugs in the face of negative consequences (see Table 4.1). The differential diagnosis of adolescent SUDs requires consideration that the symptoms of drug use are not due to premorbid or concurrent problems, such as CD or family issues. Given the frequent comorbidity of SUDs and other psychiatric disorders, it is important that the assessor comprehensively review in timeline fashion the past and present history of psychiatric symptoms. Such a timeline approach can help the assessor sort out the interrelationship between drug use and comorbid psychopathology (Riggs & Davies, 2002).

OVERVIEW OF INSTRUMENTS FOR ASSESSING ADOLESCENT DRUG USE AND RELATED PROBLEMS

Significant contributions by researchers over the past decade have provided clinicians and researchers with numerous instruments to assist in the assessment of adolescent drug use behaviors (Leccese & Waldron, 1994; Winters, 2001). Many measures have been normed for adolescents of varying ages and written to be conducive to young people’s comprehension levels. Some tools are designed to identify quickly youth at risk for drug problems, whereas other measures provide extensive, diagnostically related information.

Several summaries of adolescent screening and comprehensive assessments exist, includ-

ing two by the federal government—*Screening Assessment of Adolescents with a Substance Use Disorder* (Center for Substance Abuse Treatment, 1999) and the second edition of *Assessing Alcohol Problems: A Guide for Clinicians and Researchers* (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2003)—and others in journal articles (Leccese & Waldron, 1994; Martin & Winters, 1998) and chapters in handbooks (Winters, 2001). We provide our own summary below. Inclusion in our overview required that the instrument be developed specifically for adolescents, with its psychometric properties reported in a peer-reviewed publication, user information available in print (e.g., manual, scoring information), and the instrument's author or publisher easily accessible to answer user questions. Thus, the reviewed measures are both scientifically rigorous and have high clinical utility.

Screening Instruments

Clinicians and researchers working with adolescents have access to a wide range of screening instruments, most commonly self-report questionnaires, to describe the possible or probable presence of a drug problem (see Table 4.2 for a listing). We review four categories of screening tools: alcohol, all drugs (including alcohol), nonalcohol drugs, and multiscreens.

Alcohol Screens

Two contemporary screening tools focus exclusively on alcohol use. The 24-item Adolescent Drinking Inventory (Harrell & Wirtz, 1989) examines adolescent problem drinking by measuring psychological symptoms, physical symptoms, social symptoms, and loss of control. Written at a fifth-grade reading level, it yields a single score with cutoffs, as well as two research subscale scores (Self-Medicating Drinking and Rebellious Drinking). The Adolescent Drinking Inventory yields high internal consistency reliability (coefficient alpha, .93–.95), and has demonstrated validity in measuring the severity of adolescent drinking problems (e.g., it has revealed a very favorable hit rate of 82% in classification accuracy). The second measure in this group, the 23-item Rutgers Alcohol Problem Index (RAPI; White & Labouvie, 1989), measures consequences of alcohol use pertaining to family life, social rela-

tions, psychological functioning, delinquency, physical problems, and neuropsychological functioning. Based on a large general population sample, the RAPI was found to have high internal consistency (.92), and, among heavy alcohol users, a strong correlation with DSM-III-R criteria for substance use disorders (.75–.95) (White & Labouvie, 1989).

Screens for All Drugs

Another group of screening tools comprise the relatively short measures that nonspecifically cover all drug categories, including alcohol. Examples of these measures are the Adolescent Alcohol and Drug Involvement Scale (AADIS; Moberg, 2003), CRAFFT (Knight, Sherritt, Harris, Gates, & Chang, 2003; Knight, Sherritt, Shrier, Harris, & Chang, 2002), Personal Experience Screening Questionnaire (PESQ; Winters, 1992), and the Substance Abuse Subtle Screening Inventory—Adolescents (SASSI-A; Miller, 1985). The 14-item AADIS includes a drug abuse problem severity scale; a range of reliability and validity evidence for this screen has been reported (Moberg, 2003). The CRAFFT is a specialized, six-item screen designed to be administered verbally during a primary care interview to address both alcohol and drug use. Its name is a mnemonic device to help physicians incorporate six questions into their primary care exams. Based on a study in a large, hospital-based adolescent clinic, scores from the CRAFFT were found to be highly correlated with scores from several existing and valid measures, and a cutoff score of 2 has been found to be highly predictive of a drug problem (Knight et al., 2002, 2003). The 40-item PESQ comprises a problem severity scale (coefficient alpha, .91–.95), drug use history, select psychosocial problems, and response distortion tendencies (“faking good” and “faking bad”). Norms for normal, juvenile offender, and drug abusing populations are available. The PESQ is estimated to have an accuracy rate of 87% in predicting the need for further drug abuse assessment (Winters, 1992). The 81-item SASSI-A yields scores for several scales, including face-valid alcohol, face-valid other drug, obvious attributes, subtle attributes, and defensiveness. Validity data indicate that SASSI-A scale scores are highly correlated with Minnesota Multiphasic Personality Inventory (MMPI) scales, and that its cutoff score for “chemical de-

TABLE 4.2. Screening Instruments

Instrument	Purpose	Source	Group used	Norms	Normed groups	Format	Time (min)
Adolescent Alcohol and Drug Involvement Scale (AADIS)	Screen for drug abuse problem severity	Moberg (2003)	Adolescents referred for emotional or behavioral disorders	Yes	Substance abusers	14 items, questionnaire	5
Adolescent Drinking Inventory	Screen for alcohol use problem severity	Harrell & Wirtz (1989)	Adolescents suspected of alcohol use problems	Yes	Normals; substance abusers	24 items, questionnaire	5
CRAFFT	Screen for drug use problem severity	Knight, Sherritt, Harris, Gates, & Chang (2003)	Adolescents referred for emotional or behavioral disorders	Yes	Normals; substance abusers	6 items, questionnaire	5
Drug Abuse Screening Test—Adolescents (DAST-A)	Screen for drug use problem severity	Martino, Grilo, & Fehon (2000)	Adolescents referred for emotional or behavioral disorders	Yes	Substance abusers	27 items, questionnaire	5
Drug Use Screening Inventory—Revised (DUSIR)	Screen for substance use problem severity and related problems	Kirisci, Mezzich, & Tarter (1995)	Adolescents referred for emotional or behavioral disorders	Yes	Substance abusers	159 items, questionnaire	20
Personal Experience screening Questionnaire (PESQ)	Screen for substance use problem severity	Winters (1992)	Adolescents referred for emotional or behavioral disorders	Yes	Normals; substance abusers	40 items, questionnaire	10
Problem Oriented Screening Instrument for Teenagers (POST)	Multiscreen for substance use problem severity and related problems	Latimer, Winters, & Stinchfield (1997); Rahdert (1991)	Adolescents referred for emotional or behavioral disorders	Yes	Normals; substance abusers	139 items, questionnaire	20–25
Rutgers Alcohol Problem Index (RAPI)	Screen for alcohol use problem severity	White & Labouvie (1989)	Adolescents at risk for alcohol use problems	Yes	Normals; substance abusers	23 items, questionnaire	10
Substance Abuse Subtle Screening Inventory—Adolescents (SASSI-A)	Screen for substance use problem severity and related problems	Miller (1985)	Adolescents referred for emotional or behavioral disorders	Yes	Normals; substance abusers	81 items, questionnaire	10–15

pendency” corresponds highly with intake diagnoses of substance use disorders (Risberg, Stevens, & Graybill, 1995). However, claims that the SASSI-A is valid in detecting *unreported* drug use and related problems have not been empirically justified (Rogers, Cashel, Johansen, Sewell, & Gonzalez, 1997).

Screens for Nonalcohol Drugs

The third category of screening tools pertains to those that screen only nonalcohol drugs. Only one screen falls into this group: the Drug Abuse Screening Test for Adolescents (DAST-A; Martino, Grilo, & Fehon, 2000), adapted from Skinner’s (1982) adult tool, the Drug Abuse Screening Test. This 27-item questionnaire is associated with favorable reliability data and is highly predictive of DSM-IV drug-related disorders when tested among adolescent psychiatric inpatients.

Multiproblem Screens

The final group of screening measures comprise two “multiscreen” instruments that examine several domains, in addition to drug involvement. The 139-item Problem Oriented Screening Instrument for Teenagers (POSIT; Rahdert, 1991) is part of the Adolescent Assessment and Referral System developed by the National Institute on Drug Abuse (NIDA). It tests for 10 functional adolescent problem areas: substance use, physical health, mental health, family relations, peer relationships, educational status, vocational status, social skills, leisure and recreation, and aggressive behavior/delinquency. Cutoff scores for determining the need for further assessment have been rationally established, and some have been confirmed with empirical procedures (Latimer, Winters, & Stinchfield, 1997). Convergent and discriminant evidence for the POSIT have been reported by several investigators (e.g., Dembo, Schmeidler, Borden, Chin-Sue, & Manning, 1997; McLaney, Del-Boca, & Babor, 1994). The Drug Use Screening Inventory—Revised (DUSI-R), a 159-item instrument that describes drug use problem severity and related problems, produces scores on 10 subscales, as well as one Lie Scale. Domain scores were related to DSM-III-R substance use disorder criteria in a sample of adolescent substance abusers (Tarter, Laird, Bukstein, & Kaminer, 1992). An additional psychometric report provides norms and

evidence of scale sensitivity (Kirisci, Mezzich, & Tarter, 1995).

Comprehensive Assessment Instruments

If an initial screening indicates the need for further assessment, clinicians and researchers can employ various diagnostic interviews, problem-focused interviews, and multiscale questionnaires (see Table 4.3 for a list). These instruments yield information that can more definitively assess the nature and severity of the drug involvement, typically assign an SUD diagnosis, and identify the psychosocial factors that may predispose, perpetuate, and maintain the drug involvement.

Diagnostic Interviews

Diagnostic interviews, which focus on DSM-based criteria for SUDs, include both general *psychiatric* interviews that address all psychiatric disorders and SUD interviews that focus primarily on drug use and related domains of functioning. The majority of the diagnostic interviews are structured; that is, the format directs the interviewer to read verbatim a series of questions in a decision-tree format, and the answers to these questions are restricted to a few predefined alternatives. The respondent is assigned the principal responsibility of interpreting the question and deciding on a reply.

Two well-researched *psychiatric* diagnostic interviews address SUDs, as well as the full range of child and adolescent psychiatric disorders. The Diagnostic Interview for Children and Adolescents—Revised (DICA-R; Reich, Shayla, & Taibelson, 1992), a structured interview, is used widely among researchers and clinicians. Psychometric evidence specific to SUDs has not been published on the DICA-R, but some of the other sections have been evaluated for reliability and validity (Welner, Reich, Herjanic, Jung, & Amado, 1987). An instrument that has undergone several adaptations is the Diagnostic Interview Schedule for Children (DISC-C; Costello, Edelbrock, & Costello, 1985; Shaffer et al., 1993). Its revised DSM-IV version is the DISC-R (Shaffer, Fisher, & Dulcan, 1996; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000). Separate forms of the interview exist for the child and the parent. As part of a larger study focusing on several diagnoses, Fisher and colleagues (1993) found the DSM-IV-based DISC-C to be highly sensitive in

TABLE 4.3. Comprehensive Assessment Instruments

Instrument	Purpose	Source	Examples of group used	Norms	Normed groups	Format	Time (min)
		<u>Diagnostic interviews</u>					
Adolescent Diagnostic Interview (ADI)	Assess DSM-IV substance use disorders and problems	Winters & Henly (1993)	Adolescents suspected of drug use problems	NA	NA	Structured interview	45
Customary Drinking and Drug Use Record (CDDR)	Assess DSM-IV substance use disorders and problems	Brown et al. (1998)	Adolescents suspected of drug use problems	NA	NA	Structured interview	10–30
Diagnostic Interview for Children and Adolescents—Revised (DICA-R)	Assess DSM-IV child/adolescent disorders	Reich, Shayla, & Taibelson (1992)	Youth suspected mental, behavioral problems	NA	NA	Structured interview	45–60
Diagnostic Interview Schedule for Children—Revised (DISC-R)	Assess DSM-IV child/adolescent disorders	Shaffer, Fisher, & Dulcan (1996)	Youth suspected mental, behavioral problems	NA	NA	Structured interview	45–60
		<u>Problem-focused interviews</u>					
Comprehensive Adolescent Severity Inventory (CASI)	Assess drug use and other life problems	Meyers, McLellan, Jaeger, & Petinati (1995)	Adolescents suspected of drug use problems	NA	NA	Semistructured interview	45–55
Teen Addiction Severity Index (T-ASI)	Assess drug use and other life problems	Kaminer, Bukstein, & Tarter (1991)	Adolescents at risk for drug use problems	NA	NA	Semistructured interview	20–45
		<u>Multiscale questionnaires</u>					
Adolescent Self-Assessment Profile (ASAP)	Multiscale measure of drug use and related problems	Wanberg (1992)	Adolescents suspected of substance use problems	Yes	Normals; substance abusers	225 items, questionnaire	45–60
Hilson Adolescent Profile (HAP)	Multiscale measure of drug use and related problems	Inwald, Brobst, & Morissey (1986)	Adolescents suspected of substance use and related problems	Yes	Normals; substance abusers	310 items, questionnaire	45
Juvenile Automated Substance Abuse Evaluation (JASAE)	Multiscale measure of drug use and related problems	Ellis (1987)	Adolescents suspected of substance use problems	Yes	Normals; substance abusers	108 items	20
Personal Experience Inventory (PEI)	Multiscale measure of drug use and related problems	Winters, Stinchfield, & Henly (1996)	Adolescents suspected of substance use problems	Yes	Normals; substance abusers	276 items, questionnaire	45–60

correctly identifying youth who had received a hospital diagnosis of any SUD ($n = 8$). Both interview forms (parent and child) had a sensitivity of 75%. For the one parent-child disagreement case, the parent indicated not knowing any details about the child's substance use.

The second subgroup of diagnostic interviews primarily focuses on *diagnostic criteria for SUDs*. The Adolescent Diagnostic Interview (ADI; Winters & Henly 1993) assesses diagnostic symptoms associated with psychoactive SUDs. Other sections provide an assessment of substance use consumption history, psychosocial stressors, and level of functioning. Also, screens for several adolescent psychiatric disorders are provided. The authors have developed a revised DSM-IV version of the ADI (ADI-R). Evidence that supports the interview's psychometric properties has been reported (Winters & Henly, 1993; Winters, Latimer, & Stinchfield, 1999; Winters, Stinchfield, Fulkerson, & Henly, 1993; Winters, Latimer, & Stinchfield, 1999). A second SUD-focused interview, the Customary Drinking and Drug Use Record (CDDR; Brown et al., 1998), measures alcohol and other drug use consumption, DSM-IV substance dependence symptoms (including a detailed assessment of withdrawal symptoms), and several types of consequences of drug involvement. There are both lifetime and prior-2-years versions of the CDDR. Psychometric studies provide supporting evidence for this instrument's reliability and validity (Brown et al., 1998). The third instrument in this subgroup, the Global Assessment of Individual Needs (GAIN; Dennis, 1999), is a semistructured interview that covers recent and lifetime functioning in several areas, including substance use, legal and school functioning, and psychiatric symptoms. Very favorable reliability and validity data are associated with the GAIN, including data for the SUDs section when administered to a treatment-seeking adolescent population (Buchan, Dennis, Tims, & Diamond, 2002; Dennis, Funk, Godley, Godley, & Waldron, 2004). A shortened version of the GAIN is under development.

Problem-Focused Interviews

The second major group of comprehensive instruments—problem-focused interviews—measure several problem areas associated with adolescent drug involvement but do not provide a means to obtain a formal diagnosis of an

SUD. The interviews summarized here are adapted from the well-known adult tool, the Addiction Severity Index (ASI; McLellan, Luborsky, Woody, & O'Brien, 1980). Thus, these interviews assess drug use history and related consequences, as well as several functioning difficulties often experienced by drug-abusing adolescents.

The Comprehensive Adolescent Severity Inventory (CASI; Meyers, McLellan, Jaeger, & Pettinati, 1995) measures education, substance use, use of free time, leisure activities, peer relationships, family (including family history and intrafamilial abuse), psychiatric status, and legal history. At the end of several major topics, space is provided for the assessor's comments, severity ratings, and quality ratings of the respondent's answers. An interesting feature of this interview is that it incorporates results from a urine drug screen and observations from the assessor. Psychometric studies on the CASI support the instrument's reliability and validity (Meyers et al., 1995). The other ASI-adapted interview of note, the Teen Addiction Severity Index (T-ASI; Kaminer, Bukstein, & Tarter, 1991), has seven content areas: chemical use, school status, employment-support status, family relationships, legal status, peer-social relationships, and psychiatric status. A medical status section was not included, because it was deemed to be less relevant to adolescent drug abusers. Adolescent and interviewer severity ratings are elicited on a 5-point scale for each of the content areas. Psychometric data indicate favorable interrater agreement and validity evidence (Kaminer, Wagner, Plummer, & Seifer, 1993). Kaminer, Blitz, Burleson, and Sussman (1998) also developed a health service utilization tool that complements the T-ASI, named the Teen Treatment Services Review (T-TSR). This interview examines the type and number of services that the youth received during the treatment episode.

Multiscale Questionnaires

The third group of comprehensive instruments comprise the self-administered multiscale questionnaires. These instruments range considerably in terms of length; some can be administered in less than 20 minutes, whereas others may take a full hour to administer. Yet, as a group, many of them share several characteristics: measures of both drug use problem sever-

ity and psychosocial risk factors are provided; strategies are included for detecting response distortion tendencies; the scales are standardized to a clinical sample; and the option of computer administration and scoring is available. Four examples of instruments in this group are briefly summarized. The Adolescent Self-Assessment Profile (ASAP) was developed on the basis of a series of multivariate research studies by Wanberg (1992). The 225-item instrument provides an in-depth assessment of drug involvement, including drug use frequency, drug use consequences and benefits, and major risk factors associated with such involvement (e.g., deviance, peer influence). Supplemental scales, which are based on common factors found within the specific psychosocial and problem severity domains, can be scored as well. Extensive reliability and validity data based on several normative groups are provided in the manual. The Hilson Adolescent Profile (HAP; Inwald, Brobst, & Morissey, 1986), a 310-item questionnaire (true–false) has 16 scales, two of which measure alcohol and drug use. The other content scales correspond to characteristics found in psychiatric diagnostic categories (e.g., antisocial behavior, depression) and psychosocial problems (e.g., home life conflicts). Normative data have been collected from clinical patients, juvenile offenders, and normal adolescents (Inwald et al., 1986). Another true–false questionnaire, the 108-item Juvenile Automated Substance Abuse Evaluation (JASAE; Ellis, 1987) is a computer-assisted instrument that produces a five-category score, ranging from *No use* to *Drug abuse* (including a suggested DSM-IV classification), as well as a summary of drug use history, measure of life stress, and a scale for test-taking attitude. The JASAE has been shown to discriminate between clinical and nonclinical groups. The Personal Experience Inventory (PEI; Winters & Henly, 1989) comprises several scales that measure chemical involvement problem severity, psychosocial risk, and response distortion tendencies. Supplemental problem screens measure eating disorders, suicide potential, physical–sexual abuse, and parental history of drug abuse. The scoring program provides a computerized report that includes narratives and standardized scores for each scale, as well as other clinical information. Normative and psychometric data are available (Winters & Henly, 1989; Winters, Stinchfield, & Henly, 1996).

METHODS OF DATA COLLECTION AND SOURCES OF INFORMATION

Several types of data collection, when combined, can provide a thorough and accurate account of a young person's drug use history. Parents, peers, professionals, and adolescents themselves can all contribute important information that assists in determining the nature and extent of the drug involvement.

Self-Report

The utilization of a self-report format has been nearly universal throughout clinical and epidemiological studies. Convenience, comprehensiveness, low cost, ease of administration, and the perception that the individual is the most knowledgeable reporter have encouraged the use of this method. Self-report formats include the *self-administered questionnaire* (SAQ), *diagnostic interview*, *timeline follow-back* (TLFB; Sobell & Sobell, 1992), and *computer-assisted interview* (CAI). SAQs are completed independently by an individual, traditionally via paper-and-pencil format. An interview is completed by a trained individual and often yields specific diagnostic data related to SUDs and psychiatric comorbidity. Research on the concordance of SAQ and interview format in clinical and epidemiological samples has varied but for the most part reveals similar levels of disclosure (Stone & Latimer, 2005). The TLFB is a calendar-based tool that compiles a history of drug use over a specified time. The TLFB method uses specific dates and events (e.g., birthdays, holidays, and vacations) to enhance interviewee recollection to elicit a detailed pattern of recent drug use. Research on the psychometric properties of this method indicates favorable reliability and validity evidence (Sobell & Sobell, 1992), including that with adolescents (Dillon, Turner, Robbins, & Szapocznik, 2005). The CAI method has been utilized with drug-abusing adolescent populations (Williams et al., 2000). With this method, the respondent completes an interview independently on a computer, with the questions delivered audibly via headphones. This approach may promote a greater sense of privacy, while the subject responds to potentially sensitive questions. Research comparing CAI to in-person interviews has revealed mixed results. Some studies indicate that the CAI format is associated with higher rates of endorsement of

drug use (e.g., Lapham, Henley, & Kleyboecker, 1993; Turner et al., 1998), yet other studies have found no difference between the methods (Sarrazin, Hall, Richards, & Carswell, 2002). The CAI method, despite the uncertainty of its relative validity compared to other methods, has several advantages: Minimal training of interviewers is needed; many individuals can be assessed at a given time; the sense of privacy for the interviewee is enhanced; and data can be directly entered into a database upon completion of the interview.

The overall validity and reliability of the self-report method of assessment for adolescent drug use remains somewhat ambiguous. Stinchfield (1997) found that adolescents attending a treatment program for drug dependence generally reported notably more past drug use and consequences compared to disclosures at the start of intervention. In other studies, underreporting occurred more frequently with less socially acceptable drugs, such as cocaine or opiates, compared to marijuana (Harrison, 1995; Williams & Nowatzki, 2005). Improved urinalysis techniques (immunoassays), and the more recent sophistication of examining hair strands, are being used to corroborate adolescent self-report of drug use (Dolan, Rouen, & Kimber, 2004). Williams and Nowatzki (2005) reported that some adolescents disclosed drug use in an interview, though the urinalysis conducted immediately after the interview showed a negative finding. Some of this discrepancy was accounted for by limitations in the urinalysis "detection window" for different drugs and individuals' varying metabolic rates, but the authors hypothesized that deliberate fabrication, poor memory, and boastfulness may also have been contributing factors (Williams & Nowatzki, 2005). These findings are not surprising given the circumstances under which an adolescent assessment may be conducted. Defiance, fear, and apprehension can influence the results of an assessment. In addition, youth may see the assessment as an opportunity to "cry for help" and exaggerate their responses. Despite possible limitations, the validity of self-report for adolescent drug use has been supported by several lines of evidence: Only a small percentage of youth endorse improbable questions; adolescent self-reports agree with corroborating sources of information, such as archival records, and for the most part, urinalyses; and the base rate of elevations on

"faking good" and "faking bad" scales are relatively low (Johnston & O'Malley, 1997; Maisto, Connors, & Allen, 1995; Winters, Anderson, Bengston, Stinchfield, & Latimer, 2000; Winters, Stinchfield, Henly, & Schwartz, 1990–1991).

Drug Testing

Four biologically based tests (urine, hair, saliva, and sweat) are currently utilized to detect drugs in the body (Dolan et al., 2004). The main aspect that distinguishes these specimens is the period or window of time for which the drug can be detected. In addition, cost, access, tampering vulnerability, invasiveness, and reliability–validity are other factors that differentiate these biological sampling procedures. Urinalysis is the most commonly used procedure to detect drug use and to validate self-report. The window of detection varies considerably for illicit drugs; the detection period for alcohol is only about 8 hours. Tampering can be minimized by directly monitoring collection of the urine. Hair analysis has been utilized more commonly to detect exposure to drugs over a longer period of time than that afforded by urine testing (Dolan et al., 2004). A hair sample of approximately pencil width in size is necessary for accurate testing. However, significant limitations in hair analysis exist. Chemical processing, differences in hair structure, growth, porosity, and hygiene, along with exposure to drugs in the air (e.g., marijuana smoke) have all been shown significantly to impact the concentrations of drugs in the hair (see Kidwell & Blank, 1996; Kidwell, Lee, & DeLauder, 2000; Reid, O'Connor, Deakin, Ivery, & Crayton, 1996; Sachs, 1995; Rohrich, Zornlein, Pötsch, Skopp, & Becker, 2000). The testing of saliva to detect drug exposure is still being refined. Advantages of this method include a noninvasive collection and the detection of very recent drug use (12–24 hours). However, the cost of saliva analysis is greater than that for urinalysis, and several collection requirements may be difficult to enforce (e.g., individual must refrain from eating, drinking, or smoking up to 30 minutes prior to sample collection). A final biological assay to detect illicit drugs is sweat. A sweat patch provides an estimate of drug exposure over several days (Dolan et al., 2004). Disadvantages with this technique include accidental or purposeful re-

removal of the patch during the evaluation period and the lack of validation of this technology.

Clinical Observation

In addition to self-report and biological tests, direct observation by the assessor for behavioral and psychological symptomatology may be an objective and useful supplement to adolescent drug use assessment. A simple checklist of items, such as the presence of needle marks, unsteady gait, slurred or incoherent speech, shaking of hands or twitching of eyelids, and so forth, can indicate problematic use. A 14-item checklist of observable signs that may indicate a drug problem is contained in the Simple Screening Instrument for AOD Abuse (SAMHSA, 1994).

Parent Report

Although parent report is relatively valid in the identification of many mental health problems, such as ADHD and conduct problems, it is unlikely that parents can provide detailed reports about the types, frequency, and quantity of drug use by their son or daughter. Winters, Stinchfield, Opland, Weller, and Latimer (2000) found that parents tend to underreport the extent to which their adolescent experiments with drugs. Parental reports may be helpful, however, in providing valuable information on risk and protective factors associated with drug use.

Peer Report

Collecting information from an adolescent's friends may prove to be a valuable resource, especially if the peers are not currently using drugs or are in recovery. Peers may be able to detail a change in an adolescent's recent behavior or provide information substantiating drug use behaviors they witnessed or in which they collaboratively participated.

Archival Records

Data collected from sources other than family and friends may help to document the severity of an adolescent's drug use and identify resulting consequences. Archival records include information from school reports, police reports, and medical records.

ASSESSMENT FOR TREATMENT PLANNING AND OUTCOME EVALUATION

Treatment Planning

The primary goal of assessment is to establish client characteristics that may influence treatment planning and ultimately contribute to the success of treatment (Donovan, 2003). Treatment planning involves the integration of the client's drug use involvement, drug-related problems, and other areas of psychosocial functioning to assist in developing and prioritizing short- and long-term goals for treatment, selecting the most appropriate treatment approaches to address the identified problems, identifying perceived barriers to treatment engagement and compliance, and monitoring progress toward the specified treatment goals (Allen, 1991). As an example of how assessment may inform treatment referral decisions, we propose a general referral model for matching level of treatment, and severity of drug involvement and related problems (see Table 4.4). The model presents three levels of treatment: brief intervention, nonintensive drug treatment, and intensive drug treatment. Brief interventions are appropriate responses for adolescents with relatively mild drug involvement problems, such as when an individual meets a diagnosis for a substance abuse disorder (Winters et al., 2007). On the other hand, nonintensive and intensive drug treatments are more specialized; thus, they are more appropriate for youth who meet criteria for a substance dependence disorder. The referral model becomes more complex as more client characteristics are included in the decision-making process. For example, an adolescent with a mild drug use problem who also has ADHD may require more treatment than a brief intervention.

Evaluating Outcome

Quality drug use assessment tools are not only crucial in the identification of youth who abuse drugs but also invaluable in the multifaceted evaluation of drug treatment programs. These instruments help to identify the types of clients the centers are serving (e.g., type of substance abused; gender, ethnic, and racial information), determine the efficacy of a program, including distinct intervention strategies; provide data for a cost-benefit analysis; and document areas for necessary program enhancement. Treat-

TABLE 4.4. Guidelines for Drug Abuse Treatment Placement along a Continuum of Care

Level of intervention or treatment	Suggested characteristics
Brief intervention (2–4 sessions)	Mild-to-moderate drug use; absence of dependence disorder, polydrug use pattern, abuse coexisting with psychiatric disorder, relatively supportive and stable home life.
Low-intensive treatment (e.g., 7–20 days or sessions)	Substance abuse disorder(s), or a single substance dependence disorder with recent onset; if a coexisting disorder is present, then mild symptoms; relatively supportive and stable home life.
Intensive treatment (e.g., 21 or more days or sessions)	Substance dependence disorder; severe coexisting disorder present; relatively unsupportive and unstable home life.

ment outcome information is useful to treatment providers not only in terms of outcomes but also to obtain an overview of the clientele coming for treatment and to improve treatment and obtain improved outcomes. Therefore, treatment program staff need scientifically valid information about the effectiveness of their treatment programs.

Researchers have outlined parameters for selecting treatment outcome evaluation tools (Newman, Ciarlo, & Carpenter, 1999). Some of the guidelines are related to the need to develop a sound and valid evaluation plan, such as gathering input from multiple respondents (e.g., youth and parent) and using measures that are relevant to the target group and associated with objective referents and adequate psychometric properties. Other guidelines are important in the context of developing a useful evaluation of the program, such as including measures that assess extent of engagement by the client in treatment, and other treatment process variables and perceived satisfaction with clinical services. We are familiar with three treatment evaluation tools that are generally consistent with these outcome instrumentation guidelines. Each represents an evaluation version of their intake assessment “cousin”: the ADI (Winters & Henly, 1993), the CASI (Meyers et al., 1995), and the GAIN (Dennis, 1999). These three instruments were reviewed in an earlier section, “Comprehensive Assessment Instruments.”

SUMMARY

Drugs are prevalent among teenagers in the United States; nearly half of American eighth graders reported having already used alcohol

(Johnston et al., 2005). To complicate the issue, researchers have found that drug use frequently co-occurs with psychological disorders (Clark & Bukstein, 1998; Rhode et al., 1996), making the assessment process even more complex. In addition, new research on neurobiology has revealed differences in the adolescent brain that bring to light the importance of distinguishing between “normal” use and an SUD. Given this large proportion of drug-using youth, along with these other commonly mitigating factors, the need for efficient, easily administered, and psychometrically sound assessment tools is even more imperative.

The evaluation of adolescent drug use has evolved over the past 15 years, with methodology becoming more distinct from adult procedures and taking into account numerous developmental considerations. Multiple valid, reliable screening and comprehensive measures are available to assess not only level but also patterns of use accompanying drug use behaviors, comorbidity, and outcome. The continued development of new and improved biological assays is a welcome accompaniment to methods of self-report. Valid and reliable adolescent drug assessment is key to understanding the true scope of adolescent drug involvement, identifying biological indicators and behavior patterns associated with risk for the development of an SUD, obtaining a more thorough and ongoing understanding of the costs to society, and evaluating short- and long-term outcomes.

Nonetheless, future research is needed to fill important measurement gaps. Many tests do not report validity evidence among subpopulations of young people defined by age, race, and type of setting (e.g., juvenile detention program, treatment program). And most measures

have not been formally tested to determine their adequacy as a measure of change (Stinchfield & Winters, 1997). A good measure of change should meet the condition that its standard error of measurement is sufficiently minimal to permit its use in detecting small to medium change over time (Jacobson & Truax, 1991). As we have already noted, it is unclear whether the distinction between substance abuse and dependence is diagnostically meaningful when applied to adolescents, and there is a need to improve our measurement of individual abuse and dependence criteria for youth, given that some criteria appear to have questionable relevance when applied to young people (Martin & Winters, 1998). A related unresolved area is the need for more precise identification of related psychosocial problems that may contribute to the onset and maintenance of drug involvement. Many existing tools assess psychosocial risk factors historically, which does not permit an understanding of the extent to which risk factors may precede the drug use or be a consequence of it.

PART III

Mood Disorders and Suicide Risk

Child and Adolescent Depression

**Karen D. Rudolph
Sharon F. Lambert**

Depression strikes a significant minority of youth during critical stages of development, with a particularly high prevalence during adolescence (for reviews, see Lewinsohn & Essau, 2002; Rudolph, Hammen, & Daley, 2006). Moreover, depression frequently follows a pernicious course across development and creates impairment in many spheres of youths' lives. Given these features of depression, there is a great need for assessment methods that allow for the accurate identification of depression, and for the evaluation of prevention and intervention efforts with depressed youth. Determining the most appropriate assessment strategy is a complicated endeavor that requires both a thorough understanding of the heterogeneous nature and causes of depression, and a careful consideration of the goals and targets of assessment.

This chapter presents an overview of contemporary issues and methods in the assessment of youth with depression. To provide a background for evaluating various assessment approaches, we first summarize the basic features and causes of youth depression. This discussion emphasizes the need to consider developmental aspects of the disorder and to place our understanding of depression within the context of emerging knowledge about gender, ethnic, and cultural

differences in the phenomenology and etiology of depression. Second, we discuss major considerations that arise in determining the optimal approach for assessing youth with depression. Third, we provide a critical, selective review of the predominant methods of assessment, with a focus on those that have established reliability, validity, and clinical utility.

DESCRIPTION OF YOUTH DEPRESSION AND DIAGNOSTIC ISSUES

Developing a comprehensive base of knowledge about depression in young people has been complicated by the heterogeneous taxonomic systems that psychologists use to conceptualize depression. This heterogeneity creates a challenge for psychologists in several areas: delineating basic clinical characteristics of depression (e.g., prevalence, course), determining the etiology of depression, selecting appropriate assessment approaches, and evaluating the efficacy and effectiveness of prevention and intervention efforts. Here we present a brief summary of taxonomic issues relevant to depression (for comprehensive reviews, see Compas, Ey, & Grant, 1993; Klein, Dougherty, & Olino, 2005).

Taxonomy of Depression

Psychologists use three different broad approaches to define depression (Compas et al., 1993). The first approach, which focuses on depressed *mood*, views depression as an individual symptom of unhappiness. Depressed mood is most often assessed via self-report on checklists. The second approach, which focuses on the depressive *syndrome* (i.e., an empirically derived constellation of behaviors and emotions that cluster together in multivariate analyses), views depression in terms of quantitative deviations in levels of symptoms that vary along a continuum. Although the most widespread application of this approach suggests that depressive symptoms cluster together with anxiety symptoms into an anxious–depressive syndrome in youth (e.g., Achenbach, Connors, Quay, Verhulst, & Howell, 1989), researchers also have established validity for a cluster of pure depressive symptoms (e.g., Lengua, Sadowski, Friedrich, & Fisher, 2001). The depressive (or anxious–depressive) syndrome most often is assessed via multi-informant (e.g., youth, parent, teacher) report on behavior checklists. The third approach, which focuses on depression as a *diagnosis*, views depression as a categorical disorder that is distinguished along quantitative (e.g., number of symptoms) and qualitative (e.g., change from prior functioning, significant levels of distress and impairment) dimensions. According to this approach, most commonly reflected in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR; American Psychiatric Association, 2000) and the International Classification of Diseases (ICD-10; World Health Organization, 1993), depression is characterized by features such as number and configuration of symptoms, frequency, severity, duration, and associated disability. Diagnoses of depression are assessed through structured, clinician-administered interviews. Although there is some overlap among these three conceptualizations of depression (e.g., the presence of negative affectivity), there also are distinct characteristics (e.g., the depressive syndrome often includes symptoms other than depression, such as anxiety; somatic and vegetative symptoms are not well represented in the mood or syndrome definitions). Which conceptualization of depression is applied greatly influences the selection of assessment approaches, the information derived from assessment, and the implications of

this information for treatment planning and evaluation.

A related, long-standing debate concerns whether depression is best conceptualized as a discrete category or as a continuum of symptoms (Klein et al., 2005). On the one hand, it has been argued that subsyndromal symptoms and clinical depression represent qualitatively different phenomena. On the other hand, research indicates that subsyndromal forms of disorder are associated with significant functional impairment and future risk for major depression (Angst, Sellaro, & Merikangas, 2000; Pine, Cohen, Cohen, & Brook, 1999). Recent taxometric analysis reveals that depression in youth is better conceptualized along a continuum than as a discrete entity (Hankin, Fraley, Lahey, & Waldman, 2005). This evidence, combined with the impairment associated with subsyndromal depression, suggests that it is important to assess not only clinical depression but also the presence of mild, enduring symptoms that might portend functional impairment and a more severe disorder in the future. This is especially important in youth, because even mild depressive symptoms may interrupt normative developmental trajectories, potentially resulting in impairment that persists beyond the symptoms.

Diagnostic Criteria and Associated Features

In a categorical approach, depressive disorders are a subset of the mood disorders. In this chapter, we focus on the description and assessment of unipolar depression (see Youngstrom, Chapter 6, this volume, for a discussion of pediatric bipolar disorder). DSM-IV-TR criteria for a major depressive episode (MDE) are depressed or irritable mood and/or loss of pleasure, combined with at least four somatic or cognitive symptoms (see Table 5.1). Symptoms must persist at least 2 weeks and cause impaired functioning or significant distress. Criteria for dysthymic disorder are chronic mood symptoms, combined with at least two somatic or cognitive symptoms (see Table 5.1). Symptoms must persist at least 1 year. Some researchers have questioned whether the distinction between major depressive disorder (MDD) and dysthymia is meaningful, although data indicating more significant impairment in youth with “double depression” (both MDD and dysthymia; Goodman, Schwab-Stone, Lahey, Shaffer, & Jensen, 2000) suggest that indepen-

TABLE 5.1. DSM-IV-TR Diagnostic Criteria for Depressive DisordersMajor Depressive Disorder

- A. Five (or more) of the following symptoms during the same 2-week period; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
- (1) depressed mood most of the day, nearly every day, as indicated by either subjective report or observation made by others. Note: In children and adolescents, can be irritable mood.
 - (2) markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)
 - (3) significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. Note: In children, consider failure to make expected weight gains.
 - (4) insomnia or hypersomnia nearly every day
 - (5) psychomotor agitation or retardation nearly every day (observable by others)
 - (6) fatigue or loss of energy nearly every day
 - (7) feelings of worthlessness or excessive or inappropriate guilt nearly every day
 - (8) diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
 - (9) recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

Major Depressive Episode (unipolar) can be further specified as mild, moderate, severe (based on functional impairment and severity of symptoms), with or without psychotic features, with or without melancholic features, whether or not recurrent, or chronic.

Dysthymic Disorder

- A. Depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years. Note: In children and adolescents, mood can be irritable and duration must be at least 1 year.
- B. Presence, while depressed, of two (or more) of the following:
- (1) poor appetite or overeating
 - (2) insomnia or hypersomnia
 - (3) low energy or fatigue
 - (4) low self-esteem
 - (5) poor concentration or difficulty making decisions
 - (6) feelings of hopelessness
- C. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without symptoms in Criteria A and B for more than 2 months at a time.
- D. No Major Depressive Episode during the first 2 years of the disturbance (1 year for children and adolescents); i.e., the disturbance is not better accounted for by chronic Major Depressive Disorder, or Major Depressive Disorder, In Partial Remission).

Note Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*. Copyright 2000. American Psychiatric Association.

dent assessment of the two conditions is worthwhile.

Youth depression also might include psychotic symptoms (Mitchell, McCauley, Burke, & Moss, 1988) and endogenous features, such as lack of reactivity, distinct quality of mood, and diurnal variation (McCauley et al., 1993). In addition to the core diagnostic criteria, depression in youth frequently is associated with social withdrawal (Bell-Dolan, Reaven, & Peterson, 1993; Puura et al., 1998), somatic complaints (Puura et al., 1998; Ryan et al., 1987), and body image dissatisfaction, particularly in adolescent girls (Wichstrom, 1999).

Epidemiology of Depression

Prevalence

Prevalence estimates vary according to the conceptualization of depression (i.e., as a mood, syndrome, or disorder). In community samples, epidemiological surveys reveal lifetime depressive disorders prevalence rates of less than 3% in preadolescents and 15–20% in adolescents (for reviews, see Kessler, Avenevoli, & Merikangas, 2001; Lewinsohn & Essau, 2002). A growing body of research indicates that the prevalence of depression has increased in recent birth cohorts (Kessler et al., 2001).

In addition to diagnosable depression, a significant minority of youth experience depressed mood, subsyndromal symptoms, and minor depression. Depending on the informant (e.g., youth vs. parent), age, and gender, 10–40% of youth experience an unhappy, sad, or depressed mood (Achenbach, 1991; Compas et al., 1993). Use of formal diagnostic criteria indicates that 10–20% of youth experience subsyndromal levels of symptoms or minor depression (e.g., Kessler & Walters, 1998; Roberts, Lewinsohn, & Seeley, 1991), whereas self-reports of symptoms indicate that 20–50% of youth exceed conventional cutoffs for clinically significant levels of depression (Kessler et al., 2001). As discussed earlier, these elevated levels of symptoms are meaningful and may forecast more severe disorders in the future.

Age of Onset, Clinical Features, and Developmental Course

Retrospective studies of depressed adults and prospective studies of youth suggest that major depression is most likely to emerge during the

midadolescent years (about ages 13–15), with a somewhat younger age of onset for dysthymia (e.g., Burke, Burke, Regier, & Rae, 1990; Hankin et al., 1998; Lewinsohn & Essau, 2002). In community samples of untreated youth, MDEs have a median duration of about 8 weeks (Lewinsohn, Rohde, & Seeley, 1994). Longer mean durations (e.g., 7 to 9 months) generally are found in clinical versus community samples (e.g., Birmaher, Arbeleaz, & Brent, 2002; Kovacs, 1996). Dysthymic disorder has a mean duration of 4 years, and many youth with dysthymia eventually experience MDEs (for a review, see Birmaher et al., 1996).

Although the majority of MDEs remit within a few months, with almost all remitting within 2 years (for a review, see Birmaher et al., 1996), depression frequently has a recurrent or chronic course, with continuity across time and developmental periods (Birmaher et al., 2002; Kessler et al., 2001). Self-reported symptoms also show significant stability over several years (Verhulst & van der Ende, 1992). Risk for chronicity and recurrence is predicted by a variety of factors, such as severity, personal or family history of MDD, suicidality, comorbidity, negative beliefs, and family adversity (Birmaher et al., 2002; Rohde, Lewinsohn, Klein, & Seeley, 2005).

Research suggests that adolescent-onset depression is likely to portend depression in adulthood. Large-scale studies of community samples (e.g., Lewinsohn, Rohde, Klein, & Seeley, 1999; Pine, Cohen, Gurley, Brook, & Ma, 1998) and studies of clinical samples (Birmaher et al., 2002; Weissman, Wolk, Goldstein, et al., 1999) demonstrate significant continuity in depressive diagnoses from adolescence through young adulthood. Continuity of depression from childhood to adulthood is less clear. Although a subgroup of youth with childhood-onset symptoms and disorders go on to experience depression in adulthood (i.e., *disorder-specific continuity*), particularly those with recurrent childhood depression and family histories of depression (Weissman, Wolk, Wickramaratne, et al., 1999), a significant majority, particularly those with comorbid disruptive behavior disorders, demonstrate *disorder-nonspecific continuity*, that is, high rates of psychological disorders and adjustment difficulties other than depression at later developmental stages (Harrington, Fudge, Rutter, Pickles, & Hill, 1990). This pattern suggests

that certain childhood-onset depressive disorders might be a different form of depression than those with an onset in adolescence or adulthood. However, more research is needed to clarify dimensions on which the forms of disorder might differ across developmental stages.

In summary, depression often emerges during adolescence and follows a recurrent course, with a great deal of associated impairment. However, most depressive episodes do remit naturally. These characteristics of depression have important implications for the selection and implementation of assessment strategies in the context of treatment planning and evaluation. For example, assessment protocols need to account for the fact that improvement might be expected over time even in nontreated youth, but recurrence is the rule rather than the exception.

Associated Comorbid Disorders

Research reveals high rates of co-occurrence between depression and other symptoms and disorders in youth. A meta-analysis by Angold, Costello, and Erkanli (1999), using a categorical approach, revealed significant comorbidity between depression and anxiety disorders (odds ratio [OR] = 8.2), conduct/oppositional defiant disorders (OR = 6.6), and attention-deficit/hyperactivity disorder (OR = 5.5). Depression also co-occurs frequently (rate of 20%) with substance use disorders in adolescents (Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993). Research that uses a continuous approach also reveals significant covariation between depression and other forms of internalizing distress (e.g., anxiety, somatic problems), as well as externalizing behavior problems (e.g., aggression, oppositionality).

A variety of explanations might account for these high rates of co-occurrence. "Artifactual" comorbidity might reflect problems with the specificity of assessment tools, or with the taxonomic systems on which diagnostic categories are based (Angold et al., 1999). True comorbidity might result from the presence of shared risk factors (e.g., genetic liability for depression and anxiety), co-occurring risk factors (e.g., co-occurring parental depression and family discord, creating a risk for both youth depression and youth conduct disorder), or a causal relation between two disorders (e.g., disruptions in social and academic functioning associated

with behavior disorders, creating a risk for depression). Distinguishing between artifactual and true comorbidity is a crucial goal for the development and application of valid assessment approaches. Knowledge about functional relations between other disorders and subsequent depression can guide early identification of youth who may be at risk for depression due to the disruptive influence of earlier anxiety or behavior problems. Unfortunately, as we discuss later, because many assessment instruments show poor specificity for depression, it is difficult to distinguish between artifactual and true sources of comorbidity.

Progress has been made in understanding the high rates of co-occurrence between depression and anxiety (Watson et al., 1995). Historically, the high co-occurrence between these disorders led psychologists to question their distinctiveness. However, contemporary conceptualizations and assessment instruments emphasize both shared and unique components of the two disorders. For example, the tripartite model (Watson et al., 1995) distinguishes among three major clusters of affective symptoms: negative affect or general emotional distress (common to anxiety and depression), physiological arousal or somatic tension (unique to anxiety), and anhedonia or lack of positive affect (unique to depression). Preliminary research supports the tripartite model in youth, with some differences across age and gender (e.g., Chorpita, Daleiden, Moffitt, Yim, & Umemoto, 2000; Jacques & Mash, 2004; for a review, see Laurent & Ettelson, 2001). Additional research is needed to develop assessment instruments that identify overlapping and distinct features of depression and disorders that frequently co-occur with depression.

Developmental Features

Diagnostic criteria are the same in youth and adults, except for the inclusion of irritability as one of the mood disturbances and a shorter duration criterion for dysthymia in youth. However, there are some developmental differences in the expression of symptoms and in the structure of the depressive syndrome (for reviews, see Hammen & Rudolph, 2003; Weiss & Garber, 2003). With regard to symptom expression, depressed young children show more depressed appearance, somatic complaints, and irritability, whereas depressed adolescents show more anhedonia, vegetative symptoms

(e.g., eating and sleeping difficulties), and diurnal variation of mood. With regard to the structure of symptoms, factor analysis reveals that vegetative symptoms, affective symptoms, and concerns about the future are more a part of depression in adolescents, whereas cognitive symptoms and externalizing behavior are more a part of depression in preadolescents. Patterns of comorbidity also differ somewhat by age. For example, depressed preadolescents are more likely to display separation anxiety, whereas depressed adolescents are more likely to display eating disorders (particularly females) and substance use disorders (particularly males) (e.g., Lewinsohn et al., 1993). These developmental patterns can inform decisions about which associated disorders should be thoroughly assessed.

Gender Differences

One of the best established findings in depression research concerns the emergence of higher rates of depression in girls than in boys at about 13–15 years of age (Hankin et al., 1998; Wichstrom, 1999; for a review, see Hankin & Abramson, 2001). This sex difference is robust across conceptualizations of depression as a mood, syndrome, and disorder, although the difference is more consistent in referred than in nonreferred samples (Compas et al., 1997).

Several models that have been proposed to explain the origins of sex differences in depression focus on the role of hormonal changes and pubertal maturation, stress and coping, and interpersonal processes that characterize the adolescent transition (for reviews, see Hankin & Abramson, 2001; Nolen-Hoeksema, 2002; Rudolph et al., 2006). Collectively, these theories and supportive evidence suggest that heightened risk for depression in adolescent girls is driven by interactions among biological and social aspects of puberty; an interpersonal orientation that emphasizes affiliation and social approval; heightened exposure and sensitivity to interpersonal stress; and a ruminative style of responding to depressive symptoms and stressors. Moreover, girls experience more adverse interpersonal consequences of depression, such as deterioration in close friendships (for a review, see Rudolph, Flynn, & Abaid, in press). Appreciation for this backdrop of risk in adolescent girls can guide early identification of youth who are likely to be vulnerable during the adolescent transition, as well as highlight

potential disruptions that might emerge following the onset of a depressive episode in girls. Assessment efforts can then be directed toward the appropriate domains of vulnerability and disruption.

Ethnic and Cultural Considerations

Few epidemiological studies include samples with sufficient ethnic diversity to compare rates of depression in youth from different ethnic backgrounds, and findings are mixed. Some research indicates no differences in rates of depression across ethnic groups (e.g., Costello et al., 1996; Kandel & Davies, 1982; Manson, Ackerson, Dick, Baron, & Fleming, 1990), whereas other research suggests that ethnic/minority youth have higher rates of depression. For example, in a large epidemiological survey examining differences in rates of adolescent depressive symptoms, African American, Hispanic, and Asian adolescents reported significantly more depressive symptoms than did white adolescents (Rushton, Forcier, & Schectman, 2002), but specific differences between groups were not described. In another large study using an ethnically diverse sample, adolescents reported few differences in the prevalence of MDD across nine ethnic groups, with the exception of higher rates for Mexican American youth (Roberts, Roberts, & Chen, 1997), after adjustment for age, gender, and socioeconomic status. Similarly, Latino adolescents reported greater depressed mood than did African American, Asian American, and white adolescents, independent of socioeconomic status (Siegel, Aneshensel, Taub, Cantwell, & Driscoll, 1998). Unfortunately, it is difficult to draw firm conclusions about differences in the prevalence of depression due to different methods for assessing depression, inclusion of different racial and ethnic groups across studies, and examination of racial groups without attention to ethnicity (Chang, 2002). In addition, findings may vary depending on whether socioeconomic status is taken into account (e.g., Doi, Roberts, Takeuchi, & Suzuki, 2001).

There is some evidence that correlates and predictors of depressive symptoms vary across ethnic groups. For example, Hayward, Gotlib, Schraedley, and Litt (1999) found that pubertal status was a better predictor of depressive symptoms than chronological age in white adolescents as compared to African American and Hispanic adolescents. Dolan, Lacey, and Evans

(1990) reported that disordered eating and depression were correlated for white but not Afro-Caribbean adolescents. There also is evidence to suggest that youth of different ethnicities experience depression differently. In one study comparing the factor structure of the Children's Depression Inventory in African American and white inpatient youth, African American youth were less suicidal but scored higher on behavioral dimensions of depression, whereas white youth scored higher on affective dimensions (Politano, Nelson, Evans, Sorenson, & Zelman, 1986).

It is important to note that sole reliance on race or ethnic status to examine group differences in youth depression can be problematic. Conceptions of depression might vary across cultures, having implications for whether or not youth are referred for treatment, how symptoms manifest, and how individuals describe their symptoms (Choi, 2002; Okazaki, 2000). Culture also might influence the behaviors that clinicians observe during an assessment. For example, in some cultures, youth are socialized to display deferential behavior to authority figures (Yee, Huang, & Lew, 1998), which may include limited eye contact and limited initiation of verbal interaction. Similarly, youth whose cultural norms include suppressing emotions and keeping problems in the family might limit self-disclosure of their own difficulties and restrict their display of emotions with the clinician (Yeh & Yeh, 2002). Because some correlates of depression might indicate positive adjustment in certain cultures, it is important for clinicians to consider cultural factors when interpreting data obtained from depression assessment measures.

Culture also has important implications for the validity and utility of measures to assess depression. A scale developed and normed in one cultural group might not assess the same construct or have the same psychometric properties in another group (Arnold & Matus, 2000). Cross-cultural differences in language used to describe depression also are important to consider. For example, whereas psychological and physical symptoms typically are considered separate entities in mainstream American culture, these two sets of concerns are integrated in many Asian cultures (Ying, 2002); thus, youth from these cultures might describe their depressive symptoms in terms of somatic rather than affective concerns. Relatedly, linguistic issues, such as language proficiency and ethnic

language variations, might affect the assessment of depression in diverse youth (Choi, 2002). Linguistic concerns are not addressed by translation alone, because translation does not necessarily indicate cultural equivalence of constructs assessed.

Research is needed to examine the validity of instruments to assess depression in youth from different racial, ethnic, cultural, and linguistic backgrounds, as well as the strength of their psychometric properties across diverse groups. In addition, assessments with diverse youth must include an evaluation of other factors with particular relevance to depression that vary across racial and ethnic groups, including ethnic identity (e.g., Roberts et al., 1999), acculturation and acculturative stress (Hovey & King, 1996), immigration history, and experiences with racism and discrimination (Hammack, 2003; Nyborg & Curry, 2003), each of which has been linked to depression in ethnic minority youth. Because ethnicity and culture can have a significant impact on both the assessment process and the interpretation of assessment results, a comprehensive evaluation of depression should consider these factors.

Domains of Impairment

Youth depression is associated with impairment in several key life domains. Depressed youth demonstrate compromised academic performance, interpersonal difficulties (e.g., social withdrawal, conflict in relationships), negative self-perceptions, and disruptions in important social roles, as reflected in problems such as school dropout and early pregnancy (for reviews, see Garber & Horowitz, 2002; Hammen & Rudolph, 2003; Rudolph et al., 2006). A particularly dangerous correlate of depression is suicidal ideation and attempts (see Goldston & Compton, Chapter 7, this volume, for a discussion of suicidal behavior). Although research is inconsistent regarding the stability of impairment and its endurance beyond acute depressive episodes, a growing body of evidence suggests that depression predicts subsequent difficulties in the psychological, academic, and social realms (e.g., Cole, Martin, Peeke, Seroczynski, & Hoffman, 1998; Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1993; Pomerantz & Rudolph, 2003), and that depressed youth experience some ongoing impairment even fol-

lowing remission or successful treatment of depression (Puig-Antich et al., 1985; Rao et al., 1995). Youth with depression also often develop new comorbid disorders, including substance use, anxiety, and personality disorders (e.g., Lewinsohn et al., 1999; Weissman, Wolk, Goldstein, et al., 1999). Moreover, depression early in life predicts impairment into adulthood (Lewinsohn, Rohde, Seeley, Klein, & Gotlib, 2003; Weissman, Wolk, Goldstein, et al., 1999). These correlates and consequences of depression indicate the need to assess multiple domains of functioning along with the core symptoms.

ETIOLOGY OF YOUTH DEPRESSION

Contemporary conceptualizations of youth depression have two defining characteristics with implications for assessment (for reviews, see Cicchetti & Toth, 1998; Garber & Horowitz, 2002; Hankin & Abramson, 2001; Rudolph et al., 2006). First, recent perspectives focus on interactional and transactional influences among biological, cognitive, interpersonal, and contextual factors in the onset and maintenance of depression. This integrative focus highlights the need to evaluate diverse areas of impairment in addition to formal diagnostic criteria and related symptoms. Assessing these areas of impairment can (1) facilitate the identification of youth at particular risk for depression, (2) guide predictions about the course of depression, (3) help determine collateral targets for intervention (e.g., family adversity, interpersonal difficulties, academic deficits), and (4) provide information about potential processes of change over the course of treatment (e.g., whether improvement in social-cognitive processes predicts declines in depressive symptoms). Second, recent perspectives emphasize a developmental approach to understanding youth depression, with an elaboration of both similarities and differences in the nature, course, risk factors, and consequences of depression across the lifespan. This developmental focus highlights the need to consider the developmental stage of youth in selection of appropriate assessment strategies and formulation of hypotheses about potential causes and consequences of depression. Here we provide a brief overview of the major components of integrative models of youth depression. Later in the chapter, we provide a more detailed review

of key constructs and measures that assess different aspects of these models.

Genetic Influences

Research using a variety of methods establishes a strong aggregation of depression in families. Indeed, a family history of depression, particularly in a parent, is one of the best predictors of depression, especially recurrent depression (Klein, Lewinsohn, Rohde, Seeley, & Durbin, 2002) in youth (for a review, see Goodman & Gotlib, 1999). Moreover, biometric modeling studies that provide direct assessments of heritability reveal a significant genetic component to depression (estimates of 20–45% for milder forms and 40–70% for severe forms); heritability seems to be particularly high during adolescence (for reviews, see Sullivan, Neale, & Kendler, 2000; Wallace, Schneider, & McGuffin, 2002). Genetic liability may be coupled with environmental risks linked to parental depression, such as family adversity and problematic parenting styles (Kessler et al., 2001). This consistent evidence for the family transmission of risk indicates that a comprehensive evaluation of youth depression should include a thorough assessment of current symptoms and past history of parental affective disorder.

Biological Influences

Research examining biological vulnerability to depression focuses primarily on four areas: dysregulation of neuroendocrine systems; disruptions in neurotransmitter processes; dysregulation of biological rhythms, as reflected in sleep patterns; and atypical activation of particular brain regions, especially the left frontal cortex. Studies of these biological processes reveal somewhat inconsistent evidence regarding patterns of dysregulation in depressed youth.

Adult depressives demonstrate consistent abnormalities in the hypothalamic–pituitary–adrenal (HPA) axis, suggesting dysregulation of the stress response system (for a review, see Thase, Jindal, & Howland, 2002). Specifically, depression in adults is associated with higher levels of basal cortisol, abnormal responses to the dexamethasone suppression test (DST; used to measure the response of the adrenal glands to adrenocorticotrophic hormone [ACTH]), and abnormalities in corticotropin-releasing factor (CRF). Differences in basal cortisol and re-

sponses to CRF infusion are not apparent in depressed youth (Kaufman, Martin, King, & Charney, 2001; Kutcher et al., 1991). Although depressed children, and adolescents to a lesser extent, do demonstrate nonsuppression of cortisol on the DST at rates similar to those of depressed adults, the specificity of this index to youth depression is unclear (Kaufman et al., 2001). Depressed preadolescents also show blunted growth hormone responses to pharmacological stimulation (Dahl et al., 2000). This atypical response persists following remission of depression (Dahl et al., 2000) and is present in high-risk youth with no personal history of depression (i.e., those with depressed parents; Birmaher et al., 2000), suggesting that it might be an important marker of a predisposition to depression (for a review, see Kaufman et al., 2001).

Some research indicates abnormalities of the serotonergic neurotransmitter system in depressed youth. For example, both high-risk and currently depressed youth demonstrate atypical responses (blunted cortisol and increased prolactin) to a pharmacological challenge, namely administration of L-5-hydroxytryptophan (L-5HTP) (Birmaher et al., 1997). Moreover, recent research suggests that a polymorphism in the serotonin transporter (5-HTT) gene serves as a vulnerability to depression in the face of life stress (Caspi et al., 2003). Efficacy of antidepressants that target serotonergic systems (selective serotonin reuptake inhibitors [SSRIs]) also indirectly implicates disrupted neurotransmitter systems in depressed youth (e.g., Emslie et al., 1997).

Research on sleep abnormalities in depressed youth yields mixed findings. Depressed adolescents show some similar patterns of disruption to those of adults, including reduced rapid-eye-movement (REM) latency and increased REM density, although conflicting results emerge for other sleep disturbances. Moreover, studies of sleep behavior and neurophysiology in younger depressed children do not reveal similar abnormalities (Birmaher et al., 1996; Kaufman et al., 2001). Inconsistent findings across studies and developmental differences in the nature and function of sleep suggest that measures of sleep abnormalities are not likely to be useful diagnostic tools for youth depression (Emslie, Rush, Weinberg, Rintelmann, & Roffwarg, 1994).

Both structural and functional brain abnormalities have been linked to depression in

adults, including reduced blood flow and metabolism in the prefrontal cortex, reductions in amygdala volume, and hippocampal abnormalities (for a review, see Davidson, Pizzagalli, & Nitschke, 2002). Moreover, electrophysiological research in adults with depression reveals relative hypoactivation in the left frontal cortex, suggesting possible underactivation of brain systems that drive the experience of pleasure and positive engagement (Davidson et al., 2002). Few studies have been conducted with youth; thus, little is known about the relevance of these findings for youth depression. However, research does reveal similar patterns of asymmetry (i.e., relative left frontal hypoactivation) in the infants and toddlers of depressed mothers (Dawson, Frey, Panagiotides, Osterling, & Hessler, 1997), suggesting possible links to early risk for depression.

Social-Cognitive Influences

Social-cognitive theories focus on the role of maladaptive thought processes and negative belief systems as risk factors for depression. Specifically, negative appraisals of the self and the world are hypothesized to heighten vulnerability to depression, particularly in the face of stressful life experiences. Variants of these theories focus on different aspects of social-cognitive processes, including self-schemas; beliefs and attitudes about the self and others; inferences about the causes and consequences of life events; and perceptions of control and competence.

Consistent with Beck's (1967) pioneering information-processing theory of depression, research reveals that depressed youth show idiosyncratic processing of self- and other-relevant information (Cole & Jordan, 1995; Rudolph, Hammen, & Burge, 1997; Shirk, Van Horn, & Leber, 1997), and endorse statements that reflect low self-worth, irrational beliefs, and dysfunctional attitudes (for reviews, see Garber & Horowitz, 2002; Hankin & Abramson, 2001; Kaslow, Adamson, & Collins, 2000; Rudolph et al., 2006). Moreover, consistent with helplessness-hopelessness (Abramson, Metalsky, & Alloy, 1989) and self-regulation (Cole, Martin, & Powers, 1997; Weisz, Southam-Gerow, & McCarty, 2001) theories of depression, research links youth depression with a negative attributional style (i.e., a tendency to make internal, global, and stable attributions for negative experiences), hope-

lessness, and low perceptions of control and competence (for reviews, see Garber & Horowitz, 2002; Hankin & Abramson, 2001; Kaslow et al., 2000; Rudolph et al., 2006).

Despite evidence for the role of maladaptive social-cognitive processes in depression, research reveals that certain aspects of cognitive vulnerability do not emerge until adolescence (Abela, 2001; Cole & Jordan, 1995; Weisz et al., 2001). These developmental changes in vulnerability suggest that supplementing assessments of depression with an evaluation of particular social-cognitive processes should be guided by the developmental stage of the child.

Interpersonal Influences

According to interpersonal models that emphasize the social context of depression, depressed individuals both react to and contribute to disruption in their close relationships (Gotlib & Hammen, 1992; Joiner, Coyne, & Blalock, 1999). These models emphasize the ongoing transactions between individuals and their social environments. Specifically, particular interpersonal styles and social deficits of depressed youth elicit negative responses from others. These negative interpersonal experiences maintain or exacerbate depression.

Within the family, disturbances that disrupt early social bonds and undermine the achievement of key developmental tasks (e.g., creation of a healthy sense of self, acquisition of emotion regulation and coping skills) are believed to create a vulnerability to depression. Theory and research implicate various forms of family adversity, including the loss of a caregiver, maltreatment, insecure parent-child attachment, family discord, and parenting styles characterized by low levels of warmth, heightened rejection, and overcontrolling behavior. Such disruption in the family environment might account in part for the intergenerational transmission of depression. Depressed youth in turn show less effective communication, problem solving, and support during interactions with their parents than do nondepressed youth (for reviews, see Garber & Horowitz, 2002; Goodman & Gotlib, 1999; Rudolph et al., in press).

Depressed youth also show significant social-behavioral deficits and impairment in their peer relationships, friendships, and romantic relationships. For example, compared to nondepressed youth, depressed youth are

more aggressive and less prosocial with peers; engage in more excessive reassurance seeking; and demonstrate less active, assertive, and problem-focused, and more passive, avoidant, ruminative, and helpless responses to challenges, including interpersonal problems and conflict. Not surprisingly, given these deficits, depressed youth experience higher levels of rejection by familiar and unfamiliar peers, less stable friendships, and poorer friendship and romantic relationship quality than do nondepressed youth. This interpersonal disruption appears to be both an antecedent and a consequence of depression, particularly in adolescent girls (for a review, see Rudolph et al., in press).

Collectively, research suggests a transactional relation between youth and their social contexts, such that depressed youth are exposed to higher levels of interpersonal adversity and create more adverse relationship contexts. Thus, assessing interpersonal relationships might provide information about not only possible risk factors for depression but also the social difficulties that depression creates in youths' lives.

Contextual Influences

Theory and research implicate several types of environmental adversity as triggers of depression in vulnerable individuals, including acute negative life events, chronic stressors and daily hassles, and broader stressful conditions, such as socioeconomic disadvantage, parental unemployment, and low levels of parental education. Consistent with these perspectives, a significant amount of research reveals an association between contextual stressors and depression in youth (for reviews, see Garber & Horowitz, 2002; Rudolph et al., 2006).

Although early life stress models viewed stress as a contributor to depression, more recent perspectives emphasize the transactional nature of stress and depression (Hammen, 1992). Research supports the idea that depressed youth both react (Garber, Keiley, & Martin, 2002) and contribute (Rudolph et al., 2000) to life stress. In fact, genetic liability to depression might be expressed in part as heightened exposure to self-generated life stress (Rice, Harold, & Thapar, 2003). Stress within close relationships is an especially salient predictor and consequence of depression, particularly in adolescent girls (Hankin & Abramson, 2001; Rudolph, 2002). Researchers have pro-

posed a variety of personal attributes and environmental conditions that either dampen or enhance stress reactivity, including genetic liability, physiological reactivity, cognitive appraisals, emotion regulation and coping responses, and external resources (for reviews, see Garber & Horowitz, 2002; Hankin & Abramson, 2001; Rudolph et al., 2006).

ASSESSMENT CONSIDERATIONS

Selecting and implementing appropriate assessment approaches has implications for both research and clinical practice with depressed youth. In research settings, accurate assessment of depression is required for establishing relatively homogeneous subgroups of youth in an effort to determine the phenomenology, course, and etiology of depression. In clinical settings, comprehensive assessments are essential for formulating diagnoses and prognoses, determining the appropriate type and setting of treatment, monitoring treatment progress, and evaluating treatment effectiveness (Klein et al., 2005). Despite this integral role of assessment in clinical practice, few formal guidelines exist to assist in decision making during the assessment process. In recent years, however, efforts have been made to articulate evidence-based guidelines for the assessment of psychological symptoms and disorders in youth (Mash & Hunsley, 2005). These guidelines integrate standard psychometric information about the reliability and validity of assessment methods derived from scientific research, with pragmatic considerations regarding the utility of particular assessment approaches in applied settings. Evidence-based guidelines for the assessment of depression are discussed in detail elsewhere (Klein et al., 2005). Here we highlight a few key considerations relevant to the assessment of youth with depression.

Identifying the Purpose of Assessment

Determining the optimal assessment approach is contingent on the goals of the assessment. These goals likely vary across research and clinical practice, as well as across different clinical settings (Mash & Foster, 2001). At a broad level, there are several purposes of clinical assessment (Mash & Hunsley, 2005): (1) diagnosis and case formulation; (2) screening; (3) prognosis; (4) treatment design and planning;

(5) treatment monitoring; and (6) treatment evaluation. The specific purpose of the assessment might in part determine the most appropriate methods due either to differing psychometric strengths of the methods (e.g., the relative balance of sensitivity and specificity) or to pragmatic concerns (e.g., the intensiveness of the method or the implications of making a misdiagnosis). For example, for screening purposes (e.g., detecting youth who might benefit from further in-depth assessment), researchers or clinicians might be most interested in minimizing false negatives—that is, ensuring that they do not misidentify a child who is depressed. Thus, they might be interested in a measure that casts a wide net and “catches” most possible cases of depression (Angold, Costello, et al., 1995). In contrast, researchers or clinicians who are selecting youth to participate in an intensive intervention might be most interested in minimizing false positives—that is, ensuring that they do not provide intensive services to a child who is not depressed. More intensive assessment methods that might be useful for initial diagnosis and treatment planning are less practical for weekly monitoring of progress. Indeed, assessing treatment effectiveness requires methods that are sensitive to change (Mash & Hunsley, 2005). Unfortunately, relatively little is known about this characteristic of assessment methods for depression. Furthermore, assessment methods need to be sensitive to context-specific symptoms (e.g., social withdrawal at school vs. at home). Because assessment goals also might vary depending on the stage of assessment and the results of prior assessment, selection of the most appropriate strategy might involve delineating a sequence of methods rather than an individual method or instrument (Klein et al., 2005).

Determining the Target of Assessment

As discussed earlier, it also is important to consider the level of depression—mood, syndrome, or disorder—that is being targeted. Analyses of item overlap among commonly used youth- and other-report checklists, which tap depressed mood and the depressive syndrome, and formal diagnostic criteria (assessed with clinical interviews), as well as empirical analyses of the correspondence among data derived from these three methods, reveal only moderate correspondence (Compas, 1997; Compas et al., 1993). Thus, different information is gath-

ered with each method, and careful thought must be given to which level of depression is of interest. If the goal is to evaluate the severity of depressive symptoms, self-report questionnaires, behavior checklists, or clinician-rated depression scales might be sufficient, but if the goal is to determine a formal clinical diagnosis, then an interview-based method is required. Questionnaires might be useful for screening purposes, but because they often yield a high false-positive rate, they are typically followed up with a clinical interview (Angold, Costello, et al., 1995; Klein et al., 2005; Reynolds, 1994).

Integrating Information across Informants and Methods

A major challenge in the assessment of youth depression is the selection of informants and methods of assessment. Comprehensive assessments involve gathering information from multiple sources (e.g., youth, parents, teacher), methods (e.g., questionnaires, interviews, observations), and contexts (e.g., clinician's office, home, school). However, much evidence suggests a lack of convergence in data obtained across informants, methods, and contexts (Jensen et al., 1999; Kazdin, 1994). Moreover, few formal guidelines are available to determine the relative validity of these different types of information or to guide the integration of information. A few assessment methods (e.g., structured clinical interviews) have established algorithms for integrating information. For semistructured diagnostic interviews, one common solution is a clinician-driven "best estimate" approach (Klein, Ouimette, Kelly, Ferro, & Riso, 1994), wherein information from parent and youth interviews is integrated and weighted based on clinical judgment regarding the validity of the information. Some guidelines (e.g., giving preference to adults' report of depressive symptoms in young children) are available to increase the reliability of this "best estimate" method and to reduce idiosyncrasies in clinician decision making (Jensen et al., 1999). However, these decisions are still quite subjective; thus, this process might be variable across interviewers. Some interviewers might rely on the "or" rule (assuming that a symptom is present if at least one informant reports it), whereas others might rely on the "and" rule (assuming that a symptom is pres-

ent only if it is reported by multiple informants) (Klein et al., 2005). Moreover, structured and semistructured interviews rarely are used in clinical practice. Information from multiple sources also might be combined according to statistical algorithms to optimize prediction (e.g., Rubio-Stipec et al., 1994). However, prediction rules from statistical equations do not necessarily or easily translate into practice, and might not provide an advantage over other methods (Bird, Gould, & Staghezza, 1992).

Additional informal guidelines have been proposed to reconcile cross-informant data. For example, one might take into account both the subjective nature of many depressive symptoms and the developmental stage of the child. Self-report typically is useful for assessing internal experiences, such as feelings of sadness and low self-worth. However, because very young children have difficulty reflecting on their internal experiences, information from adults is essential. In contrast, adolescents possess the cognitive and linguistic ability to reflect on their experiences, and can provide essential information about subjective symptoms that might be difficult to observe (Edelbrock, Costello, Dulcan, Kalas, & Conover, 1985; Jensen et al., 1999). However, even adolescents might have difficulty placing their experiences in the context of typical norms for youth, and reporting on the timing and duration of symptoms. Parent and teacher perspectives might therefore still provide critical information about observable symptoms, and about the onset, course, severity, and prior history of symptoms even in adolescents.

Although discrepancies across informants clearly complicate the assessment process and often are viewed as evidence for poor reliability or validity of the methods, these discrepancies might be meaningful and worthy of attention. Discrepancies might be driven by systematic rater biases, such that they provide important information about characteristics of the informant. For example, depressed mothers may overestimate depressive symptoms in their offspring, resulting in low parent-child agreement (Boyle & Pickles, 1997; Youngstrom, Izard, & Ackerman, 1999). Alternatively, discrepancies might reflect cross-situational specificity in behavior, such as differences across home versus school (Clarizio, 1994). Therefore, rather than dismissing lack of convergence as "noise"

in the assessment process, it might be important to consider these inconsistencies as useful data that can help guide case formulation and treatment planning.

Given the possibility that different informants might provide useful information about different aspects of depression and associated impairment, it is important to consider the incremental validity of various measures, namely, the degree to which the measure adds data that improve the outcome of the assessment (e.g., increasing diagnostic accuracy). Surprisingly little research has examined whether different informants and methods provide incremental validity in the assessment of depression. Among the few available studies that examine the incremental validity of multi-informant data, results are mixed. Some research suggests that parent and teacher ratings, and clinician judgments of emotional and behavioral problems contribute uniquely to the prediction of poor outcomes, such as receipt of mental health services and school difficulties (Ferdinand et al., 2003). However, few studies examine the relative contribution of different informants to the assessment of depression specifically, rather than more global ratings of emotion and behavior. One study (Hope et al., 1999) did reveal that adolescent reports of internalizing problems on the Youth Self-Report (Achenbach, 1991) accounted for a significant increment in variance over parent reports on the Child Behavior Checklist (Achenbach, 1991) when predicting the number of internalizing symptoms endorsed by parents on the Diagnostic Interview for Children and Adolescents (Reich, Shayka, & Taibleson, 1991). Although depression and anxiety were not examined separately, these results suggest that parents and youth likely contribute unique sources of information to the assessment of depression.

Although the incremental validity of self-report versus interview methods has not been examined directly, one might assume that diagnostic interviews provide important incremental information necessary for making a diagnosis, such as data about the frequency, severity, and duration of each symptom. Diagnostic interviews also provide important data necessary for making a differential diagnosis, such as information about exclusionary criteria (e.g., the presence of a medical disorder associated with depression), and about other types of psycho-

pathology. Other information often gathered from such interviews, such as family history of psychopathology and depression-related impairment, also may aid in making a differential diagnosis and in distinguishing between normative levels of sad mood and clinical depression. Research has not examined the incremental validity of methods other than rating scales and interviews (e.g., behavior observations) in the assessment of depression, possibly as a result of their limited use due to costs associated with training, accessibility of observation techniques and settings, and time to conduct and code the observations (Garber & Kaminski, 2000).

Clearly, more research is needed to establish the incremental validity of assessment measures for depression, although this endeavor is challenging. The incremental validity of a measure depends on the quality of other measures included in the assessment; thus, incremental validity is difficult to demonstrate for any one measure when other valid measures are part of the assessment. Incremental validity of youth depression measures also depends on other factors, such as developmental status (e.g., parent reports might add significant information that young children are not able to provide) and culture (e.g., given cultural norms about self-disclosure, youth may be reluctant to disclose information that might be obtained from other informants).

Establishing the Clinical Utility of Assessment Approaches

Typically, systematic evaluations of assessment methods for depression focus on traditional psychometric properties (e.g., reliability, convergence with other methods). Far less is known about the utility of various methods for clinical application. Clinical utility includes features such as usefulness for monitoring treatment progress, incremental validity, and prognostic utility (e.g., ability to predict treatment outcome) (Klein et al., 2005; Mash & Hunsley, 2005). Determining the clinical utility of different methods depends on the specific purpose of assessment. For example, the clinical utility of an assessment method for diagnosis depends on its ability to maximize the accuracy of diagnostic classification; thus, the focus is on the positive and negative predictive power of the measure. The clinical utility of a method

for evaluating treatment progress and outcome depends on its sensitivity to change and the feasibility of repeated administrations. In many cases, practical considerations might outweigh scientific evidence regarding the strength of different assessment approaches.

Considering Developmental Factors

Although similar methods are used to assess depression at different ages, developmentally sensitive assessment approaches require a consideration of developmental factors that might complicate assessment of depression in youth. As noted earlier, there are some developmental differences in the expression of depression, such that young children might not articulate a depressed or anhedonic mood, and might not experience typical vegetative symptoms of depression. Moreover, because irritability rather than sadness might be the predominant mood, depressive symptoms might be mistaken for other forms of psychopathology. Distinguishing between normative fluctuations in mood and clinically meaningful depression in youth also might be difficult due to ongoing developmental changes in the expression and regulation of mood. Despite the fact that many early myths about depression in youth (e.g., depression in young children is “masked” in the form of other disturbances; depression in adolescents just reflects normative “storm and stress”) have been dispelled, significant others in their lives might still misattribute symptoms to normative developmental experiences and disruptions. Thus, assessment of depression requires a careful consideration of developmental norms in emotions and behavior.

A developmental perspective also can inform which domains of impairment to target in a comprehensive assessment. Depression is likely to interfere with developmentally salient tasks (Garber, 1984), such as academic achievement and success with peers during middle to late childhood, and the formation of romantic relationships during adolescence. Thus, assessments should target particular domains of functioning during particular life stages.

A final developmental issue is whether certain assessment methods are most valid and useful at certain stages of maturation. For the most part, similar methods have been used across a wide age span. For example, the same or slightly modified self-report questionnaires

and clinical interviews often are used across developmental levels (e.g., ages 8–18). The relative validity and clinical utility of these methods at different ages have not been systematically evaluated.

Assessing Associated Symptoms and Characteristics

A comprehensive assessment of youth with depression involves an evaluation of co-occurring psychopathology and depression-related impairment. We noted earlier the high co-occurrence between depression and other forms of psychopathology, including anxiety disorders, disruptive behavior disorders, substance abuse disorders, eating disorders, and somatic problems. Moreover, depressed youth with comorbid disorders experience more impairment than those with depression alone (Marmorstein & Iacono, 2003; Rudolph, Hammen, & Burge, 1994; Rudolph et al., 2000), and are at risk for a more severe and persistent course of depression (Birmaher et al., 1996; Lewinsohn, Rohde, Seeley, Klein, & Gotlib, 2000). Thus, assessing associated disorders is essential for accurate diagnosis (e.g., making a differential diagnosis or determining whether depression or a comorbid disorder should be the primary diagnosis), case conceptualization (e.g., understanding the complex pattern of symptoms in youth with comorbid disorders and how other symptoms may interact with depression in the expression of dysfunction), and treatment planning (e.g., decision making regarding appropriate treatment options and needs given the presence of comorbid disorders). Assessment of co-occurring problems should include an evaluation of developmental and medical conditions associated with depression and specific features of depression that might have implications for prognosis, treatment planning, and monitoring (e.g., suicidal ideation, psychotic symptoms, hypomania).

Because depressed youth experience disruptions in multiple psychological and life domains, including biological dysregulation, maladaptive social-cognitive processes, academic performance deficits, family conflict, and peer stress (see earlier sections), the assessment process should include an evaluation of other relevant domains. Indeed, as discussed earlier, even youth with subclinical levels of symptoms demonstrate significant psychosocial impairment

and often go on to experience more severe depression (Angst et al., 2000; Pine et al., 1999), suggesting that impairment and subjective distress are important targets of assessment beyond formal diagnosis (Mash & Hunsley, 2005). Gathering information about depression-related impairment is critical not only for case formulation and treatment planning, but also for determining prognosis and assessing processes of change during treatment. For example, assessments in youth might include evaluating whether negative cognitive style or maladaptive responses to stress improve over the course of treatment. Unfortunately, because many of the methods used to assess these domains lack normative information or evaluation of their clinical utility, it is difficult to develop specific criteria for inclusion in an assessment battery.

Finally, an essential part of assessment is the evaluation of clinical and family characteristics that predict the course of depression and have implications for treatment planning. As discussed earlier, continuity of depression across developmental stages is high. Moreover, research indicates a significant family aggregation of depression. In fact, a prior history of recurrent depression in youth or their families is a strong predictor of recurrence (Birmaher et al., 2002; Rohde et al., 2005), suggesting that a thorough assessment of personal and family history of depression is critical. Of course, given limited resources, decisions need to be made regarding the most relevant areas to target. Unfortunately, at present, few criteria are available to guide this decision-making process.

Interpreting Changes in Depression

Because a key goal of assessment is to evaluate treatment progress and effectiveness, assessments must be sensitive to changes over time. Two important considerations complicate efforts to evaluate this aspect of clinical utility. First, the majority of MDEs remit naturally over time. Second, reported levels of depressive symptoms tend to decrease across repeated assessments (Twenge & Nolen-Hoeksema, 2002). Thus, tracking the course of disorder during treatment requires an awareness of the possibility that apparent, treatment-related improvement is due to natural remission of symptoms or to artifacts resulting from an attenuation effect.

OVERVIEW OF ASSESSMENT METHODS

In this section, we provide a selective review of assessment methods for depression. When evaluating the measures, we consider standard psychometric indexes of reliability (internal consistency, test–retest reliability, interrater reliability) and validity (content, convergent, discriminant, and incremental validity; sensitivity and specificity), as well as clinical utility (sensitivity to change, prognostic utility, feasibility for use in a clinical setting).

It is difficult to establish strict criteria for evaluating the psychometric properties of youth depression measures. Depressive syndromes in youth tend to fluctuate naturally over time, possibly reducing stability estimates (Kovacs, 1992). Similarly, normative developmental changes (e.g., intellectual, affective) may lower stability estimates (Flannery, 1990) and result in varying levels of validity at different ages (Kessler et al., 2001). Estimates of test–retest reliability that use structured interviews might be lower than those with other assessment measures (e.g., rating scales), because a change in a single response can change diagnostic status and lower reliability estimates. Continuous measures are less sensitive to such small differences in ratings. An additional challenge in evaluating test–retest reliability coefficients is the attenuation effect. Moreover, establishing the validity of measures is difficult given the absence of a “gold standard.” Specifically, many evaluations of validity compare information from diagnostic interviews and information from rating scales, which leads to some circularity in determining the strength of each method. Consideration of alternative forms of validity and utility (e.g., prognostic utility), can help to circumvent these complications.

Standard assessment approaches for youth depression fall broadly into two major categories: diagnostic interviews and rating scales. Although physiological, performance-based, and observational measures of depression and related constructs have been developed (for a review, see Garber & Kaminski, 2000), insufficient normative information, idiosyncratic aspects of these assessments (e.g., investigator-specific coding systems), and lack of feasibility (e.g., time intensiveness, cost, training requirements) prevent their standard application in clinical settings. Thus, we provide only a brief review of these types of measures.

Diagnostic Interviews

Diagnostic interviews are used to determine depression diagnoses, as well as to rule out alternative diagnoses. These interviews are classified as unstructured or structured. The content and format of unstructured diagnostic assessments vary by clinician; therefore, these interviews vary in the amount and type of information elicited. Thus, diagnoses based solely on unstructured interviews might fail to consider all necessary diagnostic criteria. Unstructured interviews also might be subject to a number of biases, such as the tendency to collect information selectively to confirm or rule out a particular diagnosis (Angold, 2002; Jensen & Weisz, 2002).

Structured interviews are standardized interviews in which the interviewer determines the presence or absence of diagnostic criteria and associated clinical features, including duration and past history, using a prescribed set of probes. Structured interviews also are useful for differential diagnosis and assessment of comorbid conditions. Parallel child and parent versions often are available (Hodges, 1994). The primary benefit of structured compared to unstructured interviews is standardization in terms of format, language, sequencing of inquiries, methods for rating severity and impairment, and criteria for assigning a diagnosis (Rogers, 2003).

Structured interviews may be classified further as either fully structured, respondent-based or semistructured, interviewer-based (Rogers, 2003). Respondent-based interviews require adherence to a prescribed set of probes; diagnoses are based solely on respondents' answers. Interviewer-based interviews permit the interviewer to supplement a prescribed set of inquiries with additional probes. As a result, respondent-based interviews may be administered by well-trained laypeople, whereas interviewer-based interviews can only be administered by interviewers trained in clinical diagnosis.

In terms of validity, it is increasingly recognized that diagnostic assessments guided solely by clinical judgment may be less accurate than evidence-based diagnoses informed by standard assessment procedures with established reliability and validity, such as structured diagnostic interviews (Doss, 2005). The selection of a fully structured or semistructured interview depends in part on the availability of trained

mental health professionals to conduct interviews. Fully structured interviews are preferred when the costs associated with training and administration are prohibitive, such as in large epidemiological studies. When trained interviewers are available, the flexibility of semistructured interviews may yield greater validity (Kessler et al., 2001). Another consideration is whether respondents are deemed able to make judgments about symptom presence or absence without any interviewer input. In cases in which respondents may have difficulty understanding or evaluating interview probes, an interviewer-based interview may increase diagnostic accuracy.

Rating Scales

Depression rating scales and behavior checklists assess depressive mood and symptoms. Symptoms might be rated by the youth, clinicians, or others familiar with the youth (e.g., parents, teachers). Respondents typically rate the extent to which each symptom applies, using Likert scales to select among response options that vary in symptom frequency or severity. Summary scores are created by aggregating across symptoms. These scores do not provide information about the duration of symptoms or about specific configurations of symptoms required for a diagnosis (e.g., a youth might score high on a rating scale despite the absence of depressed mood or anhedonia). Moreover, many items on standard rating scales are not core symptoms of depression but are associated features (e.g., behavior problems, academic impairment). Thus, rating scales do not provide sufficient information to inform diagnoses.

Rating scales are widely used because of their convenience, ease of administration, and low cost. Self-report scales are well suited to assess symptoms that are not observable by others, such as feelings of hopelessness and guilt (Reynolds, 1994). However, these scales share problems characteristic of self-report in general. Youth might be reluctant to disclose depressive symptoms due to social desirability or concern about others' reactions. Alternatively, depressed youth might overestimate their difficulties (Garber & Kaminski, 2000). Also, self-report scales often do not discriminate between depression and other types of negative affect, particularly anxiety. In addition, these measures require a certain level of

reading and comprehension, and youth must rate the frequency, intensity, and duration of multiple symptoms. Reports from other informants address these limitations (Clarizio, 1994) but also are subject to biases. Unfortunately, little empirical evidence documents the added value of obtaining information about depression from different sources (Johnston & Murray, 2003), making it difficult to evaluate the relative costs and benefits associated with a multi-informant assessment approach.

Alternative Methods: Observational, Performance-Based, and Physiological Methods

Several laboratory and performance-based methods are available to assess depression and its correlates. For example, observations in laboratory settings may provide useful information about symptoms such as depressive affect, psychomotor abnormalities, and sleep difficulties, as well as correlates of depression, such as interpersonal difficulties. Such methods have several benefits. First, performance-based methods and analogue behavior observations (i.e., structured observations designed to parallel situations encountered in natural settings) (Mash & Foster, 2001) are less subject to difficulties associated with interviews and rating scales, such as self-presentation demands or limited self-reflection capability. Second, these methods provide a means of systematically eliciting and observing responses or behaviors of interest, thereby allowing for the assessment of low base-rate or situation-specific behaviors (Mash & Foster, 2001). Thus, these methods may provide an important supplement to traditional methods.

Unfortunately, several issues limit the utility of these methods in applied settings. One concern is their lack of ecological validity, namely, that the situations and observed behaviors do not accurately reflect real-world experiences (Sanders, Dadds, Johnston, & Cash, 1992). However, these methods may be useful for certain clinical assessment purposes even in the absence of ecological validity (Mash & Foster, 2001). For example, a clinician may wish to evaluate youth behavior in a specific, structured situation (e.g., a problem-solving discussion between a depressed youth and parent) as a step in determining whether an intermediate treatment goal has been met (e.g., whether the family has learned certain communication

skills), even though the conditions and behaviors do not mirror those in natural settings. Pragmatic constraints (e.g., cost, training, and time requirements) also may limit the utility of these methods in clinical settings. Moreover, because these methods were designed for use in research, their focus is on differentiating between groups of relatively homogeneous youth rather than providing idiographic information about an individual youth and the complexity of his or her presenting problems (Mash & Foster, 2001). Even within research settings, the psychometric adequacy of these measures is not always sufficiently established, and idiosyncratic administration and coding procedures are used; this lack of standardization makes it difficult to transport these methods into clinical settings (Mash & Foster, 2001). In addition, many constructs assessed with these methods (e.g., social interaction) are characteristic of not only depression but also other disorders, resulting in limited discriminant validity. Evidence is limited concerning the clinical utility and incremental validity of laboratory and performance-based measures (Johnston & Murray, 2003; Mash & Foster, 2001), although these methods may provide information about targets for treatment (Garber & Kaminski, 2000). Given the time and cost necessary to use these methods, it is important to determine whether they provide information that other methods do not, and whether inclusion of these methods in an assessment battery significantly aids in diagnosis and case formulation, prognosis, treatment planning, or treatment outcome.

Review of Diagnostic Interviews

Schedule for Affective Disorders and Schizophrenia for School-Age Children

The Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Kaufman et al., 1997; Puig-Antich & Chambers, 1978), an interviewer-based schedule to assess psychopathology in youth ages 6 to 18, is designed for use by mental health professionals trained to make psychiatric diagnoses. Parent and child are interviewed separately; major discrepancies are resolved through a joint interview. Three versions are compatible with the DSM-IV. The K-SADS-P assesses current and past year diagnoses only. The K-SADS-E (epidemiological version) and

K-SADS-P/L assess lifetime and current diagnoses, and the K-SADS-P/L includes an 82-item screening interview. Although both the K-SADS-P/L and K-SADS-P include a global assessment scale, the K-SADS-P also includes clinical severity and improvement ratings, and the Hamilton Depression Rating Scale, making it more sensitive to treatment effects. Administration of the K-SADS ranges between 1.5 and 3 hours (Ambrosini, 2000).

Preliminary data for the K-SADS-P IV-R, the DSM-IV version of the K-SADS-P, indicate excellent agreement for current ($\kappa = .90$) and lifetime ($\kappa = 1.00$) MDD diagnoses (Ambrosini, 2000; Kaufman et al., 1997). Studies that use the K-SADS as the *criterion* for establishing validity reveal that scores from self-report, parent-report, and clinician rating scales distinguish between youth with MDD and nondepressed youth (Kaufman et al., 1997). Moreover, youth who met criteria for depression on the K-SADS at age 9 reported more depressive symptoms on the Diagnostic Interview Schedule for Children at ages 11 and 13 (McGee & Williams, 1988).

Child and Adolescent Psychiatric Assessment

The Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 1995) is a semistructured interview designed to assess psychiatric diagnoses occurring in the past 3 months in youth ages 9 to 17. Administration time is 1 to 2 hours. The interview includes an assessment of psychosocial impairment and clinician ratings of behaviors observed in the interview. The CAPA includes a glossary with operational definitions of symptoms, facilitating its use by not only clinicians but also highly trained lay interviewers. The CAPA is appropriate for use in clinical and epidemiological research (Angold & Costello, 2000).

Test-retest reliability of CAPA depression diagnoses is high for MDD ($\kappa = .90$) and dysthymia ($\kappa = .85$). Interrater reliability of MDD diagnoses also is high (intraclass correlation coefficient [ICC] = .88; Angold & Costello, 1995). There are limited data on the association of the CAPA with other depression measures. In one study, adolescents with a CAPA MDD diagnosis scored higher on the Mood and Feelings Questionnaire than youth without an MDD diagnosis (Thapar & McGuffin, 1998). Other support for the validity of CAPA depression diagnoses includes

higher prevalence of MDD diagnoses in adolescent girls than in boys (Angold, Costello, & Worthman, 1998), and higher concordance of MDD diagnoses in monozygotic than in dizygotic twins (Eaves et al., 1997).

Diagnostic Interview for Children and Adolescents

The most recent version of the Diagnostic Interview for Children and Adolescents (DICA), the DICA-IV (Reich, 2000), is a semistructured interview designed to assess lifetime psychiatric diagnoses in youth ages 6 to 17. This version of the DICA assesses DSM-III-R and DSM-IV criteria. Separate interviews are available for children (ages 6–12) and adolescents (ages 13–17). The DICA can be administered by laypeople after 2 to 4 weeks of training; the computer version may be self-administered. Administration time is typically 1 to 2 hours.

One week test-retest reliability for the DICA-IV is high for adolescents ($\kappa = .80$) but lower for children ($\kappa = .55$). In one community sample using the DICA-R (revised version), interrater agreement was poor for interviews of children ($\kappa = .00$) and moderate for interviews of adolescents ($\kappa = .45$); agreement between child and parent reports was better than that between adolescent and parent reports ($\kappa = .77$ and $.31$, respectively) (Boyle et al., 1993). Low to moderate agreement between clinicians also has been obtained in outpatient samples of youth (Ezpeleta et al., 1997). Youth diagnosed with MDD using the DICA score higher on the Depression Self-Rating Scale (McClure, Rogeness, & Thompson, 1997), the Beck Depression Inventory (Beck & Steer, 1993), and the Center for Epidemiologic Studies Depression Scale (Olsson & von Knorring, 1997) than do youth without a diagnosis.

Diagnostic Interview Schedule for Children

The Diagnostic Interview Schedule for Children (DISC; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) is a structured, respondent-based interview for children, with content corresponding to the adult Diagnostic Interview Schedule (Robins, Helzer, Croughan, & Ratcliff, 1981). The DISC-IV assesses diagnoses in the past year and in the past 4 weeks, as well as lifetime diagnoses. The DISC and its revisions, the most recent of which is the DISC-IV (Shaffer et al., 2000), can be administered

by lay interviewers after training. Child (DISC-C) and parent (DISC-P) versions are available. In the C-DISC-4.0, the computerized version of the DISC-IV, the computerized format aids in standardization of assessment, which is useful for research studies. However, because the C-DISC-4.0 is a structured interview, it is not possible to address problems such as misinterpretation of probes. Administration time is 1 to 2 hours.

Test-retest reliability of DISC-IV past-year MDD diagnoses was moderate for parent report ($r = .66$) and high for child report ($r = .92$) in a clinic sample. Estimates of diagnostic agreement in a community sample were low for child report ($\kappa = .37$) and moderate for parent report ($\kappa = .55$). Use of symptom counts to assess reliability in the same sample yielded higher reliability estimates (ICCs = .52 for child report and .79 for parent report). Validity information is not available for the DISC-IV affective disorder scales. Earlier versions of the DISC showed low correlations with the Children's Depression Inventory (Angold, Prendergast, et al., 1995) and low concordance between DISC depression diagnoses and clinician diagnoses (e.g., Pellegrino, Singh, & Carmanico, 1999). Earlier versions of the DISC yielded high numbers of false-positive depression diagnoses.

Review of Self-Report Rating Scales

Beck Depression Inventory

Although designed for adults, the Beck Depression Inventory (BDI; Beck & Steer, 1993) is the rating scale most often used with adolescents. For each of the 21 items, respondents indicate which of four statements varying in severity best describes how they have been feeling for the past week. Scores range from 0 to 63. The BDI can be completed in less than 10 minutes. A 13-item short form is available (Bennett, Ambrosini, et al., 1997). The BDI for Primary Care (BDI-PC; Beck, Guth, Steer, & Ball, 1997), a 7-item scale, has been used successfully with adolescents in medical settings (e.g., Winter, Steer, Jones-Hicks, & Beck, 1999).

Internal consistency of the BDI in adolescent samples generally is high (e.g., Ambrosini, Metz, Bianchi, Rabinovich, & Undie, 1991), and the BDI has demonstrated validity in adolescent samples, as evidenced by correlations with other depression self-report measures

(e.g., Roberts et al., 1991). A comparison of the BDI and the Reynolds Adolescent Depression Scale (RADS) revealed that the BDI was more sensitive to changes in severity of depression due to treatment (Reynolds & Coats, 1986). The BDI discriminates between depressed and nondepressed adolescents in hospital (Carter & Dacey, 1996) and outpatient (Ambrosini et al., 1991) settings. However, some research shows that elevated scores on the BDI yield a high number of false-positive cases—that is, adolescents with elevated BDI scores who do not meet diagnostic criteria for depression—and few true-positive cases of depression (Roberts et al., 1991). Also, some research suggests that high scores on the BDI are not specific to depression, but indicate dysphoria or general psychological distress (Kutcher & Marton, 1989).

Cutoff scores of 16 and 10 on the BDI maximize sensitivity and specificity of MDD and dysthymia diagnoses, respectively, in community samples (Barrera & Garrison-Jones, 1988); optimal cutoff scores for outpatient and inpatient adolescent samples generally are lower (e.g., Ambrosini et al., 1991). Additionally, sensitivity and specificity in treated samples are considerably lower than that in community samples (Barrera & Garrison-Jones, 1988; Kashani, Sherman, Parker, & Reid, 1990). Other concerns include the lack of items relevant to school and the absence of parallel parent and teacher forms (Myers & Winters, 2002).

The BDI-II (Beck, Steer, & Brown, 1996), the most recent revision of the BDI, is updated to be consistent with DSM-IV criteria for MDD. According to the manual, the BDI-II is appropriate for adolescents as young as age 13; however, expert raters and inpatient adolescents identified some items that are less relevant to adolescent depression (e.g., “loss of interest in sex,” “past failure”) (Osman, Kopper, Barrios, Gutierrez, & Bagge, 2004). The BDI-II has high internal consistency (estimates $\geq .90$) in samples of adolescent inpatients (Krefetz, Steer, Gulab, & Beck, 2002; Kumar, Steer, Teitelman, & Villacis, 2002) and correlates with other depression rating scales, such as the RADS ($r = .84$; Krefetz et al., 2002), and suicide risk measures, such as suicidal ideation and feelings of hopelessness (Osman et al., 2004). BDI-II scores discriminate between adolescents who meet criteria for MDD and those who do not (Krefetz et al., 2002; Kumar et al.,

2002). In one study of adolescent inpatients (Kumar et al., 2002), a cutoff score of 21 demonstrated the highest positive predictive power of .85 (i.e., the proportion of adolescents scoring above the cutoff who meet diagnostic criteria for depression) and negative predictive power of .83 (i.e., the proportion of adolescents scoring below the cutoff who do *not* meet diagnostic criteria for depression).

Children's Depression Inventory

The Children's Depression Inventory (CDI; Kovacs, 1992) is a downward extension of the BDI, with language and format changes to accommodate youth age 7 and older. For each of 27 items, youth select one of three response alternatives that vary in severity. For approximately half of the items, alternatives are listed in order of increasing severity; the order is reversed for the remaining items. The CDI takes about 10–20 minutes to complete. An abbreviated version (Kovacs, 1992) and a parent version (Wierzbicki, 1987) are available. Correspondence of parent and teacher ratings with self-reports is low to moderate, with highest agreement about school functioning (Bennett, Pendley, & Bates, 1997; Ines & Sacco, 1992).

Internal consistency of the CDI exceeds .80 in most studies (e.g., Crowley, Worchel, & Ash, 1992; Smucker, Craighead, Craighead, & Green, 1986). Most studies report test-retest reliability coefficients close to .70, but coefficients range from as low as .38 (Saylor, Finch, Spirito, & Bennett, 1984) to as high as .88 (Finch, Saylor, Edwards, & McIntosh, 1987). The CDI correlates significantly with other depression self-report measures (e.g., Shain, Naylor, & Alessi, 1990). Evidence for discriminant validity is mixed. Some studies indicate that the CDI distinguishes between youth with depression and nondepressed youth (e.g., Timbremont, Braet, & Dreesen, 2004), but others suggest poor discriminant validity, sensitivity, and specificity (e.g., Ambrosini, 2000). For screening purposes, a cutoff score of 19 or 20 has been suggested for youth in the general population, where the prevalence of depression is low; cutoff scores of 12 or 13 have been recommended for clinic-referred samples (Kovacs, 1992). The CDI seems to be more sensitive to change in response to treatment than the Children's Depression Rating Scale—Revised and the Reynolds Child Depression Scale

(Stark, Reynolds, & Kaslow, 1987). However, some research documents significant reductions in CDI scores at a second assessment, when no treatment was provided (Meyer, Dyck, & Petrinack, 1989). Therefore, clinicians should use the CDI in combination with other information before concluding that there are positive treatment effects on depression.

Center for Epidemiologic Studies Depression Scale

The Center for Epidemiologic Studies Depression Scale (CES-D; Radloff, 1977), a 20-item measure, was originally developed for use with community samples of adults. Respondents indicate the frequency of depressive symptoms using a 3-point scale. Item content does not include all DSM criteria. Internal consistency of the CES-D with adolescent samples is high, with coefficients exceeding .85 (Garrison, Addy, Jackson, McKeown, & Waller, 1991; Roberts et al., 1991). The CES-D has only a moderate correlation with the Hamilton Depression Rating Scale (HDRS; $r = .48$; Roberts et al., 1991), but a high correlation with the RADS (r 's $> .74$; Reynolds, 1987). Test-retest reliability in a community sample of adolescents was adequate ($r = .61$). The most frequently used cutoff score for the CES-D is 16, which indicates moderate depression, although several studies indicate that this cutoff yields false-positive diagnoses of depression in nondepressed youth (e.g., Roberts et al., 1991). Optimal cutoff scores for determining MDD in adolescents range from 12 to 22 for boys and 22 to 24 for girls (Garrison et al., 1991; Roberts et al., 1991). Convergence between CES-D scores indicating depression and K-SADS depression diagnoses is low (Roberts et al., 1991).

The child version of the CES-D, the CES-DC, does not correlate with the CDI in young children, but it has a moderate correlation ($r = .61$) in adolescents (Faulstich, Carey, Ruggiero, Enyart, & Gresham, 1986). Generally, the discriminant validity of the CES-DC is poor (Faulstich et al., 1986), because scores correlate moderately with conduct disorder (Andrews, Lewinsohn, Hops, & Roberts, 1993) and do not distinguish between depressed children and children with no diagnosis (Fendrich, Weissman, & Warner, 1990). Like the CES-D, the CES-DC has problems with sensitivity and specificity (Blatt, Hart, Quinlan, Leadbeater, &

Auerbach, 1993). Use of the CES-D or CES-DC to assess change in symptoms should be avoided given these problems.

Mood and Feelings Questionnaire

The Mood and Feelings Questionnaire (MFQ; Angold, Costello, et al., 1995), developed to assess symptoms of depression in youth ages 8–18, includes 30 or 35 items (depending on the version used) assessing DSM-III-R criteria for depressive disorders and other clinically significant symptoms. Respondents indicate the degree to which each statement applies to their experiences in the past 2 weeks using a 3-point Likert scale. A short form of the MFQ (SMFQ), composed of 13 items that showed optimal discriminative ability and internal consistency, is available. Parent versions of the full and short forms are available. The MFQ and SMFQ are strongly correlated (r 's > .90) for both the child and parent versions (Angold, Costello, et al., 1995). The MFQ can be completed in about 10 minutes.

Stability estimates using the full MFQ exceed .70 (e.g., Costello, Benjamin, Angold, & Silver, 1991; Wood, Knoll, Moore, & Harrington, 1995). Concordance between child and parent reports is low (r 's = .25 and .30, for the full and short forms, respectively). The full and short forms of the MFQ have moderate correlations with the CDI and the DISC-C, but the parent versions have low correlations with the CDI and DISC-P (Angold, Costello, et al., 1995). With a diagnosis of MDD on the K-SADS as the criterion, diagnostic accuracy of the MFQ child version is generally better than the MFQ parent version, and similar to the CDI and BDI (Wood et al., 1995). Scores on the MFQ child version discriminate between psychiatric inpatients with a DISC affective diagnosis and those with no affective diagnosis (Pellegrino et al., 1999).

Reynolds Adolescent Depression Scale and Reynolds Child Depression Scale

The Reynolds Adolescent Depression Scale (RADS; Reynolds, 1994) is a 30-item scale designed to assess depressive symptoms in youth ages 13 to 18. Seven items are uncharacteristic of depression to reduce the likelihood of response sets. Respondents indicate the frequency of each symptom on a 4-point scale;

possible scores range from 30 to 120. Content of the RADS does not include all symptoms of depression. Norms are based on an ethnically and geographically diverse sample of adolescents. The RADS takes about 10 minutes to complete (Reynolds, 1994).

Several studies report high internal consistency of the RADS in community and clinical samples, with estimates exceeding .90 (e.g., Dalley, Bolocofsky, Alcorn, & Baker, 1992; Reynolds, 1987, 1989). Test-retest reliability at 6 and 12 weeks is approximately .80 (Reynolds, 1987). The RADS has strong correlations with other depression measures, such as the CDI and CES-D, with correlations exceeding .70 (Reynolds, 1987). The RADS also is strongly correlated with the HDRS (r = .83; Reynolds, 1987) and the Children's Depression Rating Scale—Revised ([CDRS-R], r = .78; Shain et al., 1990). A cutoff score of 77 indicates clinically significant impairment in daily functioning. Using this cutoff score and diagnoses based on the HDRS, the RADS had high specificity (96%) but considerably lower sensitivity (62%) (Reynolds, 1987). The RADS can detect alleviation of adolescents' depressive symptoms but is less sensitive than the BDI in this regard (Reynolds & Coats, 1986). It is concerning that the recommended cutoff score misses one-third of depressed adolescents.

The Reynolds Child Depression Scale (RCDS; Reynolds, 1989), designed for use with children ages 8–13, consists of 30 items. Like the RADS, the normative sample for the RCDS is socioeconomically and ethnically diverse. Internal consistency of the RCDS in the normative sample (.90) is similar to that in other studies (e.g., Reynolds, 1989). Four-week test-retest reliability is .85 (Reynolds & Graves, 1989). The RCDS correlates strongly with the CDI (r 's = .70–.79) (e.g., Bartell & Reynolds, 1986; Reynolds, 1989) and the CDRS-R (r = .76) (Reynolds, 1989). Additionally, several studies indicate that the RCDS is sensitive to change in depressive symptoms due to treatment (Crosbie-Burnett & Newcomer, 1990; Rawson & Tabb, 1993).

Review of Clinician Rating Scales

Hamilton Depression Rating Scale

The Hamilton Depression Rating Scale (HDRS; Hamilton, 1960; Warren, 1997) was designed to assess the severity of depressive symptoms in

adults, but it is often used with adolescents (Myers & Winters, 2002). The HDRS includes 21 items, but Hamilton (1960) suggested that only the first 17 be used to compute the total score. Assessors rate both the presence or absence, and, if applicable, the severity of specified depressive symptoms during the past week. Objective criteria are available for some items; for others, the assessor uses judgment to decide whether symptoms are *mild*, *moderate*, or *severe*. There are no standardized interview questions; therefore, the quality of the data depends a great deal on the skill of the clinician or researcher. Administration time is 10–30 minutes.

There are limited data describing the psychometric properties of the HDRS in youth. One-week test–retest reliability in adolescents is high ($r = .90$) (Kutcher & Marton, 1989). In community samples, the HDRS has moderate correlations with the BDI ($r = .50$) and CES-D ($r = .48$) (Roberts et al., 1991) and a high correlation with the RADS ($r = .72$) (Reynolds, 1987). Among inpatient adolescents, the HDRS has high correlations with the CDRS ($r = .92$), BDI ($r = .72$), and CDI ($r = .73$) (Shain et al., 1990). The HDRS distinguishes between adolescent outpatients with major depression and nondepressed adolescents (Kutcher & Marton, 1989). Some studies indicate that the HDRS is sensitive to changes in response to pharmacotherapy (Ambrosini et al., 1999) and cognitive-behavioral therapy (Franklin et al., 1998). There is some concern that items assessing somatic complaints and anxiety minimize the ability of this measure to differentiate between depression and anxiety (Myers & Winters, 2002). In addition, differential weighting of items, overrepresentation of vegetative symptoms, and incomplete representation of DSM criteria make it difficult to interpret scores on the HDRS (Zimmerman, Posternak, & Chelminski, 2005).

Children's Depression Rating Scale—Revised

The Children's Depression Rating Scale—Revised (CDRS; Poznanski, Cook, & Carroll, 1979), a modification of the HDRS, is designed for use with children ages 6–12, but it is also used with adolescents (Myers & Winters, 2002). The current revised version, the CDRS-R (Poznanski & Mokros, 1999), includes 17 items. Fourteen items are rated on a 7-point severity scale, and

the remaining items are rated on a 5-point severity scale. Assessors rate both the presence or absence, and, if applicable, the severity of each depressive symptom, and depressed facial affect, speech, and activity based on observations during the interview. It is recommended that the assessor interview youth and parents or other informants separately, then combine information from all sources. Possible scores for the child interview range from 17 to 113; possible scores for interviews with other informants range from 14 to 94. Administration time can exceed 30 minutes, depending on how many informants are interviewed (Overholser, Brinkman, Lehnert, & Ricciardi, 1995).

Two-week test–retest reliability of the CDRS is high ($r = .86$; Poznanski et al., 1984), and internal consistency is adequate (Myers & Winters, 2002). A number of studies show poor agreement between informants (e.g., Mokros, Poznanski, Grossman, & Freeman, 1987). The CDRS-R correlates significantly with the HDRS and with the CDI and RADS for females (r 's = .89 and .86, respectively) but not for males (r 's = .41 and .48, respectively). The CDRS-R has been used in treatment studies to assess change in severity of depression (e.g., Emslie et al., 1997). However, in preadolescent children, it might be less sensitive than the CDI (Stark et al., 1987). Given the inclusion of physiological symptoms, the CDRS might overpredict depression in children with medical or physical complaints (e.g., Aronen et al., 1996).

Review of Parent and Teacher Behavior Checklists and DSM-Referenced Scales

Achenbach Scales

The Achenbach System of Empirically Based Assessment (ASEBA) was designed to assess behavior problems and social competencies in preschool (ages 1½ to 5 years) and school-age (ages 6–18) youth. The Child Behavior Checklist (CBCL/6–18; Achenbach & Rescorla, 2001), one of the most widely used behavior rating scales, consists of 118 items, each rated on a 3-point scale. The CBCL yields information about a range of behavior syndromes, including anxious–depressed behavior, somatic complaints, withdrawn behavior, attention problems, social problems, and aggression–delinquency. These empirically derived scales

can be combined to create overall internalizing, externalizing, and total problem scores. The CBCL has been normed in clinical and community samples by age and gender. A parallel Teacher Report Form (TRF/6–18; Achenbach & Rescorla, 2001) is available, with most items identical to the parent form. The CBCL and TRF can be completed in 8–10 minutes.

The reliability of CBCL depression items is low compared to the other scales (Clarizio, 1994), perhaps because these symptoms are less easily observed. The CBCL distinguishes between referred and nonreferred youth (Achenbach, 1991; Drotar, Stein, & Perrin, 1995), although it is less sensitive to variations in youth scoring in the normal range (Drotar et al., 1995) and less able to differentiate among specific dimensions of internalizing problems (Song, Singh, & Singer, 1994). For example, the Withdrawn scale predicts anxiety and depressive disorders (Kasius, Ferdinand, van den Berg, & Verhulst, 1997). Another concern is that the Anxious–Depressed subscale combines symptoms of anxiety and depression that have been shown to be distinct (e.g., Cantwell, 1988), and some items assessing depression (e.g., “unhappy, sad, depressed”) are included on more than one scale. Consequently, the empirically derived scales of the CBCL have limited ability to predict depression. One study indicated that a subset of depression items from the CBCL discriminates between youth with MDD and those with no diagnosis (e.g., Rey & Morris-Yates, 1991); in another study, adolescents’ scores on the Anxious–Depressed subscale predicted MDD analogue scores (Gerhardt, Compas, Connor, & Achenbach, 1999). Similarly, an empirically derived set of depression items showed greater sensitivity to MDD than did the Anxious–Depressed subscale (Lengua et al., 2001), suggesting that a subset of depression items might be useful for depression assessments.

Child Symptom Inventory

The Child Symptom Inventory (CSI) is a DSM-IV–referenced rating scale that screens for affective and behavioral symptoms of the major childhood disorders, including MDD and dysthymia (Gadow & Sprafkin, 2002). Items are rated on a 4-point scale. Parent and teacher versions are available. The 97-item parent version and the 77-item teacher version can be

completed in 15–20 minutes. There are two options for scoring the CSI: a symptom severity score and a symptom count.

Internal consistency of the Major Depression and Dysthymia scales is moderate for the parent version (.59 and .68, respectively) and high for the teacher version (.75 and .73, respectively). Interrater reliability of the symptom severity scores for both depression scales is adequate ($r = .52$). The depression scales are significantly correlated with the Withdrawn, Somatic Complaints, and Anxious–Depressed subscales of the CBCL and TRF (Gadow & Sprafkin, 2002), providing evidence for good convergent validity but poor specificity (Mattison, Gadow, Sprafkin, Nolan, & Schneider, 2003). The teacher-rated CSI Depression scale distinguishes between youth classified as depressed and nondepressed according to DSM-IV criteria (Mattison et al., 2003).

Review of Peer Ratings

Many symptoms of depression (e.g., dysphoria, lack of involvement in activities) may be observed by peers during daily interactions. Peer ratings can be obtained in a number of settings, increasing their ecological validity. The best known peer-report method for assessing depression, the Peer Nomination Inventory for Depression (PNID; Lefkowitz & Tesiny, 1980), includes 20 items that assess four domains of functioning: affective, cognitive, motivational, and vegetative. Internal consistency is high ($r = .85$) (Lefkowitz & Tesiny, 1980), but there is limited information regarding the ability of the PNID to discriminate between youth with subclinical depressive symptoms and those with clinical depression. One study found that the PNID did not discriminate between major depression and dysthymic disorder (Ezpeleta, Polaino, Domenech, & Domenech, 1990). Use in clinical settings is limited by a variety of practical constraints, including time required to complete ratings and the absence of a stable peer group with sufficient familiarity to provide accurate ratings.

Review of Assessment Measures in Young Children

The only scale designed specifically to assess depressive symptoms in preschool age children is the Preschool Feelings Checklist (Luby,

Heffelfinger, Koenig-McNaught, Brown, & Spitznagel, 2004), a 16-item brief screening measure for parents. This measure has good internal consistency ($\alpha = .76$) and discriminates between depressed and nondepressed preschool children. When used with a version of the DISC-IV modified for use with parents of preschool children, sensitivity and specificity are better than that found with the CBCL Internalizing scale (Luby et al., 2004).

The Berkeley Puppet Interview (BPI; Ablow et al., 1999), an interactive, semistructured interview, uses puppets to elicit ratings of psychiatric symptoms in young children. Test-retest reliability is moderately low in clinic and community samples (r 's = .42 and .43, respectively). Internal consistency of the depression subscale is good in clinical samples ($\alpha = .75$), but much lower in community samples ($\alpha = .36$). The depression subscale of the BPI distinguishes between clinic-referred and community samples of children (Ablow et al., 1999).

The McArthur Health Behavior Questionnaire (HBQ; Essex et al., 2002) is designed to assess several aspects of young children's functioning, including depressive symptoms. Parent and teacher forms are available. Mother and teacher reports on the HBQ show adequate internal consistency and good test-retest reliability in clinic and community samples, and discriminate between clinic-referred and community samples of children (Ablow et al., 1999). In addition, mother report on the HBQ identifies more children with internalizing psychopathology than does the DISC-IV and is associated with teacher reports of impairment (Luby et al., 2002).

The CBCL and TRF have downward extensions that can be used with children as young as 18 months. These are the most widely used parent and teacher rating scales to assess psychopathology in young children (Achenbach & Rescorla, 2004), but the sensitivity of these measures to early MDD warrants further research (Luby et al., 2004). Diagnostic interviews also have been modified for use with young children. A downward extension of the CAPA, the Preschool Age Psychiatric Assessment (PAPA) (Egger & Angold, 2004), was developed for children ages 2 to 5. Interrater reliability is comparable to that of other semistructured diagnostic interviews. Similarly, a downward extension of the DISC-IV is being developed (Lucas, Fisher, & Luby, 1998).

ASSESSMENT OF CO-OCCURRING SYMPTOMS AND RELATED CONSTRUCTS

As noted earlier, a comprehensive assessment of depression includes the evaluation of co-occurring psychopathology and impairment across a variety of domains. Here we provide a brief summary of some relevant constructs of interest. Because many of the measures of related constructs have been used primarily in a research context, it is not always clear which of these would have utility in a clinical setting. Adapting these measures for application in practice and determining their clinical utility await further research.

Assessment of Co-Occurring Psychopathology

Both diagnostic interviews and rating scales may be used to assess co-occurring symptoms and disorders. However, self-report and other-informant rating scales often have limited discriminant validity. In particular, these measures tend not to distinguish adequately between depressive and anxiety disorders, due to their focus on symptoms of general distress (Joiner, Catanzaro, & Laurent, 1996). Consistent with contemporary theoretical conceptualizations of depression and anxiety, such as the tripartite model (Watson et al., 1995), it is becoming increasingly clear that assessment measures must differentiate between the shared (i.e., general distress) and unique components of depression (i.e., anhedonia and low positive affect), and anxiety (i.e., physiological arousal or somatic tension) (Lonigan, Carey, & Finch, 1994).

A few measures distinguish between components of depression and of anxiety. The Positive and Negative Affect Scale for Children (PANAS-C; Laurent et al., 1999) has high internal consistency, and good convergent and discriminant validity in community and inpatient samples (Laurent et al., 1999; Lonigan, Hooe, David, & Kistner, 1999). The PANAS-C includes 27 adjectives that reflect positive and negative affect. Youth rate the applicability of each adjective in the past few weeks, using a 5-point scale. Consistent with the tripartite model, the Negative Affect scale of the PANAS is associated with both anxiety and depression, whereas the Positive Affect scale is more strongly associated with depression than with anxiety (e.g., Lonigan, Phillips, & Hooe, 2003). The 18-item Physiological Hyperarousal Scale for Children (PH-C; Laurent,

Catanzaro, & Joiner, 2004), designed as a companion to the PANAS-C, has shown preliminary evidence of validity. The Affect and Arousal Scale for Children (AFARS; Chorpita et al., 2000) is a 27-item, self-report measure of positive and negative affect, and physiological hyperarousal. Respondents rate each item on a 4-point scale. The AFARS has high internal consistency and validity in a community sample (Chorpita et al., 2000; Daleiden, Chorpita, & Lu, 2000). In one study, both the PANAS-C and AFARS Negative Affect scales predicted self-reports of depression and anxiety. The PANAS-C Positive Affect scale discriminated between mood disorders and other disorders, but the AFARS Positive Affect scale did not (Chorpita & Daleiden, 2002), suggesting that the PANAS-C might be more useful for identifying depression. Although these measures include an assessment of (low) positive affect, they do not assess other aspects of anhedonia characteristic of depression (e.g., loss of pleasure, loss of interest in activities, boredom). Factor analyses of another recently developed measure, the Youth Mood and Anxiety Symptom Questionnaire (Y-MASQ; Rudolph et al., 2007), adapted from the adult version of this measure (MASQ; Watson et al., 1995), reveal that anhedonia emerges as a distinct factor from other dimensions of depression and anxiety in youth, suggesting that the specific assessment of anhedonia might be useful.

Assessment of Depression-Related Impairment

Biological Processes

Empirical examination of biological processes hypothesized to be associated with depression in youth has yielded mixed findings. Here we provide a brief overview of some methods to assess biological processes. If further research reveals evidence for the specificity of these methods to depression, their use in clinical practice to assess vulnerability to depression, to aid in diagnosis, or to evaluate treatment response should be considered.

Pharmacological challenge tests examine physiological responses to the administration of dexamethasone and growth hormone-releasing hormone (GHRH). Levels of hormones typically affected by these agents (cortisol for the former and growth hormone for the latter) are measured prior to and following the test. Atypical responses to these

challenges (i.e., failure to suppress cortisol and blunted growth hormone responses) are characteristic of depressed and high-risk youth, but the specificity of these responses to depression is unclear (Dahl et al., 2000).

Possible sleep disturbances can be assessed using sleep polysomnography. This method typically requires an overnight stay in a sleep laboratory, where the individual is monitored while sleeping. Common forms of monitoring include electroencephalography (EEG; to record brain waves), electro-oculography (EOG; to record eye movement), and electrocardiography (ECG; to measure electrical activity in the heart). This procedure is minimally invasive. However, inconsistent findings regarding sleep abnormalities in depressed youth suggest that this method is not likely to be a useful approach for diagnosing depression (Bloch, 1997).

Identification of structural and functional brain abnormalities associated with depression requires the use of imaging techniques (e.g., magnetic resonance imaging [MRI] and computed tomography [CT]), and functional brain imaging techniques (e.g., single-photon emission computed tomography [SPECT] and positron emission tomography [PET]). The cost and equipment required for these methods limit their use in most settings, and minimal data recommend their use with depressed youth at this point. Other practical concerns also must be considered. For example, although MRI scanners do not use radiation, they might be noisy and are very sensitive to movement, which might make it difficult to obtain valid results in young children. Additionally, closed MRIs might cause discomfort in some youth. CT scans involve exposure to radiation in the form of X-rays, and the contrast dye used (often iodine) may cause an allergic reaction. Radioactive drugs also are used in PET (Rauch & Renshaw, 1995).

Thus, although emerging evidence points to some possible biological markers of depression in youth, many of the methods are not feasible in clinical settings due to the need for sophisticated equipment, invasive procedures, and appropriate training. Several of the methods are, of course, more feasible in hospital settings, in which access to equipment and training is more common. However, the inconsistency of evidence for particular types of biological dysfunction in depressed youth and the lack of specificity of many measures to depression limit their usefulness as diagnostic tools.

Social-Cognitive and Cognitive Processes

A large number of self-report measures have been developed to assess negative cognitions associated with depression, including constructs such as dysfunctional attitudes, pessimistic attributional style, low perceptions of competence and control, and hopelessness (for a review, see Winters, Myers, & Proud, 2002). These measures vary in their psychometric properties, and most lack sufficient normative information, which make recommendation of specific measures for use in clinical practice difficult.

Laboratory methods are less subject to the demand characteristics that might compromise the validity of self-report (Garber & Kaminski, 2000). Several information-processing tasks have demonstrated utility in distinguishing between youth with depressive symptoms or disorders and other youth. Incidental recall tasks present respondents with information of different valence and assess differential recall of positive versus negative information. It is hypothesized that depressed individuals recall information that is congruent with their depressive schemas regarding the self and others. Research generally supports this proposition (e.g., Cole & Jordan, 1995; Rudolph et al., 1997; Shirk et al., 1997), lending validity to these tasks as useful measures of depression-related memory biases. However, some aspects of memory biases might be age-dependent, not arising until adolescence (Cole & Jordan, 1995). Information-processing tasks (e.g., Stroop color-naming task) also have been used to assess attentional biases characteristic of depression, but research generally does not indicate an attentional bias for negative words among depressed youth (Neshat-Doost, Moradi, Taghavi, Yule, & Dalgleish, 2000). Because these studies employ methods developed for adults, additional research using developmentally based instruments is needed to examine attentional biases in depressed youth.

Depressed youth also may experience cognitive impairment, including deficits in intellectual functioning, speed of processing, and memory, although deficits may be more apparent in school performance than in cognitive abilities (Kovacs & Goldston, 1991). Empirical evidence is mixed, but some research indicates that, compared to nondepressed youth, depressed youth perform more poorly on complex reasoning and problem-solving tasks

(Kaslow, Tanenbaum, Abramson, Peterson, & Seligman, 1983), demonstrate larger Performance IQ deficits relative to their Verbal IQ (Brumback, Wilson, & Staton, 1984), and show a decreased posterior right-hemisphere bias in the processing of emotion (Flynn & Rudolph, 2007).

Selection of measures to assess social-cognitive processes depends on the construct(s) of interest and the purpose of the assessment (e.g., some measures show better discriminant validity for depression vs. anxiety). Developmental stage also is important to consider. Many of the measures were modified from those developed for adults, and adequate psychometric properties and clinical utility of these measures have not been established in youth, especially prior to adolescence. This is of particular concern given evidence that some aspects of cognitive vulnerability do not emerge until adolescence. Because assessment of these processes may inform possible targets for intervention or predictors of treatment outcome, further research aimed at standardization and validation for use in clinical settings would be helpful.

Interpersonal Processes

Impairment in social relationships may be assessed to a certain degree with depression rating scales and interviews, many of which assess certain aspects of interpersonal functioning (e.g., social withdrawal, feelings of loneliness). Structured behavioral observations of social interactions are another means of assessing the interpersonal aspect of depression. For these tasks, youth are observed participating in an interaction with another person in a controlled setting. For instance, specific tasks might focus on cooperation, problem solving, or conflict resolution (for a review, see Garber & Kaminski, 2000). Interactions typically are videotaped and coded for behaviors characteristic of depression. Behaviors of particular relevance include, for example, depressive affect or behaviors (e.g., dysphoria, withdrawal), aggression (e.g., irritability, argumentativeness), and deficits in problem solving. This method has demonstrated the ability to discriminate between depressed and nondepressed youth (e.g., Rudolph et al., 1994; Sanders et al., 1992). One advantage is that social interaction tasks provide information about sequences of behavior between depressed youth and others

(e.g., how parents respond to youth depressive behaviors) that might prove useful for treatment planning. However, as discussed, questions remain about the extent to which these methods can be adequately and systematically transported for use in clinical practice. Other methods also have demonstrated utility for obtaining information about interpersonal functioning. These include assessments of youth responses to hypothetical social situations (e.g., Narrative Completion Task; Shirk, Boergers, Eason, Van Horn, 1998), semistructured interviews (e.g., Social Adjustment Inventory for Children and Adolescents; John, Gammon, Prusoff, & Warner, 1987), and self-report rating scales (e.g., Social Adjustment Scale—Self Report; Weissman, Orvaschel, & Padian, 1980). Once again, the lack of normative information and data about clinical utility for many of these measures limits their usefulness in clinical practice at this time.

Other Domains

Several other domains are reasonable candidates for inclusion in an assessment of depression given their relevance for prognosis, treatment planning, and evaluation of treatment outcome. Given the aggregation of depression in families, assessment of family history of psychopathology, especially affective disorders, is informative both for determining risk and predicting course. This information may be obtained from diagnostic interviews with family members or by asking informants about history of psychopathology in other family members. Several standardized and well-validated semistructured interviews to assess family history of psychopathology are available, such as the Family Informant Schedule and Criteria (Mannuzza & Fyer, 1990) and the Family History—Research Diagnostic Criteria (Andreasen, Endicott, Spitzer, & Winokur, 1977). The time required to complete these interviews can range from 10 to 50 minutes per family member. Screening measures, such as the Family History Screen (Weissman et al., 2000), are a useful alternative when interviews are not possible.

Because stressful life circumstances are associated with the onset and maintenance of depressive symptoms (Kessler, 1997), they may be a useful part of an assessment. Life stress can be assessed with self-report measures (e.g., Johnson & McCutcheon, 1980) or semistruc-

ured interviews (e.g., Rudolph et al., 2000; Williamson et al., 2003). Although interviews provide richer information about the context and timing of stress (Duggal et al., 2000), administration and coding of these interviews are quite time-consuming and may not always be practical in clinical settings.

Assessment of general psychosocial functioning is useful to determine severity of impairment. Some diagnostic interviews (e.g., CAPA) and rating scales (e.g., Achenbach scales) assess psychosocial functioning. Alternatively, psychosocial functioning can be assessed with measures specific to functional impairment, such as the clinician-rated Children's Global Assessment Scale (C-GAS; Shaffer et al., 1983), Child and Adolescent Functional Assessment Scale (Hodges, 1999), and the Psychosocial Schedule for School-Age Children—Revised (Puig-Antich, Lukens, & Brent, 1986). The Social Adjustment Scale—Self Report (Weissman et al., 1980), a self-report rating scale, has demonstrated greater sensitivity to treatment effects in adolescents with comorbid MDD and conduct disorder than the C-GAS (Rohde, Clarke, Mace, Jorgensen, & Seeley, 2004). Overall, a comprehensive assessment of depression should include evaluation of multiple domains of functioning to determine the severity of impairment, to inform prognosis and treatment planning, and to evaluate the effects of treatment and possible change processes.

SUMMARY AND RECOMMENDATIONS FOR ASSESSMENT OF YOUTH DEPRESSION

Research has established adequate psychometric properties and, to a more limited extent, clinical utility for a range of methods and measures designed to assess youth depression. A number of criteria must therefore be considered when determining the most appropriate assessment approach within both research and clinical settings.

1. *Select measures that are appropriate for the specific purpose and stage of assessment.* Selection of an appropriate assessment tool depends in part on the level of depression being assessed, which in turn reflects the taxonomic system of interest. Rating scales are appropriate if the goal is to assess symptom severity, whereas structured or semistructured inter-

views are required if the goal is to determine whether diagnostic criteria are met. The goal might depend in part on the stage of assessment. For example, in a “multiple-gating” approach (Reynold, 1994), ratings scales of depression and associated symptoms are used as screening tools, followed by more intensive interviews where indicated. Some ratings scales (e.g., CBCL/TRF, CDI) have extensive normative information and established cutoff scores that maximize their potential to select youth who will likely meet criteria for a diagnosis. However, these scales cannot be used as diagnostic instruments, because they have only moderate specificity for depression and do not provide information about the timing and duration of symptoms, history of disorder, associated impairment, or exclusionary criteria. Some rating scales demonstrate sensitivity to change in symptoms following treatment, suggesting that they may be useful at later stages of assessment to monitor treatment progress. Evaluating the psychometric adequacy of a measure also depends on the general purpose of the assessment. For example, the relative balance of desired sensitivity and specificity might be different for case formulation and prognosis versus treatment planning versus evaluation of treatment effectiveness. Different criteria for psychometric characteristics also are likely to be used in research versus clinical settings. Finally, the psychometric adequacy of measures must be considered for the particular population of interest (e.g., one with a low vs. a high base rate of depression; different ethnic and cultural groups).

2. *Select measures that are developmentally appropriate.* Another issue to consider is the developmental appropriateness of assessment tools. As discussed, the phenomenology of depression, the frequency of particular co-occurring symptoms and types of impairment, and the predictors of depression vary across development. These factors need to be considered both when selecting an assessment instrument and when interpreting results. For example, measures of adolescent depression that represent downward extensions of measures developed for adults might not fully assess the symptoms and domains of impairment most relevant to youth. Moreover, measures adapted from those used in adults tend not to have normative information on parallel parent and teacher versions, which are useful for assessing youth depression.

Additionally, the cognitive and language abilities of youth should guide the assessment strategy. Young children’s reports of depressive symptoms are less reliable than those of adolescents (Edelbrock et al., 1985), because accurate reporting requires cognitive skills not present in preadolescents, such as the ability to gauge how often and how intensely they experience symptoms, and whether symptoms represent a change from prior functioning (Clarizio, 1994). Reading and language ability also should be considered in selection of measures and determination of how to administer self-report measures, particularly when measures originally designed for adults are used with youth. Self-report should be used with caution in children under 8 years of age, although the validity of self-report of depression has been shown in children as young as 5 (Ialongo, Edelsohn, & Kellam, 2001). Recently, methods for the assessment of depression in preschoolers have received more attention and show some promise. Given preliminary evidence that child-versus adolescent-onset depressive disorders might differ, more research on developmental changes in the nature of depression is needed to determine whether the best assessment methods vary across developmental stage.

3. *Carefully consider how to integrate information across informants and methods.* Regardless of the age of youth, multi-informant report typically is desirable. Unfortunately, few formal guidelines exist regarding how to integrate this information and to resolve discrepancies. Moreover, limited data are available on the incremental validity of particular measures when added to a comprehensive assessment battery, and no information is available on incremental validity for predicting clinically relevant outcomes (e.g., whether youth will benefit from certain types of treatment, optimal length of treatment). The recommended use of multiple measures, methods, and informants also must be balanced with the time and cost-effectiveness and the availability of trained personnel. One reasonable approach is the multiple-gating procedure described earlier, in which relatively low-cost screening methods are used at earlier stages of assessment, followed by more intensive methods as indicated. Continued research is needed to determine the incremental validity of measures and their ability to predict clinical outcomes.

4. *Select measures that are feasible and useful for the setting.* The choice of assessment

tools is clearly informed by pragmatic issues, such as the time and cost associated with training, administration, and scoring, and by their utility in a particular setting of interest. Because most measures of youth depression were developed for use in research, less attention has been devoted to establishing feasibility and utility of the measures, and their ecological validity in clinical settings. However, time-intensive measures might be modified for use in clinical settings. For example, if time and cost constraints prohibit the administration of a full semistructured interview, portions most relevant to youth (based on rating scales and family interviews) might be administered. Similarly, analogue behavioral observations developed for research may be modified for use in clinical settings. For example, instead of using highly trained, but uninvolved, observers to rate behaviors, therapists and clients can review target behaviors together as a part of treatment planning and evaluation (Mash & Foster, 2001).

5. Assess co-occurring psychopathology. Given high rates of comorbidity, a thorough assessment of depression should include an evaluation of other major disorders. This supplemental evaluation is needed to facilitate differential diagnosis, to determine whether depression is the primary diagnosis, and to provide information about concurrent symptoms that might influence the prognosis, selection of treatment, or treatment response. Diagnostic interviews and many rating scales include an assessment of other relevant psychopathology. Selection of other domains of assessment may be guided in part by knowledge about base rates of co-occurring problems. For example, although many ratings scales do not include an evaluation of eating disorders or substance abuse, the heightened rates of eating disorders in depressed female adolescents and of substance abuse in depressed male adolescents suggest the usefulness of screening for these symptoms within these particular groups. A comprehensive assessment also must include an evaluation of specific features of depression that might influence prognosis and treatment, such as suicidal ideation, symptoms of mania or hypomania, and psychosis.

6. Assess related areas of impairment. A thorough assessment involves examining several key areas of functioning that often are compromised in depressed youth, such as social-cognitive processes, academic perfor-

mance, and interpersonal relations. At a most basic level, this information can identify areas of dysfunction and distress that warrant attention. Moreover, this information may influence decisions about the setting (e.g., inpatient, outpatient) and the modality of treatment (e.g., family therapy, social skills training). An ongoing assessment of these areas throughout treatment also provides information about processes of change and clinically relevant outcomes (e.g., improvement in peer relations or academic performance). Although relatively little is known about the implications of impairment in various life domains for clinical outcomes, preliminary research identifies several factors that predict the course of depression. For example, a strong family history of depression, high levels of borderline personality disorder symptoms, and conflict with parents (in females) predict an increased likelihood of recurrence, whereas low levels of excessive emotional reliance, low levels of antisocial and borderline personality disorder symptoms, and a positive attributional style (in males) protect against recurrence (Lewinsohn et al., 2000; Rohde et al., 2005). More research is needed to examine the power of other characteristics of youth and their contexts to predict course and outcome, and to determine treatment-specific responsiveness. Based on this information, a better determination may be made about the utility of evaluating particular characteristics and experiences associated with depression.

Another challenge that arises in determining appropriate supplemental areas of assessment is that many of the measures for evaluating related constructs (e.g., life stress interviews, physiological assessments) were developed for use in research and are less practical in clinical settings. Moreover, these measures often lack normative information and are less standardized than measures of depression. Thus, recommendation of many of these measures in clinical settings is premature. More research is needed to standardize and adapt these measures for use in clinical settings and to determine their utility for predicting clinical outcomes.

7. Consider the natural course of depression. Data on the course of depression suggest that most disorders remit over time, but that ongoing subsyndromal symptoms and recurrence are common. Research points to some specific features that predict the likelihood of recurrence (see earlier sections). Assessment of

these aspects of personal and family history provides important supplemental information that may guide features of treatment such as involvement of family members and the need for periodic “booster” sessions after the completion of treatment. However, few scientific data are available on the utility of such features of treatment for decreasing the likelihood of recurrence. It also is important to consider that the course of depression is characterized by both disorder-specific and disorder-nonspecific continuity; that is, early onset of depression might predict not only future depression but also other disorders. Thus, even if depression is the primary initial diagnosis, ongoing evaluation for other disorders is necessary. Unfortunately, little research is available to guide prediction of whether depression will follow a disorder-specific or nonspecific course, with the exception that youth with a personal or family history of depression are more likely to show depression recurrence (Weissman, Wolk, Wickramaratne, et al., 1999) and those with co-occurring behavior disorders are more likely to show subsequent disorders other than depression (Harrington et al., 1990).

CONCLUSION

Given the prevalence of depressive symptoms and disorders in youth, particularly during adolescence, along with the accompanying impairment and risk for subsequent dysfunction, it is critical to develop guidelines for assessing depression that maximize the success of early identification, prevention, and intervention efforts for youth. Significant progress has been made in developing psychometrically sound methods for assessing depression and associated impairment in youth, but less attention has been paid to establishing the clinical utility and feasibility of these methods in applied settings. Future work should be directed toward facilitating the application of knowledge and methods developed in research to clinical settings.

Pediatric Bipolar Disorder

Eric Youngstrom

THE CONTROVERSY SURROUNDING PEDIATRIC BIPOLAR DISORDER

Pediatric bipolar disorder (PBD) is currently one of the most controversial diagnoses in child mental health (cf. Harrington & Myatt, 2003; Healy, 2006; Klein, Pine, & Klein, 1998; McClellan, 2005). Conventional wisdom has held that PBD is a relatively rare and serious mental illness, affecting about 1 in 100 adults in the general population. The age of onset also typically has been thought to be late adolescence or early adulthood (Klein et al., 1998). However, there has been an explosion of interest over the last decade in the diagnosis of “bipolar disorder” in children and adolescents. Bipolar diagnoses of preschoolers have been made by researchers (Tumuluru, Weller, Fristad, & Weller, 2003), and of toddlers by practicing clinicians (Papolos & Papolos, 2002). Parents sometimes describe their children as being bipolar “from birth,” or even *in utero* (Papolos & Papolos, 2002).

Attention to the diagnosis also has dramatically increased. Whereas occasional case studies were published from the 1930s to the 1970s, the number of scholarly publications has risen geometrically since 1995 (Lofthouse & Fristad, 2004). There also has been a surge of attention in the popular media, ranging from special segments on news shows or Music Television (MTV™) to a cover article in *Time* mag-

azine (Kluger & Song, 2002), to nearly two dozen trade books aimed at parents and families, as well as health professionals (Lofthouse & Fristad, 2004).

Given this expansion of the age range and the surge of media attention, it is perhaps less surprising that the actual rates of diagnosis have increased. Even so, the magnitude of the change is remarkable. From virtually never being diagnosed prepubertally, PBD has become one of the more frequent diagnoses in many mental health settings. Rates of bipolar diagnoses in youth wards of the county in Illinois more than doubled, from 4 to 11% between 1994 and 2001 (Naylor, Anderson, Kruesi, & Stoewe, 2002), and similarly large increases have been documented in community mental health (Youngstrom, Youngstrom, & Starr, 2005) and other settings (Blader & Carlson, 2006). Marketing research estimated that nearly 100,000 youth were already taking medication for PBD in the United States in 2000, even prior to the wave of publicity around the diagnosis (Hellander, 2002).

Although there is speculation about both genetic and environmental changes that might lead to an increase in the rate of PBD (as discussed below), the acceleration in prevalence of the diagnosis is too rapid to be explained entirely by changes in risk factors. A major driver of the rise is changes in mental health practice. Changes in families’ and practitioners’ aware-

ness of possible PBD, as well as changes in the conceptualization of what is considered “bipolar” disorder, play a huge role.

The surging diagnostic prevalence has provoked concern about “disease mongering”: pathologizing behaviors that might be within normal limits, or promoting pharmacological interventions for problems that might be responsive to interpersonal interventions (Healy, 2006). PBD is much more rarely diagnosed in countries other than the United States (Soutullo et al., 2005). This is often attributed either to the “overdiagnosing” PBD (Harrington & Myatt, 2003), or possibly a greater incidence of PBD in the United States, perhaps as a result of the much more commonplace use of psychotropic medications (Reichart & Nolen, 2004).

Psychology as a profession has been much more skeptical than other health care professions about diagnosing bipolar disorder (BD) in children. Although critical thinking is certainly warranted, the skepticism has meant that there has been little in the way of development of rigorous assessment strategies. Similarly, relatively little effort has been invested in exploring psychosocial interventions: Only a few pioneering research groups have worked in this area, and without much extramural grant support until recently. As a consequence, the field of psychology has not been well prepared for the recent flood of referrals. Without proven assessment and psychosocial treatment techniques, there is a tremendous unmet need for helping families to make sense of their struggles and to address them constructively. Pediatricians, general practitioners, social workers, teachers, nurses, and parents have been trying to fill the gap, but psychological approaches clearly would be beneficial, too.

WHY BOTHER TO ASSESS FOR PBD?

In light of the justifiable reluctance to diagnose BD in children and adolescents, why should clinicians bother to assess for PBD? There are good reasons to be agnostic about PBD. “Agnosticism” in this context means being neither dogmatically certain that one will not encounter PBD in one’s practice, nor suspending critical thought and labeling large numbers of cases with a trendy but probably relatively rare condition. The arguments for caution, which are described in detail below, include (1) the likely rarity of bipolar disorder in youth, (2) the diffi-

culty in disentangling mood symptoms from developmentally appropriate behavior or problems due to more common conditions (e.g., attention-deficit/hyperactivity disorder [ADHD] or unipolar depression), (3) frequent comorbidity that further obscures the clinical presentation, (4) lack of information about the developmental continuity of mood problems from youth into later life, and (5) a historical lack of proven assessment and therapeutic tools even if PBD were present.

On the other hand, BD has a large genetic contribution (Faraone, Tsuang, & Tsuang, 1999). The genes conveying risk are present from the moment of conception. Thus, the issue is determining how early adverse environmental experiences interact with genes to produce a pattern of behavior problems that we recognize as a mood disorder. Kraepelin (1921) diagnosed “manic depressive insanity” with some frequency in youth ages 13 and older, and more rarely in younger children. Case notes that paint a picture of mania in children extend back into the 17th century (Findling, Kowatch, & Post, 2003), and numerous other examples of published case presentations are scattered through the 20th century prior to 1990 (see Glovinsky, 2002, for a review). There is also no strong theoretical argument for why BD does not manifest until adulthood. Whereas some evidence suggests that changes in endocrine functioning associated with puberty might increase the hazard of developing BD, there are no models describing commonplace mechanisms that would later trigger a bipolar diathesis.

Perhaps the most compelling arguments in favor of careful assessment of possible PBD are pragmatic. In general, assessment should contribute to the clinical enterprise by *predicting* meaningful outcomes, by *prescribing* interventions (or contraindicating other approaches), or by measuring *processes* related to successful intervention. A case formulation involving PBD addresses all three of these domains. In terms of prediction, a bipolar diagnosis is associated with higher risk for many poor outcomes, including substance use, delinquency, and suicidality (Lewinsohn, Klein, & Seeley, 2000). Even when standard clinical care is available, PBD is associated with long periods of illness and high rates of relapse, and considerable functional impairment in terms of family conflict, educational failure, and poor peer relations (Birmaher et al., 2006; Geller, Tillman,

Craney, & Bolhofner, 2004; Lewinsohn et al., 2000).

With regard to prescription, a bipolar case formulation alerts a clinician to a set of potential concerns that extends beyond management of anger, impulse control, and internalizing problems, although these issues are likely also to be part of the presenting problem. In addition, a bipolar diagnosis should trigger a focus on sleep hygiene, activity scheduling, management of both positive and negative events, and evaluation of adherence to treatment (Danielson, Feeny, Findling, & Youngstrom, 2004). At present, there are no psychosocial or pharmacological treatments with enough demonstrated efficacy in youth samples to satisfy the highest standards for “empirically supported treatments” (Chambless & Hollon, 1998) or evidence-based practice (Guyatt & Rennie, 2002; Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). However, a growing body of evidence suggests that psychoeducational (Fristad, Gavazzi, & Mackinaw-Koons, 2003), family therapy (Miklowitz et al., 2004), cognitive behavioral therapy (Feeny, Danielson, Schwartz, Youngstrom, & Findling, 2006; Pavuluri et al., 2004), and other psychosocial interventions have value as adjunctive treatments. Practice parameters currently indicate that pharmacotherapy should be considered the first line of treatment for PBD, but they also make clear that psychosocial interventions are an essential component of the treatment package (Kowatch, Fristad, et al., 2005).

A bipolar diagnosis is also clinically helpful in terms of what approaches it contraindicates. At a pharmacological level, a bipolar diagnosis should probably rule out the use of stimulant medications as a way of managing hyperactivity and distractibility, at least without an additional mood-stabilizing agent already in use (Scheffer, Kowatch, Carmody, & Rush, 2005). Similarly, the U.S. Food and Drug Administration (FDA) has recommended that manufacturers of antidepressants voluntarily include language in packaging inserts alerting consumers and prescribers that thorough evaluation should rule out the possibility of bipolar illness before a person takes antidepressant medication to treat a depressive episode. There is widespread clinical concern that the well-intentioned use of stimulants or antidepressants is at best ineffective in managing bipolar illness and may even exacerbate the course of

illness instead (DelBello, Soutullo, et al., 2001; Geller, Fox, & Fletcher, 1993). Although it has proven difficult to demonstrate evidence of pharmacotoxicity in research studies (Carlson, 2003; Carlson & Mick, 2003), even the “best-case scenario” suggests that selection of inappropriate pharmacological interventions exposes patients to all of the potential risks, with little potential for benefit. Even though less work has targeted psychosocial interventions, it is also becoming evident that efficacious treatments for depression need some modification for work with BD, lest they accidentally trigger manic or mixed episodes (Fristad & Goldberg Arnold, 2004; Newman, Leahy, Beck, Reilly-Harrington, & Gyulai, 2002; Scott & Colom, 2005).

Additionally, a case formulation including a bipolar diagnosis generates a set of assessment goals and techniques geared toward supporting treatment. Besides routine evaluation of internalizing and externalizing symptoms, a bipolar formulation requires more systematic tracking of mood and energy levels. Unlike unipolar depression (see Rudolph & Lambert, Chapter 5, this volume), a bipolar diagnosis requires monitoring of highs, as well as lows and periods of irritability. Relapse prevention becomes an important formal component of treatment, so identification of “triggers” and early warning signs of mood destabilization (“roughening” of mood) (Sachs, Guille, & McMurrich, 2002) become paramount.

Finally, thorough assessment helps to reduce the rate of overdiagnosis of a trendy condition. Good evaluation not only leads to improved identification of those cases actually affected by PBD (i.e., raising the diagnostic “sensitivity”) but also enhances correct recognition of cases without PBD (i.e., bettering the diagnostic “specificity”). Accurate identification of nonbipolar illnesses is of tremendous value to families. Correct diagnosis avoids unnecessarily exposing children to pharmacological agents that are less well investigated than stimulants or antidepressants in youth populations, yet clearly have risks of much more serious side effects (Findling, Feeny, Stansbrey, DelPorto-Bedoya, & Demeter, 2004). Besides lessening the risk of iatrogenic treatments, correctly labeling the nonbipolar condition connects to a much larger evidence base that can guide treatment. When we appropriately discern that the problems are due to ADHD, unipolar depression, or parent-child conflict, and not a bipolar

illness, researchers and clinicians bring to bear much more experience and evidence.

For all of these reasons, it seems useful that cautious clinicians shift to an agnostic stance. Likewise, to avoid overdiagnosis, practitioners who have been diagnosing PBD would be prudent to adopt the most rigorous methods available. It behooves us to become familiar with the complexities of assessing BD in children and adolescents, as well as to learn about the tools and strategies that aid this high-stakes clinical decision.

DIAGNOSTIC CRITERIA

Diagnostic Categories

The challenges of assessing BD begin with the diagnostic criteria themselves. The fourth, text revised edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) currently delineates four different diagnoses that are clearly on the bipolar spectrum: bipolar I and bipolar II disorder, cyclothymia, and BD not otherwise specified (NOS) (American Psychiatric Association [APA], 2000). The In-

ternational Classification of Diseases (ICD-10) uses the same categories, but with slightly different criteria. However, diagnosing a mood disorder first requires gathering information about the lifetime history of mood states. Different diagnoses require different combinations of mood states, introducing a level of complexity not found in most other diagnoses. Adding more barriers to correct identification, people are unlikely to seek treatment for hypomania and rarely self-refer for treatment of mania. As a result, clinicians are much more likely to see patients during the depressed phase of a bipolar illness.

The mood states that must be assessed correctly to ascertain a DSM-IV-TR diagnosis of mood disorder include manic episode, mixed episode, major depressive episode, hypomanic episode, dysthymic episode, and dysthymia with superimposed hypomanic symptoms. Although the last mood state is not formally distinguished in DSM-IV-TR, it has been proven necessary to diagnose cyclothymia (which requires marked hypomanic symptoms, but not necessarily hypomanic episodes with duration of 4 or more days). Table 6.1 reviews the symp-

TABLE 6.1. Criteria for Manic or Hypomanic Episode

-
- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, clearly different from usual mood. *Duration:* At least 1 week (unless severe enough that hospitalization is necessary) for mania; at least 4 days for hypomanic episode.
- B. During the mood episode, at least three of the following symptoms are also present to a significant degree (four or more if mood is mostly irritable):
- (1) inflated self-esteem or grandiosity
 - (2) decreased need for sleep (such as feeling rested with only 3 hours of sleep)
 - (3) pressured speech or more talkative than usual
 - (4) flight of ideas or racing thoughts
 - (5) distractibility
 - (6) increased goal-directed activity or psychomotor agitation
 - (7) excessive pleasurable activities with a high risk for painful or damaging consequences
- C. If showing sufficient symptoms for both a manic episode and also major depressive episode for at least 1 week (or until hospitalized), then classify as “mixed episode”
- D. *Mania:* Causes marked impairment in school, at home, or with peers; may also require hospitalization to prevent harm to self or others; may also have psychotic features.
Hypomania: An unequivocal change in functioning from typical for person when not symptomatic, observable by others; but *not* severe enough to cause marked impairment, and with no psychotic features.
- E. Rule out symptoms due to physiological effects of a substance (including stimulant or antidepressant medication), or symptoms due to a general medical condition.
-

toms and criteria for a DSM-IV-TR diagnosis of manic or hypomanic episodes. Rudolph and Lambert, Chapter 5, this volume, review the criteria for unipolar depression and dysthymia.

Some additional complexities are stipulated in the diagnosis of bipolar spectrum disorders. Bipolar II disorder requires both a major depressive episode and a hypomanic episode at some point in the person's life. Cyclothymia, on the other hand, involves depressive and hypomanic symptoms that are insufficient in severity to qualify for a full-blown major depressive or manic episode, at least during the first year of mood disturbance in children or adolescents, yet clearly mark a change from typical functioning or temperament. A bipolar I disorder diagnosis may be based on a single manic or mixed episode. One need never be depressed to be diagnosed with what used to be called "manic-depression"!

Little additional guidance is offered for assessment of mood disorders in children or adolescents. Besides noting that irritable mood may be more common than sad mood in depression for children, DSM-IV-TR does not make any developmental modifications of the symptom criteria for diagnosing any of the aforementioned mood states. The only developmental modification to the durational criteria is to accept a 1-year duration instead of a 2-year duration for dysthymic and cyclothymic episodes. Without good normative developmental data, it is difficult to tell whether these minimal adjustments are adequate. Research has concentrated on validating the extant diagnostic criteria in youth, then proposing incremental modifications for depression (Kovacs, 1989; Luby et al., 2003) and mania (Geller & Luby, 1997).

The following description of diagnoses is intended to provide an overview of the criteria, along with a discussion of the strengths and limitations of the current framework, especially as applied to children and adolescents.

Bipolar I

Considered the most serious form of bipolar illness, a bipolar I disorder diagnosis requires the presence of at least one manic or mixed episode during a person's lifetime. Once a manic or mixed episode has occurred, DSM and ICD nosologies consider the individual to have a lifetime diagnosis of bipolar I disorder. If the individual is currently functioning well, then

the classification is bipolar I "in remission." If the person develops classic major depression, even years after the mania, then the correct diagnosis is "bipolar I, current episode: depressed." Both mania and mixed states require that the behavior be a change from typical functioning for the individual, and that the behavior causes impairment (even though it may not distress the person experiencing the mood disturbance). The mood disturbance must either occur much of the day for most days over a period of at least 1 week, or the mood disturbance must be so extreme as to result in psychiatric hospitalization, in which case the 1-week duration requirement is waived. Although a person need never be depressed to be diagnosed with bipolar I, depression is the more common phase of illness, at least in adults; and depression appears to impose a greater burden than does mania over the course of illness (Judd et al., 2005).

Bipolar II

Diagnosis of bipolar II disorder requires at least two lifetime mood states: both a major depressive episode and a hypomanic episode. Although generally considered less severe than bipolar I disorder, recent data indicate that bipolar II disorder may be associated with higher risk of suicide (Rihmer & Kiss, 2002). It is also much more difficult to diagnose than bipolar I, because hypomania is by definition more subtle and less impairing than mania. In addition, an affected individual is much more likely to seek treatment during the depressed phase of the illness, and neither the individual nor the interviewing clinician is likely to disclose or assess for the hypomanic episodes that distinguish between bipolar II illness and unipolar depression. Furthermore, bipolar II disorder has rarely been evaluated systematically in clinical or research settings with children (Youngstrom, Youngstrom, et al., 2005).

Put another way, clinicians are most likely to encounter bipolar II disorder during the depressed phase of the illness. There are no evidence-based indications that bipolar depression consistently presents differently than unipolar disorder at the symptom level. However, the bipolar-unipolar distinction is important in terms of suicide risk, substance use, choice of pharmacological agent, and possibly choice of strategies for psychotherapy. Unfortunately, available data also indicate that individuals af-

affected with bipolar II disorder tend to first present clinically in the depressed phase of the illness, and early-onset depression may be a marker for BD (Birmaher, Arbelaez, & Brent, 2002; Kovacs, 1996). These findings suggest that many children and young adolescents afflicted with what appears to be depression might actually be experiencing the depressed phase of a bipolar illness.

Cyclothymia

The diagnosis of cyclothymic disorder requires that a period of mood disturbance last at least 1 year (2 years in adults), with no more than 2 months free of symptoms. The mood disturbance represents a clear change in the individual's typical pattern of behavior (distinguishing it from temperament) observable by others. The mood involves depressive or dysthymic symptoms, along with periods of hypomanic symptoms. During this index period, the depressive symptoms cannot become sufficiently severe to meet criteria for a major depressive episode (in which case the diagnosis changes to unipolar depression, or perhaps bipolar II disorder), nor can the hypomanic symptoms become too impairing (in which case the diagnosis changes to bipolar I disorder). It is possible to meet criteria for both cyclothymia and bipolar I disorder (much as it is possible to meet criteria for dysthymia and major depression over the course of lifetime—provided that the cyclothymic or dysthymic episode precedes the onset of the more severe mood state).

Cyclothymia is an especially slippery construct to assess on the bipolar spectrum. The long duration of the mood disturbance makes it hard to distinguish between temperamental traits and cyclothymic episodes, particularly for children: A year represents a much larger portion of a young child's life (blurring the boundary between an episode and a trait), and assessors need to rely more on collateral informants, such as parents or teachers, to identify changes in mood and energy. For this reason, in clinical practice, cyclothymia has rarely been diagnosed in youth even in the United States (Youngstrom, Youngstrom, et al., 2005). Some research groups are also reluctant to label youths with "cyclothymia," often lumping these clinical presentations into a "bipolar disorder not otherwise specified" category instead (Birmaher et al., 2006). However, it is worth

noting that pediatric cyclothymia, when labeled as such, has been shown to be linked to high levels of impairment (Findling, Youngstrom, et al., 2005; Lewinsohn, Seeley, Buckley, & Klein, 2002), yet also often shows spontaneous remission or lack of progression to more severe forms of mood disorder (Kahana, Youngstrom, Calabrese, & Findling, under review; Lewinsohn et al., 2002).

Bipolar Disorder Not Otherwise Specified

Bipolar disorder not otherwise specified (BD NOS) is a residual category used to describe clinical presentations that appear to be on the bipolar spectrum but do not fit into any of the three aforementioned categories. DSM-IV-TR gives several examples of possible presentations for BD NOS, including repeated episodes of hypomania without lifetime history of manic, mixed, or depressive episodes—a presentation that is unlikely to come to clinical attention but has been described in studies of nonclinical adolescents and young adults (Depue, Krauss, Spoont, & Arbisi, 1989). Other presentations include manifesting an inadequate number of "B criteria" symptoms in the context of episodic mood disturbance, or showing sufficient symptoms, but for an insufficient duration to meet established criteria for a diagnosis. BD NOS, like cyclothymia, tends to be diagnosed only rarely in clinical practice (Youngstrom, Youngstrom, et al., 2005). In addition, different research groups tend to use different operational definitions of BD NOS (see Table 6.2). However, BD NOS is linked to substantial clinical impairment, including poor functioning academically and interpersonally, high rates of service utilization and suicide risk, and substantial mood disturbance, whether NOS is defined as insufficient number of symptoms (Lewinsohn, Seeley, & Klein, 2003), insufficient duration (Findling, Youngstrom, et al., 2005), or a combination of the two (Axelson et al., in press). BD NOS appears to show patterns of familial risk (Findling, Youngstrom, et al., 2005) and symptom severity (Axelson et al., 2006) that are consistent with it being on the bipolar spectrum; and more than one-fourth of youth with BD NOS progress to more fully syndromal bipolar presentations (i.e., meeting criteria for bipolar I or II disorder) within a few years of initially being diagnosed with BD NOS (Birmaher et al., 2006).

TABLE 6.2. Definitions of Bipolar Disorder, Bipolar Spectrum Disorder, and Research Definitions of Pediatric Bipolar Subtypes

Definition (source)	Comment
Bipolar I	<ul style="list-style-type: none"> • Requires lifetime presence of a manic or mixed-state episode, mood disturbance duration of 7 days or until hospitalization. • No requirement of depression—ever. • ICD-10 requires multiple episodes to be confident of diagnosis; only “provisional” with single episode, even in adults.
Bipolar II	<ul style="list-style-type: none"> • Requires lifetime combination of a major depressive episode and a hypomanic episode (of at least 4 days’ duration).
Cyclothymia (DSM-IV-TR)	<ul style="list-style-type: none"> • Technically not considered a type of “bipolar NOS” in DSM. • Rarely diagnosed in children or adolescents in research or clinical settings (Youngstrom, Youngstrom, et al., 2005). • Many research groups lump cyclothymia with BD NOS (Birmaher et al., 2006). • Difficult to disentangle from normal development, temperament, and comorbid conditions due to the requirement that patient not meet criteria for full manic, mixed, or major depressive episode during initial year of illness. • Still possible to diagnose reliably, and associated with a significant amount of impairment (Findling, Youngstrom, et al., 2005).
Repeated hypomanias in the absence of lifetime mania or depression (DSM-IV-TR bipolar disorder not otherwise specified [BD NOS])	<ul style="list-style-type: none"> • Unlikely to be impairing enough to lead to treatment seeking; thus, not observed clinically. • Challenging to differentiate from behavior within developmental normal limits.
Insufficient duration of mood episodes (DSM-IV-TR). Leibenluft et al. (2003) further distinguish between cases with elated mood and/or grandiosity, and those with only irritability as mood disturbance; following Geller, Williams, et al. (1998).	<ul style="list-style-type: none"> • This appears to be a common presentation (Axelson et al., 2006; Findling, Youngstrom, et al., 2005). • It is associated with a high degree of impairment (Lewinsohn et al., 2000). • This definition may include cases with mood severity that would otherwise warrant a diagnosis of manic, mixed, or depressive state. • Also may include cases with mixed states that involve polarity shifts, if the diagnostician expects a week’s worth of duration for either polarity. • Important to note that adult data are calling durations into question (Angst et al., 2003).
Insufficient number of manic symptoms. Leibenluft et al. (2003) included “irritable hypomania” and “irritable mania” as another “intermediate” phenotype, even if accompanied by four or more other manic symptoms.	<ul style="list-style-type: none"> • This also appears to be more prevalent than cases meeting strict DSM criteria for bipolar I or II disorder, both in adolescent data and in reanalyses of adult epidemiological data (Judd & Akiskal, 2003; Lewinsohn et al., 2000). • Captures a much more heterogeneous group, and it is possible to meet criteria for this category relying entirely on nonspecific symptoms (e.g., irritable mood plus distractibility, high motor activity, and rapid speech). • Research designs typically have not documented episodicity of symptoms (Judd & Akiskal, 2003; Lewinsohn et al., 2000). • In spite of these caveats, this definition of BD NOS is still associated with high rates of impairment and service utilization (Galanter et al., 2003; Hazell et al., 2003).
Severe mood dysregulation (previously referred to as a “broad phenotype”) (Leibenluft et al., 2003, definition)	<ul style="list-style-type: none"> • Recommended criteria: Abnormal mood (anger or sadness) present at least half the day most days; accompanied by “hyperarousal” (insomnia*, agitation, distractibility, racing thoughts/flight of ideas; pressured speech, or social intrusiveness*); also shows increased reactivity to negative emotional stimuli compared to peers*; onset before age 12; duration at least 12 months, with no more than 2 months symptom free; symptoms severe in at least one setting.

(continued)

TABLE 6.2. (continued)

Definition (source)	Comment
BD NOS—research criteria from “Course and Outcomes of Bipolar Youth” Study (NIMH Grant No. R01 MH059929) (Birmaher et al., 2006; Axelson et al., 2006)	<ul style="list-style-type: none"> • Rule outs: elated mood, grandiosity, or episodically decreased need for sleep; distinct episodes of 4+ days’ duration; meeting criteria for schizophreniform, schizophrenia, pervasive developmental disorder, or posttraumatic stress disorder; or meeting criteria for a substance use disorder in the past 3 months; or IQ < 80; or symptoms are attributable to a medication or general medical condition. • Comments: Not yet tested against data. The <i>exclusion</i> of episodicity and of several symptoms more specific to BD both are likely to select against bipolar spectrum cases. The inclusion of chronic presentations and sensitive but nonspecific symptoms are likely to include many individuals with presentations that are not on the bipolar spectrum. This category appears likely to include a blend of different etiologies and mechanisms as a result.
Child Behavior Checklist proxy diagnosis (after Mick et al., 2003). Often operationally defined as parent-reported <i>T</i> -scores of 70+ on Aggressive Behavior, Attention Problems, and Anxious-Depressed subscales.	<ul style="list-style-type: none"> • Requires “core positive”—presence of distinct period of abnormally elevated, expansive, or irritable mood. • Minimum of two other “B criteria” symptoms if mood is mostly elated; at least three “B criteria” if irritable. • Requires clear change from individual’s typical functioning (consistent with DSM-IV and ICD guidelines for hypomania). • Requires 4+ hours of mood within a 24-hour period to be counted as an index “day” of disturbance. • Requires 4+ days at a minimum over the course of a lifetime to diagnose BD NOS; nonconsecutive days are acceptable. • Beginning to garner empirical support (Axelson et al., 2006). • Needs replication in other samples/research groups, but overlaps substantially with “insufficient duration” and “insufficient number of B criterion symptoms” definitions of BD NOS.
	<ul style="list-style-type: none"> • Convenient to use for large-sample studies. • Avoids problems of rater training and anchoring effects. • Prone to factors that might bias parent report. • Does not capture diagnostically specific symptoms; instead concentrates on sensitive symptoms that might also have high false-positive rate. • Focuses on symptoms that are likely to be “shared” with other disorders at a genetic level. • Concerns that agreement with clinical or research-interview-derived (K-SADS) diagnoses of bipolar spectrum might be modest.

Note. Expanded and adapted from Table 2 in Youngstrom, Birmaher, and Findling (under review).

*Symptom is not part of current DSM-IV nosology for mania.

Other Definitions of the Bipolar Spectrum

Several other definitions of “bipolar spectrum” diagnoses are sometimes used in the literature or clinically. One of the most important to consider clinically is “substance-induced mania.” Manic-like symptoms may be induced not only by street drugs such as cocaine but also by prescription drugs, including corticosteroids (as happened with TV personality Jane Pauley). There also is concern that stimulant medications (Carlson & Mick, 2003; DelBello, Soutullo, et al., 2001), tricyclic antidepressants (Geller et al., 1993), or selective serotonin

reuptake inhibitors (SSRIs) (Ghaemi, Hsu, Soldani, & Goodwin, 2003; Papolos, 2003; Reichart & Nolen, 2004) may induce manic symptoms. However, it is difficult to decide whether the appearance of manic symptoms in a person taking a medication represents (1) the spontaneous emergence of mania in someone already at risk, independent of the effects of the medication; (2) a side effect of the medication, irrelevant to the person’s true status with regard to bipolar illness; (3) an “unmasking” of a previously undetected bipolar illness in someone already genetically at risk; or (4) an iatrogenic effect of medication that changes the ner-

vous system in such a way that individuals not carrying genes of risk are still at risk of manifesting bipolar behaviors, even after medication is discontinued (a “scar hypothesis”). Recent research studies have failed to demonstrate clearly that medication use is associated with higher rates of mania (Carlson, 2003), and stimulants appear to be well tolerated when used in treatment for PBD in conjunction with mood-stabilizing compounds (Findling, McNamara, et al., 2005; Scheffer et al., 2005). For all these reasons, it is appropriate to follow the DSM recommendation to diagnose these cases as having “substance-induced mania” rather than “unmasked” bipolar I or bipolar II illness.

A second major category potential on the bipolar spectrum is represented by a subset of cases presenting with unipolar depression. People who have depression that onsets early, shows acute onset, is associated with atypical features (e.g., lethargy, hypersomnia, increased appetite or weight gain, and rejection sensitivity), recurrent depressive episodes, and in the context of a family history of BD are at higher risk of having depressed phases that ultimately prove to be bipolar illness (Birmaher et al., 2002; Kessler, Avenevoli, & Merikangas, 2001; Luby & Mrakotsky, 2003). Many researchers working with adults have tended to include these sorts of depressive presentations on the bipolar spectrum (Akiskal & Pinto, 1999; Ghaemi, Ko, & Goodwin, 2002; Sachs, 2004). Diagnosing depressed presentations in youth as bipolar spectrum illness is rare in clinical practice, and attempts to apply a “bipolar” label to depressed presentations in youth would be fraught with controversy. Yet epidemiological studies, longitudinal investigations of depression, and clinical referral patterns all indicate more than half of adults with bipolar illness likely sought help for depressive symptoms occurring in childhood or adolescence (Kessler, Berglund, Demler, Jin, & Walters, 2005; Perlis et al., 2004).

A third possible group on the bipolar spectrum includes those with “severe mood dysregulation,” or what has sometimes been called the “broad phenotype” of bipolar illness (Leibenluft, Charney, Towbin, Bhangoo, & Pine, 2003). Key features of this presentation include chronic irritability and mood lability, along with a lack of distinct episodes with marked change in mood or energy. In some data, these presentations appear to be on a con-

tinuum with bipolar illnesses, albeit involving more rapid rates and briefer episodes of mood disturbance. Some have noted that this clinical presentation seems highly similar to borderline personality disorder (BPD) in adults, and may in fact be a juvenile precursor to BPD (MacKinnon & Pies, 2006). On the other hand, some investigators have found evidence that “chronic irritability,” when precisely operationalized, may be more related to depression than to mania in terms of important correlates and associated features (Leibenluft, Cohen, Gorrindo, Brook, & Pine, 2006). This group must be considered potentially one of the most speculative categories on the bipolar spectrum. There are few data-based studies evaluating this presentation, and no significant longitudinal investigations, nor are treatment data informative about course and outcome. It is likely to be challenging to tease apart severe mood dysregulation from other, more common disorders of childhood, as well as from fluctuations of mood that fall within normal limits for child and adolescent behavior. Thus, it appears premature to begin applying the “severe mood dysregulation” label clinically, until sufficient data are available that the label predicts useful outcomes, prescribes intervention choices, or informs the process of treatment.

A fourth group sometimes considered on the bipolar spectrum is cases identified by means of a proxy measure rather than direct clinical interview. The two most common examples are the use of a profile of scores on the Child Behavior Checklist (CBCL; Achenbach, 1991a) or positive scores on a screener for BD, such as the Mood Disorder Questionnaire (Hirschfeld et al., 2000), as proxies for a bipolar diagnosis. These proxy definitions are typically used in research studies, especially in behavioral genetics work (Althoff, Rettew, Faraone, Boomsma, & Hudziak, 2006; Hudziak, Althoff, Derks, Faraone, & Boomsma, 2005) or in reanalyses of data initially gathered for purposes other than studying PBD (Galanter et al., 2003; Hazell, Carr, Lewin, & Sly, 2003; Reichart et al., 2004). As will become evident later in our discussion of the impact of illness base rates on the diagnostic efficiency of measures, the number of “proxy” cases that would actually be confirmed to have PBD in the event of a careful diagnostic interview can be wildly variable. The rate of “true” bipolar cases in a group of proxy-defined cases is likely to be low in most settings, especially in general population sur-

veys. The low “positive predictive value” of a proxy diagnosis of PBD makes the interpretation of research relying on the proxy definition ambiguous at best. Furthermore, the substitution of a proxy definition for careful clinical diagnosis of PBD is clearly inappropriate in clinical practice.

RECOMMENDED CONSIDERATIONS FOR DIFFERENTIAL DIAGNOSIS IN CHILDREN

Comorbidity

BD has tremendously high rates of comorbidity with other mental disorders and substance use. In the first National Comorbidity Survey (NCS), 99% of adults meeting criteria for bipolar I illness met full criteria for at least one other lifetime Axis I diagnosis (Kessler, 1999). Rates of comorbidity appear similarly high in children and adolescents meeting criteria for BD (Geller et al., 2003; Kowatch, Youngstrom, Danielyan, & Findling, 2005). It is not straightforward to compare the rates of comorbid conditions between pediatric and adult samples, due to both developmental trends in the comorbid conditions and gaps in assessment batteries. For example, the high rates of substance use and antisocial behavior in adults with BD are likely much lower in youth by virtue of the generally later age of onset for these behaviors; youths show high rates of oppositional behavior and attention problems, but potential developmental continuity in these behaviors has been obscured by the lack of a clear adult analogue to oppositional defiant disorder (although it often is a precursor to antisocial behavior) (Moffit, Caspi, Dickson, Silva, & Stanton, 1996). Similarly, adult epidemiological studies or clinical investigations of adult BD until recently did not systematically evaluate ADHD, because conventional wisdom indicated that ADHD was a disorder of childhood and likely to remit spontaneously. However, newer studies evaluating ADHD in adults have found that BD is associated with a much higher lifetime rate of ADHD, as well as significantly more ADHD persisting into adulthood (Nierenberg et al., 2005).

The most common comorbidities identified in youths meeting criteria for BD are ADHD, oppositional defiant disorder, conduct disorder, and anxiety disorders (Kowatch, Youngstrom, et al., 2005); pediatric-onset BD may also be

associated with higher risk of meeting criteria for other conditions, such as enuresis or eating disorders (Weckerly, 2002). The rate of comorbid ADHD was initially reported to be extremely high, in excess of 90% (Biederman et al., 1996; Geller et al., 2003). However, other investigations using different referral patterns or interview procedures have found that closer to 60% of youths with BD also meet criteria for ADHD. The lower rates are more similar to the rates of comorbid ADHD diagnosed clinically in youth treated for BD (Youngstrom, Youngstrom, et al., 2005). Even so, the rates for comorbid ADHD remain too remarkably high for these to be independent conditions. If ADHD were an unrelated illness that affects roughly 5% of the general population, then it should also manifest in roughly 5% of BD cases. The much higher rate of coincidence may be due to the pronounced overlap in diagnostic criteria. ADHD often involves distractibility, high motor activity, talkativeness, and impulsive behavior, all of which look like manic behaviors (Klein et al., 1998). Furthermore, youth with ADHD are often irritable and frequently meet criteria for comorbid oppositional or conduct disorders—potentially mimicking the irritable mood seen with mania. Conversely, a person who meets criteria for mania will also exhibit multiple symptoms that may appear consistent with ADHD. Thus, the high rate of comorbidity might be inflated by research interviewers or clinicians who do not sufficiently determine whether the symptom is most attributable to a mood disorder or another condition. However, other investigators argue that comorbid ADHD may represent a distinct subtype of BD, pointing to patterns of heritability and the fact that youth with comorbid ADHD and BD often show greater impairment and worse course (Biederman et al., 1996; Faraone, Biederman, Mennin, Wozniak, & Spencer, 1997).

Comorbid anxiety disorders are open to similar discussion: Rates of comorbidity vary too widely to be due merely to chance sampling differences (Kowatch, Youngstrom, et al., 2005). Higher comorbidity estimates may be due partially to diagnosis of anxiety disorders on the basis of anxious symptoms reported during the course of a mood episode. Again, “comorbid” anxiety is associated with greater impairment and worse course, but it is unclear whether this is due to the comorbidity, or whether the per-

ceived “comorbidity” is another way to describe a person experiencing a greater number of total problems in the context of the illness.

Overall, it appears premature to report specific rates of comorbidity for different disorders, in light of both the potential methodological limitations and developmental changes in potential comorbid conditions. Clinically, one can expect to see “pure” bipolar presentations only rarely. It also makes sense to assess for attention problems and anxiety, as well as substance use and other antisocial behavior, when confronted with potential PBD. In terms of research, much more work is needed that looks for patterns of heterotypic continuity (e.g., oppositional behaviors in childhood persisting as more delinquent behaviors in adolescence, then as “antisocial personality” in adulthood). What are sometimes considered patterns of comorbidity may also prove to be useful endophenotypes, because they may reflect the activity of particular genes that are not uniformly present in all cases meeting DSM criteria for either disorder. For example, persons with BD and generalized anxiety disorder (GAD) may have behavioral inhibition system–related genes that are not present in other cases with PBD, and also mood-dysregulation genes not present in most individuals meeting criteria for GAD.

Rapid Cycling

BD, even in adults, is a recurrent illness. Few affected persons have only one episode of depression or mania over the course of their entire lifetime. However, many are able to go for periods of years, or even decades, between episodes of pathological mood disturbance (Goodwin & Jamison, 1990). Most people have more frequent relapses into mood states. “Rapid-cycling” mood disorder means that a person has at least four distinct mood episodes over the course of a year (APA, 2000; Dunner, Patrick, & Fieve, 1977). This pattern is vital to recognize: Rapid cycling prognosticates a more chronic course of illness, with greater comorbidity, less responsiveness to lithium, and higher risk of mortality (Coryell et al., 2003).

What defines a “cycle” or an “episode” is not universally agreed upon, and many adults with bipolar illness show a clear pattern of labile affective disturbance that does not fit into the strict DSM-IV definition of rapid cycling

(MacKinnon et al., 2003; Maj, Pirozzi, Formicola, & Tortorella, 1999). Some of the confusion is due to the lack of a precise definition for the end of a mood episode (Frank et al., 1991). A switch in polarity of mood (e.g., from mania to depression) may often occur within the course of a single episode (APA, 2000; Kraepelin, 1921). Some authors have described youth as having “ultradian” cycling, or polarity switches in the course of the same day (Geller et al., 1995). Sometimes these rates of daily polarity switches have been extrapolated to extend over the length of a year, or over the course of an even longer episode, then reported as the “rate of cycling” for youth, with estimates climbing up to the 10’s of thousands (Geller, Williams, et al., 1998). These figures provoke understandable cynicism from those familiar with the adult presentation of BD, in which four distinct mood episodes within a single year portend a stormy course. The sheer quantitative discrepancy (four vs. thousands per year) may also raise concerns about whether we are confronting the same disorder in children and adults. Thus, it is crucial to realize that the described clinical presentations are actually quite similar, and the apparent discrepancies are due to slippage in the definition of terms. PBD is being described by multiple groups as involving rapid polarity switches, with brief durations at either extreme, yet each *episode* is a long period of dysregulated mood.

Mixed States

Mixed states involve symptoms of mania and of major depression during the same mood episode. According to DSM-IV-TR criteria, there must be an adequate number of symptoms present with sufficient intensity to meet criteria for both major depression and for mania. The duration of a mixed state is set at a week, unless symptoms are so severe as to require hospitalization, with the symptoms required to be present for “much of the day, nearly every day during at least a 1-week period (APA, 2000, p. 365). There are at least two ways that the requirement “much of the day” could be met. One would be for both manic and depressive symptoms to be present simultaneously in a single, homogeneous mood state. Kay Jamison (1995) has described this as a “black mania,” combining the hopelessness, low self-esteem, pathological guilt, and despair of depression

with the high energy, racing thoughts, and impulsivity of mania. Not surprisingly, such a mood state presents a high risk for suicide (Goodwin & Jamison, 1990).

In the other mixed presentation, mood oscillates rapidly between depressed and manic states over the course of the week, or even within the same day. Unstable and shifting moods were noted as a common presentation of mixed states by Kraepelin during his clinical observations (1921), and these have also been frequently documented in clinical observation of adults with BD (Kramlinger & Post, 1996), as well as prospective “life charting” of mood and energy (Denicoff et al., 1997) and objective markers of physical activity. This oscillating, labile form of “mixed state” is almost definitely what has been described by some as “ultradian cycling” in children (Geller & Cook, 2000).

Efforts to compare the adult and child phenomenology of BD have been hampered by terminology. Oscillating mixed states appear to be the most common presentation of BD in youth, consistent with age effects noted initially by Kraepelin (1921). At the same time, it is important to bear in mind that oscillating mixed states with pronounced mood lability are common in adults with mood disorder (MacKinnon & Pies, 2006). Conversely, the term “rapid cycling,” as used in the adult literature, refers to the number of distinct mood *episodes* within a 1-year period rather than the number of *polarity shifts* of mood within a single episode. It appears relatively rare for children or adolescents to experience multiple remissions of their mixed state, then multiple relapses within the same year (Birmaher et al., 2006; Geller et al., 2004), particularly when “remission” is defined as a period of 2 months free of impairing symptoms (Findling et al., 2001; Frank et al., 1991). Thus, “rapid cycling” in the strictest sense appears to be uncommon in children, and there is instead a high rate of oscillating mixed states.

Major Symptom Dimensions and Associated Features

The two major dimensions involved in bipolar illness are depressive and manic symptoms. Counterintuitively, depression and mania do not appear to be opposite poles of a single dimension. Instead, they are two distinct sets of symptoms that can occur independently of

each other or overlap. Mixed states involve high levels of both depressed and manic symptoms. A dimensional model resolves many of the problems noted with the current categorical classification system, including the large number of cases with “mixed hypomanias” or “anger attacks” in the context of depression, or agitated depressive presentations. Rather than requiring a proliferation of subcategories, these clinical presentations may be conceptualized as the coincidence of moderate levels of manic symptomatology during periods with higher levels of depressive symptoms. In fact, there is growing evidence that there might be different risk factors associated with triggering depressive versus hypomanic or manic symptoms (Johnson & Roberts, 1995). A major clinical implication is that assessment should include measures of both hypomanic/manic and depressed symptoms not only at intake but also as outcome measures, due to the potential for the emergence of new mood symptoms (including those of a different polarity than the presenting problem).

An alternative way of conceptualizing mania and depression is to link them to major motivational systems, such as Gray’s behavioral inhibition system (BIS) and behavioral activation system (BAS; Fowles, 1994; Gray & McNaughton, 1996), or Depue’s behavioral facilitation system (BFS; Depue & Iacono, 1989). These models put anxiety, depression, and mania within a larger evolutionary and neuro-behavioral framework, where the clinical disorders are pathologically extreme or situationally inappropriate expressions of systems that otherwise serve important roles in the development of personality and healthy functioning. These models suggest linkages between mania and dopaminergic systems related to reward, extroversion, and approach-oriented behaviors (Depue & Collins, 1999). BIS–BAS models also predict a high degree of overlap between anxious and depressive symptoms, because both anxiety and depression involve high levels of BIS activation, also conceptualized as high levels of “negative affectivity” (Tellegen, Watson, & Clark, 1999). According to the “tripartite model” of depression and anxiety, negative affect, or high BIS activity, is a shared component of both anxiety and depression, whereas physiological hyperarousal is specific to anxiety, and low positive affect (or low BAS) is a specific marker for depression (Watson et al., 1995). The tripartite model’s description of both de-

pressed states and negative affect as a shared component of anxiety and depression has been replicated in multiple child and adolescent samples (Chorpita, 2002; Chorpita, Albano, & Barlow, 1998; Chorpita & Daleiden, 2002; Lonigan, Phillips, & Hooe, 2003). Although there are measures of BIS and BAS that include nonclinical behaviors (e.g., Carver & White, 1994), it is not clear that these instruments offer incremental value to clinical assessment. Instead, the clinical value of BIS and BAS models might lie primarily in the identification of “subsyndromal” or adaptive behaviors falling along the same dimension as mania or depression. Awareness of these behaviors might help to normalize and to depathologize some aspects, and also to monitor warning signs that presage the return of more severe mood disturbance. The BIS–BAS model also contributes a potential explanation for the frequent co-occurrence of anxious and depressive symptoms, which might otherwise be perceived as “comorbidity” of multiple disorders.

A third model of the dimensions of illness was first proposed by Kraepelin (1921). He described three clusters of symptoms involved in mood disorder: *cognitive or intellectual*, including racing thoughts and heightened creativity at one extreme, and slowed thinking or dulled perceptions at the other; *vegetative*, including motor agitation and heightened energy at one extreme, and fatigue or psychomotor retardation at the other; and finally an *affective* component, ranging from manic excitement, expansiveness, and grandiosity to depressive hopelessness and despair. Kraepelin observed that these three clusters of symptoms were frequently out of phase with each other, giving rise to eight possible permutations of clinical presentation. Classic manic presentations entailed elevation of all three clusters, and classic depression reflected low levels of all three clusters. Agitated depression, in Kraepelin’s model, involved high levels of the motor activity cluster of symptoms, whereas levels on the affective and cognitive dimensions remained low. Kraepelin provided an elegant and parsimonious way to describe clinically varied phenomena using a dimensional model. This framework also provided a means for integrating neuropsychological performance into a broader conceptual model of mood disorder. However, little recent work on neuropsychological performance in children or adolescents has included this historical model.

Several other features of PBD that deserve clinical attention include temperamental traits that are often associated with BD. Youth with PBD, compared to youth with ADHD or controls with no diagnosis, show higher novelty seeking and lower reward dependence behavior, lower persistence, and less self-direction and cooperativeness (Tillman et al., 2003). Youth at risk of developing BD because a biological parent has a bipolar history tend to show higher levels of trait negative affect, lower activity, and poorer sleep and rhythmicity (Chang, Blasey, Ketter, & Steiner, 2003). Rejection sensitivity also may be a prominent feature of bipolar illness, even when mood appears relatively stable (Benazzi, 2000; Fristad & Goldberg Arnold, 2004). These temperamental traits appear similar to many of the features seen in full-blown mood episodes, blurring the distinction between *character* and *mood episode*. However, BD appears to involve fluctuations or surges that noticeably amplify any temperamental qualities, suggesting that episodicity may be helpful in identifying youth at risk (Shaw, Egeland, Endicott, Allen, & Hostetter, 2005).

Epidemiology: Base Rates, Age of Onset, and Clinical Incidence

Epidemiological Data

A crucial question is how often PBD may be occurring both in the general population and in clinical settings. Epidemiological estimates convey a sense of the relative prevalence or rarity of different conditions, and the extent to which incidence varies by age or other demographic features. Epidemiological studies have found relatively low rates of mania in adolescents (Lewinsohn et al., 2002) and virtually no cases of mania in children (Costello et al., 1996; Shaffer et al., 1996). However, studies with adults reporting retrospectively about the onset of their mood symptoms indicate that more than 50% of adults with BD had their first mood symptoms before age 18 (Kessler, Rubinow, Holmes, Abelson, & Zhao, 1997), and often before the age of 16 (Perlis et al., 2004; Post et al., 2006). Surveys of adult consumers indicate median delays of 11–19 years between the beginning of mood symptoms and when treatment is sought and a correct diagnosis is made (Calabrese et al., 2001; Hirschfeld, Lewis, & Vornik, 2003;

Lish, Dime-Meenan, Whybrow, Price, & Hirschfeld, 1994).

There are several causes for caution in interpreting epidemiological results. First, most instruments used in epidemiological studies were written at a time when the prevailing wisdom was that mania did not occur in children, and only rarely in adolescents. As a result, there was little training for recognizing manic behavior and no attempts to modify descriptions or anchors to be developmentally appropriate. Subsequent experience indicates that some instruments, such as the Diagnostic Interview Schedule for Children (DISC; Shaffer et al., 1996), appear less sensitive to mania as a result. Second, epidemiological studies, with few exceptions, have not systematically assessed for hypomania. Without careful assessment of hypomania, only bipolar I illness can be diagnosed. As a result, most epidemiological studies have not tracked bipolar II illness, cyclothymia, or BD NOS. However, when assessed, these other bipolar spectrum diagnoses appear to be at least five times as common as bipolar I illness (Judd & Akiskal, 2003; Lewinsohn et al., 2002). Adding systematic assessment of just bipolar II disorder raises the estimated lifetime prevalence of BD in the adult U.S. population to 3.9% (Kessler et al., 2005). Although these other diagnoses have flown “under the radar” of most epidemiological studies, they are still associated with substantial burden and impairment. Third, some of the epidemiological studies have relied solely on self-report. It will become evident in later sections of this chapter that self-report often underestimates the occurrence and severity of manic and hypomanic symptoms. Due to these concerns, epidemiological studies should not yet be considered definitive. A balanced interpretation might be that the evidence suggests that BD is rare in children, somewhat more common in adolescents, and still more common in adults; at the same time, the “fuzzy” spectrum presentations outnumber clear cases of bipolar I illness at all ages.

Age of Onset

The age of onset of BD is also controversial. More recent epidemiological studies suggest that the median age of onset is currently around age 16 years (Kessler et al., 2005). However, data suggest a secular trend, with earlier ages of onset of mood disorder and

higher rates of mood disorder in each U.S. generation since World War II (Post, Leverich, Xing, & Weiss, 2001; Weissman et al., 1984). The youngest age cohort surveyed in the National Comorbidity Survey—Revised (NCS-R) had at least four times the lifetime hazard of developing BD (with an estimated prevalence of 6% by age 75) compared to the rate in the oldest age cohort (with a 1.5% lifetime prevalence). Onset in the United States also appears to be significantly earlier than that in Europe, based on both self-report measures and clinical interviews, and appears to be associated with higher rates of risk factors, including more familial history of mood disorder, higher familial rates of suicide, and greater exposure to childhood physical and sexual abuse (Post et al., 2006). Age of onset is an important prognostic variable: Earlier age of onset predicts higher rates of comorbidity with anxiety disorder and substance abuse, more rapid cycling, more chronic impairment, more days in poor mood state, greater risk of suicide or violence (Masi et al., 2006; Perlis et al., 2004), and possibly less responsiveness to lithium monotherapy (Duffy et al., 2002). “Take-home messages” for clinicians are that onset often occurs earlier than conventional wisdom has thought, and that early onset predicts a more challenging course of illness, requiring different forms of pharmacotherapy (and possibly other forms of psychosocial intervention).

Clinical Incidence

Information about clinical incidence is much more useful than general population epidemiological figures to practicing clinicians. Ideally, clinicians would have accurate statistics documenting the base rate of bipolar illness at their own setting. Failing that, it would be helpful to have estimates from similar clinical settings to use as benchmarks. Table 6.3 reports a broad sampling of published estimates from different clinical settings. There are important caveats to consider for any of these estimates. Referral patterns can vary dramatically between settings. Artifacts of the assessment process also generate highly discrepant estimates: Clinical diagnoses are more prone to the effects of heuristics than are semistructured diagnostic interviews, but interviews also involve varying degrees of clinical judgment (Garb, 1998). Differing conceptualizations of bipolar illness also influence the apparent rate. Estimates based on

TABLE 6.3. Base Rates of PBD in Different Clinical Settings

Setting (reference)	Base rate	Demography	Diagnostic method
High school epidemiological (Lewinsohn et al., 2000)	0.6%	Northwestern U.S. high school	K-SADS-PL ^y
Community mental health center (Youngstrom, Youngstrom, et al., 2005)	6%	Midwestern urban, 80% nonwhite, low-income area	Clinical interview and treatment ^{p,y}
General outpatient clinic; (Geller, Zimmerman, et al., 2002)	6–8%	Urban academic research centers	WASH-UK-SADS ^{p,y}
County wards (DCFS) (Naylor et al., 2002)	11%	State of Illinois	Clinical interview and treatment ^y
Specialty outpatient service (Biederman et al., 1996)	15–17%	New England	K-SADS-E ^{p,y} (only <i>p</i> young)
Incarcerated adolescents (Teplin, Abram, McClelland, Dulcan, & Mericle, 2002)	2%	Midwestern urban area	DISC ^y
Incarcerated adolescents (Pliszka et al., 2000)	22%	Texas	DISC ^y
Acute psychiatric hospitalizations in 2002–2003— <i>adolescents</i> (Blader & Carlson, 2006)	21%	All of United States	Centers for Disease Control survey of discharge diagnoses
Inpatient service (Carlson & Youngstrom, 2003)	30% manic symptoms, < 2% strict BPI	New York City metropolitan region	DICA; K-SADS ^{p,y}
Acute psychiatric hospitalizations in 2002–2003— <i>children</i> (Blader & Carlson, 2006)	40%	All of United States	Centers for Disease Control survey of discharge diagnoses

strict bipolar I illness are much lower than those including other diagnoses on the bipolar spectrum. Estimates that include parent report are more sensitive to PBD, but they may also increase the rate of false-positive diagnoses—both of which contribute to higher rates. All of these issues apply with equal force to estimates derived from one's own clinical practice. Thus, Table 6.3 offers an opportunity to compare the effects of different definitions and assessment methodologies, and to reflect on how one's own assessment methods might compare; it justifies three overarching conclusions: (1) Rates can be highly variable, even within the same setting, but (2) PBD occurs in clinical settings, and (3) rates are higher in clinical settings than in the general population, roughly corresponding to the intensity of services offered at the setting.

Domains of Impairment

BD is not simply associated with disturbances of mood and energy. The depressed phase of the illness brings with it all of the impairment and burden associated with unipolar depression (Judd et al., 2005). Manic episodes involve externalizing behaviors, along with the increased motor activity and poor concentration that are often typical of ADHD. Extreme mood states degrade executive function and cognitive performance, although these deficits do not appear to be specific to PBD (Henin, Mick, Nierenberg, & Biederman, 2006). Both depression and mania are associated with academic underachievement, poor educational attainment, peer rejection, and increased family conflict (Geller et al., 2000, 2004; Weckerly, 2002). PBD is also linked to increased use of al-

cohol and street drugs, and the combination of substance use and other impulsive behaviors greatly increases the risk of youth with PBD coming into contact with the justice system (Pliszka, Sherman, Barrow, & Irick, 2000). BD is a well-established risk factor for suicide (Brent et al., 1988), and earlier age of onset is related to elevated risk of suicide and of violent behavior in general (Perlis et al., 2004). Overall, PBD involves pervasive impairment across most social, emotional, cognitive, and vocational-educational areas of functioning. Without proper management, PBD puts an individual at higher risk of incarceration or suicide.

Demographic and Cultural Issues in Assessment

Sex Differences

Bipolar I disorder occurs equally often in men and women (Bebbington & Ramana, 1995; Kessler et al., 1997; Robb, Young, Cooke, & Joffe, 1998; Weissman et al., 1996). Pediatric data indicate no sex differences in the diagnosis of bipolar I disorder after adjusting for the fact that more young males present to clinics for externalizing problems in general (Biederman, Kwon, et al., 2004; Duax et al., 2005; Youngstrom, Youngstrom, et al., 2005). Bipolar II disorder may be more prevalent among adult women than among men (Berk & Dodd, 2005; cf. Kawa et al., 2005; Robb et al., 1998). The evidence on sex differences in the rate of juvenile bipolar II disorder is similarly mixed, with some data showing a possibly higher rate of bipolar II disorder in female than in male adolescents (Biederman, Kwon, et al., 2004; Birmaher et al., 2006; Faedda, Baldessarini, Glovinsky, & Austin, 2004). Developmental trends may account for adolescent girls' greater rates of depression, and perhaps for their greater rates of bipolar II disorder (Cyranowski, Frank, Young, & Shear, 2000). Alternatively, females may be more likely to acknowledge and/or seek treatment for depressive symptoms (Kessler, 1998), or there may be sex bias in sampling or diagnostic systems (Hartung & Widiger, 1998). Data for other bipolar spectrum diagnoses are scarce, but there is no evidence of sex difference in rates of cyclothymia or BD NOS. Although sex differences are an important consideration in PBD, sex has not proven to be predictive of length of illness or time until relapse (Geller et al., 2004).

Apparent sex differences in PBD are complicated by comorbid diagnoses such as ADHD, oppositional defiant disorder (ODD), and conduct disorder (CD) (Kowatch, Youngstrom, et al., 2005). In particular, ADHD has repeatedly shown higher rates of comorbidity in young males than in young females with BD (Biederman, Kwon, et al., 2004; Duax et al., 2005). Externalizing disorders are more common among boys than among girls (Costello et al., 1996), potentially leading to greater rates of boys also being diagnosed with PBD. It is still important for clinicians to recognize more subtle symptoms of PBD, so that children and adolescents seeking treatment for depressive symptoms, particularly females, do not go misdiagnosed or mistreated. Findings suggest that although separate sex norms or diagnostic criteria for PBD are probably unnecessary (Biederman, Kwon, et al., 2004), clinicians need to be more vigilant about PBD in females, whose presentation is less likely to show pure mania or hypomania.

Racial and Cultural Differences

Little is known about racial or cultural differences in the prevalence or phenomenology of PBD. However, minority youth with mood disorders are more likely to be misdiagnosed with CD or schizophrenia (DelBello, Lopez-Larson, Soutullo, & Strakowski, 2001), and more likely to be treated with older and/or depot antipsychotic medications (Arnold et al., 2004; DelBello, Soutullo, & Strakowski, 2000). Clinicians should assess systematically for mood disorder in ethnic/minority patients, particularly when the presenting problem involves aggressive behavior or psychosis. Clinicians should also be alert to the potential for racial bias in diagnosis when gathering family history data (Garb, 1998). Rather than taking family members' historical diagnoses at face value, it would be prudent to gather family history data at the symptom level whenever possible.

Young Adult Outcomes

Multiple longitudinal studies have published findings about stability, course, and outcome up to 4 years after the initial assessment identifying PBD. Youth initially diagnosed with BD typically experience at least partial remission of the illness: 37% having mania remit within the

first year (Geller, Craney, et al., 2001), and 65% within the first 2 years, but 55% experience a relapse of mania within the same 2-year period (Geller, Craney, et al., 2002). Four-year follow-up of youth initially diagnosed with narrow phenotype PBD (requiring the presence of elated mood or grandiosity) indicated that they experienced hypomanic, manic, or mixed states for 57% of the follow-up period, and depressive states for 47% of follow-up (Geller et al., 2004). These findings have been cross-validated by a more recent, multisite study: 70% of patients recovered within an average follow-up period of 2 years, but 50% relapsed within the same time frame, and syndromal or subsyndromal mood symptoms were present during at least 60% of weeks during the follow-up period (Birmaher et al., 2006). Within the 2-year follow-up period, 25% of youth initially meeting criteria for cyclothymia or BD NOS had sufficiently worse mood states to meet strict criteria for bipolar II or bipolar I disorder. Youth with cyclothymia–BD NOS more often continued to have not only “subsyndromal” mood disturbance but also worse outcomes on most measures of functioning than did youth with more “classic, syndromal” presentations (Birmaher et al., 2006). In a much smaller follow-back study, in which 17 youth and parents were reinterviewed an average of 3 years after the initial diagnosis of cyclothymia or BD NOS, about one-third of youth developed more clearly syndromal bipolar presentations during subsequent years, compared to roughly one-third whose mood symptoms had remitted by the time of reevaluation (Kahana et al., under review).

These findings are similar to results from the follow-up waves of a longitudinal study of an epidemiological sample. Lewinsohn and colleagues (2000) found that adolescents meeting full criteria for BD (about 1% of the sample) showed significant risk of still meeting criteria for BD at follow-up. On the other hand, the 5% of the sample that met criteria for subsyndromal BD (the “core positive” definition provided in Table 6.2) did not show a significant rate of “conversion” into clear bipolar I or bipolar II disorder. However, the subsyndromal group continued to be highly impaired, showing increased risk for anxiety disorders, depression, antisocial behavior, suicidal ideation, and borderline personality traits (Lewinsohn et al., 2000). Taken together, findings suggest that

there are two subtypes—a more episodic version of mood disorder conforming to classic definitions and having a less chronic, although still highly impairing, course versus a more chronic pattern of mood dysregulation that does not meet full criteria for bipolar I or II disorder but tends to show developmental continuity and remain highly impairing.

Etiological Factors

A variety of risk factors are associated with BD (Tsuchiya, Byrne, & Mortensen, 2003). Genetic factors have received the most attention. BD and schizophrenia have similarly large genetic components, exceeding the heritability of all other major mental illnesses (Faraone et al., 1999; McGuffin et al., 2003). However, even monozygotic twins show roughly 80% concordance for BD, indicating that environmental factors play a role in the expression of illness even when genes are completely identical (Faraone et al., 1999). BD clearly involves multiple genes, which means that permutations or degrees of loading may be present in any given individual. There is also a genetic component to BD age of onset (Faraone, Glatt, Su, & Tsuang, 2004), suggesting that there may be a different, pediatric-onset subtype of BD with a distinct constellation of genetic factors (Biederman, Faraone, et al., 2004; Faraone, Glatt, & Tsuang, 2003). Retrospective data on adults with BD indicate that earlier age of onset is associated with more rapid cycling; more chronic course; and higher rates of comorbidity, suicidality, violent behavior, and substance use (Perlis et al., 2004)—similar to the phenomenology noted in child and adolescent samples (Kowatch, Youngstrom, et al., 2005).

Some of the work investigating the genetic architecture of PBD relies on the “bipolar profile” of scores on the CBCL described by Mick, Biederman, Pandina, and Faraone (2003). The profile has demonstrated a high degree of heritability (Althoff et al., 2006; Hudziak et al., 2005). However, in samples where PBD is rare, such as the general population, the majority of individuals with such a profile do not actually have a BD diagnosis (Volk, 2006). It is worth noting that this pattern of findings—a heritable behavior pattern that is not isolated to PBD—is entirely consistent with a polygenic model of illness. There may be a specific gene conferring risk for the “bipolar profile” of behaviors cap-

tured by the CBCL, and this gene might often be present in individuals with PBD. At the same time, the gene may also convey risk for aggressive behavior and occur in the context of other disorders, such as CD or ADHD.

Many other, more speculative mechanisms potentially contribute to risk for BD. One is genetic “anticipation,” in which children inherit multiple copies of the same gene from a parent. For some conditions, there appears to be a dose–response relationship, in which receiving more copies of the same gene is associated with earlier onset of illness and more virulent course (Post, Weiss, & Leverich, 1994). This may contribute to the higher lifetime risk of BD in younger generations (e.g., Kessler et al., 2005). Another established risk factor for mood disorder is prenatal or perinatal trauma (Hack et al., 2004). It is possible that as medical technology saves more children who previously would have perished, some of the survivors may experience mood dysregulation as a result of subtle perinatal neural damage. It is possible that exposure to a virus or bacterium may trigger an autoimmune response that creates mood dysregulation similar to BD (Soto & Murphy, 2003).

Risk of bipolar illness might be influenced by diet, too. The popularity of omega-3 fatty acids as a remedy for BD stems from observations about epidemiological differences in fish intake, with populations with higher fish consumption showing lower rates of bipolar illness (Stoll, Locke, Marangell, & Severus, 1999). It also is noteworthy that the risk of BD increases with the onset of puberty (Nottelmann et al., 2001). Dietary changes in the United States have led to a dramatic rise in childhood obesity, along with puberty starting at a much younger age (Juil et al., 2006; Karlberg, 2002; Parent et al., 2003). Recent studies indicate that 14% of U.S. girls reach Tanner Stage 2 by age 8, and the national average for reaching Stage 2 of breast development is between 9.2 and 9.5 years (Lee, Guo, & Kulin, 2001). The endocrine changes associated with puberty are beginning at a younger age than previously, suggesting a mechanism for earlier onset of depression in girls (Cyranowski et al., 2000) and possibly increased aggression in boys (Rowe, Maughan, Worthman, Costello, & Angold, 2004). If these results prove robust, then diet-related findings suggest mechanisms for prevention models.

EVIDENCE-BASED APPROACHES TO DIAGNOSIS

Risk Assessment Model

The first piece of information to consider is the “base rate,” or how common PBD is likely to be in a given setting. A practitioner in an inpatient unit is likely to see more individuals with PBD than would a school psychologist in a regular educational setting. The base rate provides an excellent foundation for the integration of additional information. Knowing that the base rate of PBD is around 5% in many outpatient clinics, for example, suggests that, on the one hand, BD is a diagnosis that should be considered and carefully assessed in some cases. On the other hand, a 5% prevalence reminds the practitioner that the diagnosis is likely to be rare, and other problems (including those with similar clinical presentations, such as ADHD or unipolar depression) are likely to be more common. This anchoring helps avoid over- or underdiagnosis due to availability heuristics that may be unduly influenced by the faddishness of a diagnosis (Davidow & Levinson, 1993). As I discussed in the earlier section “Clinical Incidence,” clinicians can either rely on their own archival records to estimate the rate of PBD or use published estimates from similar clinical settings to provide a ballpark estimate. Table 6.3 provides some published estimates for calibration purposes, along with comments about the design of each study. If computerized, abstract databases are available, then it would be even better to search for newer benchmark estimates with key words such as “prevalence or incidence” and “bipolar disorder,” along with terms describing the clinical context of interest (Youngstrom & Duax, 2005). Practitioners relying on local diagnoses should be aware that clinical diagnoses tend to underestimate the amount of comorbidity and may be particularly inaccurate in the case of PBD (Youngstrom, Youngstrom, et al., 2005).

Whether using local estimates or published values, the assessor should reflect on the procedures used to make the benchmark diagnoses, and consider the possible sources of bias and how they might influence initial estimates. A more thorough dissection of the validity of an estimate may be accomplished by comparing the design features to the 25 recommendations in the STANDARDIZED Reporting of Diagnostic (STARD; Bossuyt et al., 2003) tests criteria, or by evaluating the applicability of the findings

to the individual patient in question (Jaeschke, Guyatt, & Sackett, 1994b). Even when they are flawed, initial estimates of the base rate can lessen the impact of other factors that undermine the accuracy of the assessment process. Furthermore, if the practitioner follows other recommendations for evidence-based assessment, then periodically reevaluates the base rate of disorders, the process potentially becomes self-correcting. Reevaluation of base rates in one's own clinical setting is also good practice, because changes in public awareness and other external factors may also change the referral pattern over time.

Family History

Value of Gathering Family History

In a meta-analysis that reviewed over 100 articles discussing more than 30 different risk factors potentially associated with BD, only family history of BD was robust enough to merit clinical interpretation (Tsuchiya et al., 2003). Another meta-analysis found that, on average, 5% of children with a biological parent affected by BD already met criteria for a BD themselves at the time of the research assessment (Hodgins, Faucher, Zarac, & Ellenbogen, 2002). Conversely, no children in the "low risk" comparison groups developed bipolar spectrum illness in any of the studies reviewed. Having a bipolar parent also doubled the children's risk of developing psychopathology in general, and tripled the risk of developing mood disorders (not just bipolar spectrum illness). When interpreting the 5% rate of bipolar illness, one should remember that (1) family history of bipolar illness increases risk of psychopathology, and especially BD; (2) the vast majority of children with a parent diagnosed with BD still do not have PBD themselves; (3) they often show other, nonbipolar behavioral problems; and (4) youth participating in these studies were not followed into middle age, so it is impossible to know how many of them later developed full-blown bipolar illness.

Besides conveying information about the degree of risk of bipolarity for the youth, gathering family history also helps determine the family's strengths and challenges that may impinge upon therapy. Having a family member already in treatment for a mood disorder provides prior experience that shapes family attitudes

toward intervention. If the prior treatment went well, then the family member offers a powerful role model and excellent potential social support for the youth. If prior experiences were negative, then it is crucial to find out family members' perceptions of what was sub-optimal, so that one may pursue alternative recommendations or use other strategies to address the challenges and resistance. An adult's undiagnosed or poorly managed mood disorder often magnifies the chaos and conflict in a family, reducing the chances of good treatment adherence for the child. Family history may be informative about the likely course of illness for the youth, and may also have prescriptive value in shaping treatment selection. Children of parents with lithium-responsive BD tend to show better premorbid functioning, more distinct mood episodes, better interepisode functioning, and better response to lithium themselves (Duffy, Alda, Kutcher, Fusee, & Grof, 1998). Conversely, children whose parents had earlier onset, more rapid-cycling bipolar illness (which tends to be less lithium responsive) are themselves more likely to show a refractory and more chronically impaired course of illness (Duffy et al., 2002; Masi et al., 2006).

Challenges in Obtaining Family History

In spite of its proven clinical value, gathering a good family history may not always be possible. A common problem is that fathers often do not participate directly in the clinical evaluation process. In many families the biological father may have been absent from the child's life for years, or even since conception. When a parent is not directly evaluated, the clinician has to rely on information provided by the other available adult. Parents are often unfamiliar with the details of the other adult's mental health history, especially that in childhood. Indirect interviews are also prone to reporter bias. If the parents had an abusive relationship or an ugly divorce, then these circumstances may easily color the report about mental health history. If the child is placed in foster care or adopted, then there may be little or no information available about the biological parents. In school-based or forensic clinics, parents may not routinely be involved in clinical evaluations, and it may be difficult to include them.

Another consideration with BD is that historical diagnoses themselves may not have been

accurate. A family-history diagnosis is almost always based on a prior clinical, not research, evaluation. Thus, a historical diagnosis is prone to all of the limitations of clinical diagnoses in general (Garb, 1998). On top of that is the fog added by imperfect awareness of other family members' diagnoses, as well as imperfect memory. Even worse are the factors related to race and ethnicity that might increase the likelihood of BD going undetected or misdiagnosed in African American or Latin American families (as discussed earlier). "Schizophrenia," "psychotic disorder," "antisocial personality," "drug and alcohol problems," or "conduct disorder" are all labels that could signify an undiagnosed bipolar illness, particularly in minority families. Finally, families typically do not have formal clinical training themselves, so their labels are more likely to be filtered through their own ethnographic lens. A relative with BD might be described as having "bad nerves," a "hot temper," or "anxiety attacks," for example.

Integrating Family History into a Risk Assessment Model

The more systematic and structured the interview, the more cost is added to the evaluation process, and the greater the burden imposed on families. For these reasons, clinicians need to see clear benefits before deciding to do more than a routine clinical assessment of family history. The differential diagnosis of PBD creates a situation in which the potential gains justify some increased time and burden. Accurate evaluation of familial history indicates the child's risk, and also informs case formulation and treatment strategies. Given how prone "historical" diagnoses are to error, simply asking whether anyone in the family has been diagnosed with BD is unlikely to be an adequate shortcut to evaluating family history.

One practical approach might be to ask the parents to fill out a brief screening measure, such as the Mood Disorder Questionnaire (MDQ; Hirschfeld et al., 2000), about themselves. The MDQ is a single page, with a low required reading level, yet it demonstrates high specificity to BD. The sensitivity of the MDQ appears to be moderate (often around .4 to .6), and it is poorer at detecting bipolar II and "bipolar spectrum" illnesses other than bipolar I illness (Miller, Klugman, Berv, Rosenquist, & Ghaemi, 2004), so it likely fails to identify the

relative who actually has a history of bipolar illness. It also is not known how well the MDQ would indirectly rate another adult relative (i.e., how accurately spouses' responses on the MDQ capture their partner's bipolar status). On the positive side, the MDQ has been validated in multiple languages, cultures, and settings, and shows fairly consistent performance (Isometsa et al., 2003); it also is free to use for private purposes, and very brief. The alternative might be to use the mood disorders module of a structured diagnostic interview, such as the Mini-International Neuropsychiatric Interview (MINI; Sheehan et al., 1998), to interview the parents. Completing the mood disorders module by itself generally takes only 5–15 minutes per relative. The MINI appears to be more structured than many instruments (improving the reliability and reducing the training demands) but less cumbersome than most other structured or semistructured interviews.

If a lifetime diagnosis of BD is found in a first-degree relative (e.g., biological mother, biological father, or a full biological sibling), then the child's risk of having BD increases by a factor of at least five (Youngstrom, Findling, Youngstrom, & Calabrese, 2005). This risk estimate is based on 5% of biologically at-risk youth manifesting BD (Hodgins et al., 2002), compared to a rough estimate of 1% of the general population of youth with any bipolar spectrum illness. Counterintuitively, it is more conservative to use a higher estimate of the prevalence in the general population; lower general prevalence estimates magnify the increase in risk associated with family history.

What if a second-degree relative, such as an aunt, uncle, grandparent, or half-sibling, has a bipolar illness? On average, these relatives share half as many genes with the youth in question compared to a first-degree relative. Therefore, the youth is half as likely to share the genes of risk, and the risk of BD increases by half as much, or a factor of 2.5.

Family history of mood disorder (including depression) also roughly doubles the risk of the child developing BD (Hodgins et al., 2002). "Fuzzy" presentations suggestive of possible BD, such as moodiness and alcoholism, or "schizophrenia" diagnosed in an ethnic/minority individual with a history of impulsivity and depression might also be treated as a "fuzzy" bipolar diagnosis, increasing the risk—but much less so than would a confirmed BD diagnosis (Youngstrom, Findling, et al., 2005).

Bayesian Approaches to Test Interpretation

How does a clinician incorporate information gleaned from family history into a case formulation? How best to combine findings during assessment is not intuitive. As an example, how worried would a clinician be that a child referred to an outpatient clinic had BD if the clinician learned that the child's biological father had been diagnosed with bipolar I disorder and responded well to lithium treatment? Clinicians typically interpret information informally and impressionistically, which avoids computation but is less accurate than actuarial approaches.

The other extreme is to take a strictly quantitative and actuarial approach to synthesizing the data gathered so far. An actuary would first establish the base rate of PBD at the outpatient clinic. At many outpatient settings, the rate of bipolar spectrum illness is likely to be around 5% (Youngstrom, Findling, et al., 2005; Youngstrom, Youngstrom, et al., 2005). An actuary would then combine the initial 5% risk with the five-fold increase in risk associated with having a first-degree relative diagnosed with BD. One method for calculating the revised risk estimate would be to use the Bayes Theorem to estimate the "posterior probability" of having BD, based on the new information about family history (Sackett et al., 2000). An algebraic way of accomplishing this would be to convert the prior probability (5%) into odds (5% divided by 95% = 1/19), then multiply the odds by the change in risk. The technical name for the change in risk is the "likelihood ratio," which is estimated by comparing the rate at which bipolar individuals versus nonbipolar individuals show the sign or symptom (resulting in a "false alarm" if the sign or symptom is treated as a positive indicator of BD) (Sackett et al., 2000). Multiplying the initial odds (1/19) by the likelihood ratio (5) yields the new odds that the child has BD (5/19). Odds are a familiar metric to those who engage in gambling or sports betting, but for most, probabilities are a more interpretable metric, so the new odds should be converted to a probability (using the formula probability = odds/[1 + odds]). In this particular instance, the actuary would estimate that the child had a 20.8% chance of having BD.

The 20.8% figure might be interpreted several different ways. One interpretation would be that out of a large group of patients at the

clinic (where 5% have BD), roughly 21% of the subset of patients with a first-degree relative with BD will themselves have a bipolar spectrum illness. The other way of thinking about it is that each individual patient fitting that profile has a 21% risk of having BD. The technical name for the risk estimate is the "positive predictive power" or "positive predictive value" (PPV) of the assessment result (Kraemer, 1992). The PPV is loosely related to the diagnostic "sensitivity" of an assessment, but it is not the same thing. Sensitivity represents the rate at which a positive test result would occur in persons who truly have the disorder. PPV indicates the percentage of persons who have a positive score on the test and truly have the condition of interest. Because clinicians must make decisions about individual patients, and because they start with assessment results and need to infer the diagnosis (vs. already knowing the diagnoses for a group of patients, then comparing the test results in patients with and without the diagnosis, as would be done to estimate the sensitivity), the PPV is actually the more relevant statistic. The PPV is an estimate of how often a positive assessment result would be "right" as an indicator of the presence of illness.

Despite its greater clinical usefulness, the PPV is rarely reported, because it changes directly as a function of the disorder's base rate. The 21% risk of having BD when there is family history of BD is accurate in settings in which 5% of patients have BD. However, it would be an underestimate of a patient's risk in settings where BD is more common, and it would grossly overestimate the risk of BD in cases drawn from settings where BD is more rare. Based on the prevalence benchmarks from Table 6.3, for example, then, a positive family history would be associated with a 77% risk of BD in a child admitted to a psychiatric hospital (based on the 40% prevalence reported in clinical diagnoses reviewed by Blader & Carlson [2006]), but only a 2% risk in children seen in a public school setting. The degree of risk change associated with family history is the same in all three settings, but the degree of accuracy or decisiveness of the information changes dramatically depending on the base rate. Because base rates can change markedly across clinical settings (as in Table 6.3), it is impossible to establish PPV estimates that generalize across settings.

Introducing the Nomogram

Fortunately, there are alternatives to manual calculation of PPV with the Bayes Theorem. With the increasing popularity of “personal digital assistants” (PDAs) and other technology, it is possible to have software perform the necessary calculations. Another less technologically demanding approach is to use a “nomogram” to plot graphically the relationship between the initial risk estimate and the new

information garnered by the assessment. Figure 6.1 presents a working nomogram, in which the first column marks the “prior probability,” the second column indexes the likelihood ratio attached to the assessment result, and the third column yields the revised probability estimate. The nomogram approach is highly recommended, because (1) it requires no computation, (2) it is quick, (3) it is accurate, (4) it allows direct estimation of the PPV, and (5) it is highly flexible, allowing the inclusion of any

FIGURE 6.1. Nomogram for combining probability and likelihood ratios.

information that can be repackaged as a quantitative estimate of risk or of a likelihood ratio (Sackett et al., 2000). If one uses the nomogram in Figure 6.1 to interpret the change in risk associated with a positive family history, then one would start by finding the number corresponding to the base rate on the first line (5%, in the first example), then locating the likelihood ratio (5, for a first-degree relative) on the middle line. Connecting those two points and extending the line across the third line shows the revised probability. In this example, the line should cross the third, right-hand scale just above 20%. This corresponds quite closely to the calculated value of 20.8% if one uses the Bayes Theorem and a calculator instead. A nomogram is more flexible than a table of risk estimates, because it lets the clinician change the initial risk estimates, or change the likelihood ratio used (e.g., substituting 2.5 for the risk associated with family history, if an aunt or other second-degree relative has BD). This flexibility lends itself well to “sensitivity analysis,” or seeing how changes in assumptions change the results (Sackett et al., 2000). Handbooks on evidence-based medicine provide much more detail about the likelihood ratio approach and provide examples of applying it to different medical conditions (Guyatt & Rennie, 2002; Sackett et al., 2000). Youngstrom and Duax (2005) provide a detailed case example using a nomogram to combine information about base rate and family history to evaluate potential PBD.

Behavior Checklists and Mood Rating Scales

There has been a surge in recent interest in the potential value of behavior checklists or mood rating scales as potential aids to improve the recognition of BD in both children and adults. Often these instruments are described as “screening tools,” although, technically, screening is a relatively narrow role within the range of possible uses for tools to improve diagnosis. Screening, in the most precise sense, involves collecting inexpensive measures that are highly sensitive to a disorder, then referring patients with positive scores on the screening test for further evaluation. Screening tests need to be highly sensitive to avoid missing patients with the target condition. Negative results on a test with high sensitivity often decisively rule out the diagnosis (Sackett et al. [2000] suggest the mnemonic “SnNOuT” [on a Sensitive test, a

Negative result helps rule Out a diagnosis]), whereas positive results tend to be more ambiguous, especially for rare disorders such as PBD. Although most patients with BD would score high on the test, nonbipolar patients may be so much more numerous that even fairly specific tests generate a large number of “false-positive” results.

For this reason, it is also valuable to have available tests that are more *specific* to BD. These tests set the bar higher, making false-positive results much less common. As a result, someone scoring high on a very specific test is much more likely to have BD (the SpPI mnemonic [on a Specific test, a Positive result helps rule In a diagnosis]; Sackett et al., 2000). Ideally, clinicians would have multiple tests available, so that they could pick and choose more sensitive or specific tests based on which feature would be more helpful for a given situation, much as a golfer chooses among a variety of irons with different properties to use the tool most suited for the circumstances at hand. Almost as useful would be knowledge of the diagnostic value of multiple ranges of scores on the same test, so that the information offered by extremely low scores could be separated from indeterminate midrange or very high scores (Jaeschke et al., 1994b; Sackett et al., 2000).

Child Behavior Checklist and PBD

Systematic investigation of the diagnostic value of behavior checklists in children began with an article (Biederman et al., 1995) examining how well Achenbach’s (1991a) Child Behavior Checklist (CBCL) distinguished between youth with research diagnoses of PBD and from youth with ADHD. More than eight different research groups on three different continents have replicated the result that youth with research diagnoses of BD score significantly higher than youth with ADHD or other comparison groups on multiple scales of the CBCL (Hazell, Lewin, & Carr, 1999; Kahana, Youngstrom, Findling, & Calabrese, 2003; Mick et al., 2003; Tramontina, Schmitz, Polanczyk, & Rohde, 2003; Youngstrom, Findling, Calabrese, et al., 2004). The profile of score elevations associated with PBD appears consistent across research groups (Mick et al., 2003) and correlates highly with the average pattern of problems in youth with clinical diagnoses of PBD (Youngstrom, Youngstrom, et al., 2005). Because of the extensive replica-

tion, some have suggested that the CBCL may be used to identify individuals with PBD, or that the CBCL profile may be used as a “proxy” definition of PBD in research or clinical settings in which detailed clinical interviews were not feasible (Mick et al., 2003). Indeed, the CBCL profile has been used as an operational definition of PBD in both behavioral genetics work (Hudziak et al., 2005) and re-analyses of treatment studies (Galanter et al., 2003).

Clinically, multiple analyses indicate that the Externalizing scale score on the CBCL is most powerfully associated with a bipolar diagnosis. Although PBD is linked with elevations on multiple syndrome scales, the Externalizing score does the best job of any CBCL scale at identifying BD, and no other scale, or combination of scales, provides incremental improvement in prediction after researchers control for Externalizing scores (Kahana et al., 2003; Youngstrom, Findling, Calabrese, et al., 2004). This simplifies test interpretation for the practitioner: If concerned about potential PBD, then the Externalizing score is the main CBCL score to consider in terms of changing diagnostic impression. The other scales do not add value in changing the diagnostic formulation, but provide information about domains of functioning and areas of impairment that may be important to address in treatment planning.

Studies that directly evaluate diagnostic efficiency tend to find that the CBCL is highly sensitive to PBD, but not very specific (Youngstrom, Findling, Calabrese, et al., 2004; Youngstrom, Youngstrom, et al., 2005). This makes sense, because the CBCL does not include a mania scale, nor do expert clinicians believe that a mania scale can be extracted from the CBCL item pool (Achenbach & Rescorla, 2001; Lengua, Sadowski, Friedrich, & Fisher, 2001). The CBCL mostly picks up the externalizing, disinhibited behavior component of manic and mixed states, and most youth with BD have episodes of these sorts of behavior. For this reason, low Externalizing levels on the CBCL lower the likelihood of a bipolar diagnosis a lot, ruling out the diagnosis in most settings (an example of the SnNOut rule described earlier). However, high CBCL scores are ambiguous, because they can be associated with a wide variety of diagnoses. The more diverse the range of diagnoses and comorbidities encountered at a clinical setting, the less specific are high scores on measures of general

pathology, such as the CBCL (Youngstrom, Meyers, Youngstrom, Calabrese, & Findling, 2006a).

Estimates of the likelihood ratios attached to different ranges of CBCL Externalizing scores have been published for two large samples of youth ages 5–10 and 11–17 years (Youngstrom, Findling, Calabrese, et al., 2004). These numbers make it possible for clinicians to use the nomogram and interpret CBCL scores directly for their individual patients. Table 6.4 reproduces the likelihood ratios for the extremely low and extremely high score intervals for various instruments. Table 6.5 presents the PPV estimates that would result from high CBCL scores when used in clinical settings with different prevalences. Readers interested in learning to use the nomogram may practice using the nomogram to connect different prevalences with the likelihood ratio associated with the CBCL score (4.3 for an Externalizing *T*-score of 85 or higher, per Table 6.4) and see how closely they duplicate PPV estimates in Table 6.5. Incorporation of CBCL scores into the evaluation of PBD has also been illustrated in detail in a published case example (Youngstrom & Youngstrom, 2005). An important implication of the PPV estimates in Table 6.5 is that treating a CBCL “test positive” as a proxy for PBD will be wrong in most cases drawn from most settings. Using CBCL Externalizing (or the “bipolar profile”) as a proxy definition appears to be a reliable way to identify a group of youth with similar parent-reported behavior problems, but the majority of these youth will not meet strict criteria for a diagnosis of BD. Clinically, there is no substitute for thorough evaluation. Research based on proxy definitions cannot be interpreted as if it generalized to youth with strict diagnoses of BD (Volk, 2006).

Other Behavior Checklists

Various other measures are also in different stages of development and validation as diagnostic aids for PBD. Table 6.4 provides a listing of available measures as of April 2006, along with estimates of the area under the curve (AUC) and some comments about design features of studies that might affect clinical usage of the findings. When designs use comparable definitions of BD, as well as similar inclusion and exclusion criteria, the AUC provides a straightforward comparison of the overall di-

TABLE 6.4. Areas under the Curve (AUCs) and Likelihood Ratios for Potential Screening Measures for PBD

Screening measure (primary reference)	AUC	LR+ (score)	LR- (score)	Citation	Clinical generalizability
<i>Adolescents (11–18 years)</i>					
CBCL Externalizing <i>T</i> -score (Achenbach, 1991a)	.78 (<i>n</i> = 324)	4.3 (81+)	.04 (<54)	Youngstrom, Findling, Calabrese, et al. (2004)	High: Bipolar spectrum disorder (BPSD) versus all other diagnoses presenting to academic outpatient clinic, excluding pervasive developmental disorders and IQ < 80.
TRF Externalizing <i>T</i> -score (Achenbach, 1991b)	.70 (<i>n</i> = 324)	3.8 (77+)	.25 (<46)	Youngstrom, Findling, Calabrese, et al. (2004)	Same as above.
YSR Externalizing <i>T</i> -score (Achenbach, 1991c)	.71 (<i>n</i> = 324)	3.0 (77+)	.31 (<49)	Youngstrom, Findling, Calabrese, et al. (2004)	Same as above.
Parent-GBI—Hypomanic/Biphasic (Youngstrom, Findling, Danielson, & Calabrese, 2001)	.84 (<i>n</i> = 324)	9.2 (49+)	.06 (<9)	Youngstrom, Findling, Calabrese, et al. (2004)	Same as above. <i>Note:</i> Uses 0- to 3-point scale for scoring.
Parent-YMRS (Gracious et al., 2002)	.80 (<i>n</i> = 324) .70 (<i>n</i> = 124)	7.4 (28+)	.20 (<6)	Youngstrom, Findling, Calabrese, et al. (2004); Youngstrom, Meyers, et al. (2005)	Same as above. <i>Note:</i> Uses 0- to 4-point, 0- to 8-point scoring as per Young et al. (1978).
Adolescent-GBI—Hypomanic/Biphasic (Depue et al., 1981)	.62 (<i>n</i> = 324) .65 (<i>n</i> = 124)	3.9 (46+)	.33 (<10)	Youngstrom, Findling, Calabrese, et al. (2004); Youngstrom et al. (2005)	Same as above. <i>Note:</i> Uses 0- to 3-point scoring.
Parent-MDQ (Wagner et al., 2006)	~.84 (<i>n</i> < 150) .75 (<i>n</i> = 124)	3.9 (5+)	.32 (<5)	Wagner et al. (2006); Youngstrom et al. (2005)	High <i>Note:</i> Algorithm used by Wagner et al. (2006) requires co-occurring and at least moderate impairment.
Adolescent-MDQ (Hirschfeld et al., 2000)	~.59 (<i>n</i> < 150) .63 (<i>n</i> = 124)	1.5 (5+)	.84 (<5)	Wagner et al. (2006); Youngstrom, Meyers, et al. (2005)	<i>Note:</i> Hirschfeld's algorithm requires co-occurring and at least moderate impairment; Youngstrom, Meyers, et al. (2005) and Wagner et al. (2006) both found sensitivity improved by waiving these requirements.
Adolescent-YMRS (Youngstrom, Meyers, et al., 2005)	.50 (<i>n</i> = 124)	—	—	Youngstrom, Meyers, et al. (2005)	Very high: BPSD versus all others at community mental health center. <i>Note:</i> Do not use clinically!

TABLE 6.4. (continued)

Screening measure (primary reference)	AUC	LR+ (score)	LR- (score)	Citation	Clinical generalizability
<u>Children (5–10 years)</u>					
CBCL Externalizing T-score (Achenbach, 1991a)	.82 (<i>n</i> = 318)	3.7 (73+)	.07 (<58)	Youngstrom, Findling, Calabrese, et al. (2004)	High: BPSD versus all other diagnoses presenting to academic outpatient clinic, excluding pervasive developmental disorders and IQ < 80.
TRF Externalizing T-score (Achenbach, 1991b)	.57 (<i>n</i> = 318)	1.4 (63+)	.78 (<57)	Youngstrom, Findling, Calabrese, et al. (2004)	Same as above. Do <i>not</i> use clinically!
Parent-GBI—Hypomanic/Biphasic (Youngstrom et al., 2001)	.81 (<i>n</i> = 318)	6.3 (51+)	.10 (<11)	Youngstrom, Findling, Calabrese, et al. (2004)	Same as above. <i>Note:</i> Uses 0 to 3 scoring.
Parent-YMRS (Gracious et al., 2002)	.83 (<i>n</i> = 318) .66 (<i>n</i> = 141)	8.9 (35+)	.08 (<7)	Youngstrom, Findling, Calabrese, et al. (2004); Youngstrom, Meyers, et al. (2005)	Same as above. <i>Note:</i> Uses 0 to 4, 0 to 8 scoring as per Young et al. (1978).
Parent-MDQ (Wagner et al., 2006)	.72 (<i>n</i> = 141)	—	—	Youngstrom, Meyers, et al. (2005)	Very high: BPSD versus all others at community mental health center.
<u>Combined samples (child and adolescent not reported separately)</u>					
Parent-CMRS (Pavuluri et al., 2006)	.91 (<i>n</i> = 100)	13.7 (20+)	.19 (<20)	Pavuluri et al. (2006)	Limited: 50 BPSD versus 50 ADHD without mood disorder.
Two-Item Screen (Tillman & Geller, 2005)	.85 (<i>n</i> = 264) .70 (<i>n</i> = 500)	5.2* 1.6**	.31* .32**	Tillman & Geller (2005); Youngstrom, Meyers, et al. (2006); Papolos & Papolos (2002)	*Tillman and Geller recommend cutting at 9+ for ages 7–8 years, 8+ for 9–10 years, and 6+ for ages 11–17 years. **Threshold was chosen to be statistically optimal for entire sample.
Child Bipolar Questionnaire (Papolos & Papolos, 2002)	Not reported (<i>n</i> = 135)	7.1	N/A	Papolos, Hennen, Cockerham, Thode, & Youngstrom (2006)	Limited: K-SADS validation group comprised of bipolar spectrum, ADHD, or no diagnosis.
Child Symptom Inventory (Parent) (Gadow & Sprafkin, 1994)				No relevant data published yet	Adolescent version includes mania scale with DSM-IV items; mania items added to research version of child instrument (available from CSI authors upon request).
Adolescent Symptom Inventory (Gadow & Sprafkin, 1994)				No relevant data published yet	Includes mania scale with DSM-IV items.
Teacher Symptom Inventory (Gadow & Sprafkin, 1999)				No relevant data published yet	Includes mania scale with DSM-IV items.

Note. All studies used some version of K-SADS interview by a trained rater, combined with review by a clinician to establish consensus. LR+, change in likelihood ratio associated with a positive test score; LR-, likelihood ratio for a low score. LRs of 1 indicate that the test result did not change impressions at all. LRs larger than 10 or smaller than .10 are frequently clinically decisive; LRs of 5 or

TABLE 6.5. Examples of the Effects of Base Rate on the Positive Predictive Value (PPV) of High Scores on Two Screening Tests for Adolescent BD

Setting	Base rate	CBCL externalizing T-score (LR+)	PPV	P-GBI Hypomanic/Biphasic score (LR+)	PPV
Public high school (Teplin et al., 2002)	0.6%	85 (4.3)	3%	54 (9.2)	5%
Juvenile detention (Youngstrom, Findling, et al., 2005)	2%	85 (4.3)	5%	54 (9.2)	16%
Outpatient clinic or community mental health (Naylor et al., 2002)	6%	85 (4.3)	21%	54 (9.2)	37%
County wards receiving mental health services (Pliszka et al., 2000)	11%	85 (4.3)	35%	54 (9.2)	53%
Juvenile detention (Blader & Carlson, 2006)	22%	85 (4.3)	55%	54 (9.2)	72%
Acute psychiatric hospitalization (based on Centers for Disease Control national data for discharge diagnoses in 2002–2003 (Thayer, 1996)	40%	85 (4.3)	74%	54 (9.2)	86%
Heavily enriched mood disorders study (many published analyses of diagnostic tests compare bipolar cases to an equal number of comparison cases)	50%	85 (4.3)	81%	54 (9.2)	90%

Note. The likelihood ratios associated with a positive test result (LR+) are from Table 4 of Youngstrom, Findling, Calabrese, et al. (2004).

agnostic efficiency of the tests. It also is possible to test whether the diagnostic performance of one test is significantly superior to another (Hanley & McNeil, 1983). These comparisons have more statistical power when the instruments are evaluated in the same sample, which also eliminates a wealth of other, potential confounds that might make it otherwise difficult to compare tests (Pepe, 2003).

Perusal of Table 6.4 indicates that more than 15 published measures include some endorsement that they might be helpful in assessing PBD. All except the CBCL have been published since 2001, in keeping with the rising interest in PBD. Few of the measures have published estimates of diagnostic efficiency available. A more subtle but crucial point is that the majority of the studies have design features that seriously limit the generalizability of findings into most clinical settings. The most common limitation involves filtering the sample in ways unlikely to be mirrored in clinical practice. This could include limiting the bipolar sample to bipolar I disorder cases, or to “narrow phenotype” cases (as described in Table 6.2). Focusing on bipolar I disorder would increase the severity of the manic or mixed symptoms sampled, thus increasing the apparent sensitivity of

the test. Including only narrow phenotype presentations might also enhance the sensitivity of measures that include the relevant symptoms (e.g., requiring periods of elated mood to satisfy inclusion criteria could make measures asking about elated mood appear more sensitive).

The inclusion and exclusion criteria also often change sample composition in ways that alter the diagnostic specificity. A common design in PBD research is use of two comparison groups: One with no Axis I diagnoses, and another with ADHD but no comorbid mood disorder (e.g., Geller, Warner, Williams, & Zimmerman, 1998; Geller, Williams, et al., 1998; Pavuluri, Henry, Devineni, Carbray, & Birmaher, 2006; Tillman & Geller, 2005). This design was initially used to study the phenomenology of PBD, and to determine what behaviors indicated mania as opposed to normal childhood behaviors, or behaviors associated with ADHD—a disorder recognized as sharing many symptoms that could look like a manic presentation (Klein et al., 1998). Although the design makes good sense for phenomenological research, it distorts the performance of diagnostic tests markedly, unless practitioners employ the test in settings where children without

uncomplicated ADHD or no diagnosis are systematically excluded. Including children with comorbid depression or other diagnoses produces much lower estimates of specificity (Youngstrom et al., 2006a). However, these humbler estimates are much more likely to generalize to clinical settings. These changes in performance offer concrete examples of why clinicians must pay attention to the design features of studies (Bossuyt et al., 2003) and weigh the appropriateness of applying findings to specific patients (Jaeschke, Guyatt, & Sackett, 1994a, 1994b; Sackett et al., 2000).

In spite of these limitations, several “take home” messages emerge from the studies reviewed in Table 6.4. First, there are promising diagnostic aids for PBD, at least under “efficacy” types of conditions. Second, measures that include more content pertaining to mania (e.g., the General Behavior Inventory [GBI], with 28 relevant items, or the MDQ, which asks about all DSM symptoms of mania) are much more specific to BD. As a consequence, high scores on these measures generate much larger likelihood ratios than do high scores on more general measures of psychopathology. Put another way, high scores on measures that systematically assess symptoms of mania are more powerful tools for helping to rule in PBD, whereas global measures of externalizing problems can be quite effective at ruling out PBD. Third, parent report measures appear to identify PBD better than do self- or teacher-reported measures. This holds true across studies, where parent reports produce AUCs in the .8–.9 range, compared to AUCs of .5–.7 for youth and teacher measures. The better performance of parent report has also been demonstrated in “head-to-head” comparisons between parent and youth report on the same instrument with the Achenbach scales (Youngstrom, Findling, Calabrese, et al., 2004), the GBI (Youngstrom, Findling, Calabrese, et al., 2004; Youngstrom, Meyers, et al., 2005), questionnaire versions of the Young Mania Rating Scale (Youngstrom, Meyers, et al., 2005), and the MDQ (Wagner, Findling, Emslie, Gracious, & Reed, 2006; Youngstrom, Meyers, et al., 2005). The better performance of the parent report is clearly not limited to a single instrument, or to a single research group’s definition of PBD. It holds for both adolescents and younger children. This is an important finding, because it strongly contradicts the conventional clinical wisdom that self-report should be the

preferred information source for evaluations of mood disorder (Loeber, Green, & Lahey, 1990).

Assessment and Treatment Thresholds

Are the combination of base-rate information, family history, and behavior checklists sufficient to do good case formulation and to begin treatment of BD? Most clinicians would say “no.” Adopting these tools and the evidence-based framework described earlier would substantially improve the accuracy of clinical decision making about BD at a public health level, but it is not clear that these tools are powerful enough to justify making high-stakes decisions about individual cases.

Evidence-based medicine offers a helpful framework for answering the question, “How much is ‘enough’ confidence to have in a diagnosis to justify beginning treatment?” Certain diagnoses are so improbable that they are not worth the time and expense of clinical evaluation, even though they are theoretically possible. For example, the possibility of a heart attack in a 25-year-old is usually so low that it is not worth screening for it, let alone ordering an electrocardiogram for all 25-year-olds. However, for a specific case, other risk factors might raise the risk to a point that additional assessment makes good sense. If the 25-year-old has a family history with extensive early-onset heart disease or is taking a medication known to increase the risk of cardiac events, then the probability becomes high enough to merit additional assessment, even though the risk is still likely to be low. This exemplifies crossing a threshold of risk, below which the risk is so low that the expenditure of time, resources, and burden on the patient are not justified, and above which assessment would have utility. This has been called the “test/no-test threshold” (Guyatt & Rennie, 2002).

Similarly, there comes a point at which the diagnosis has been established with sufficient certainty that additional testing is unlikely to be helpful, and may actually become harmful due to the increased expense, burden, and risk involved for the patient, as well as the risk of potentially adding contradictory information that could lower the quality of the overall assessment (Kraemer, 1992). This has been called the “treatment threshold” (Guyatt & Rennie, 2002). The test and treatment thresholds carve the range of probability of a diagnosis into

three segments: (1) below the test/no-test threshold, where risk is too low to justify the costs associated with assessment; (2) between the test and the treatment thresholds; or (3) above the treatment threshold, where confidence is high enough to discontinue diagnostic assessment and initiate intervention. If the probability falls in the midrange, then more assessment is required, until the new findings either decrease the probability back below the test threshold, or increase it beyond the treatment threshold.

Where should the test and treatment thresholds be set? Medical ethicists suggest that the thresholds should be set based on the costs and benefits associated with testing and with treatment (Guyatt & Rennie, 2002). There are situations in which the benefits of treatment are so high, and the costs and risks of treatment are so low, that it makes sense to skip assessment and treat everyone. This is true for many public health initiatives, such as iodizing table salt regardless of risk for thyroid dysfunction. In other scenarios, the risks of treatment are high enough that much greater diagnostic confidence is needed before starting the regimen. In light of the relative risks associated with atypical antipsychotic medications or mood stabilizers versus stimulant medication (Kowatch, Fristad, et al., 2005), the treatment threshold should be higher for a diagnosis of BD than for a diagnosis of ADHD. Although there are statistical models for determining the best places to set the threshold on a diagnostic test when

the costs and benefits (i.e., the “utilities”) are known (Kraemer, 1992; Swets, Dawes, & Monahan, 2000), available data about the utilities relevant to PBD are not good. Thus it seems most appropriate for clinicians to talk individually with families and negotiate jointly the level of confidence required either to discontinue testing or to initiate treatment. Such discussions are empowering to the patient and family.

Table 6.5 presents the PPVs associated with high scores on the CBCL and the parent-completed GBI. Seen through the lens of the decision-making framework articulated here, PPVs for these tests probably fall in the “indeterminate” range. The PPVs are not high enough to justify starting high-risk interventions in most clinical settings, but they remain too high to effectively rule out a bipolar diagnosis. In other words, high scores on these tests are insufficiently accurate to be treated as a substitute for a diagnosis, but they should raise a “red flag” to trigger more thorough assessment. Table 6.6 lists other clinical features that should also provoke further assessment, even though quantitative risk estimates are not yet available.

Tests are much more helpful at ruling out PBD, reducing PBD probability below the test/no-test threshold. This is largely a function of the low base rate of PBD in most settings. If a disorder is already rare, then a test result that reduces risk is usually decisive. However, because many available tests are sensitive to PBD,

TABLE 6.6. Red Flags That Should Trigger Thorough Evaluation of Possible BD

Red flag	Description	References
Early-onset depression	Variably described as onset before age 25, or prepubertally	Kowatch, Youngstrom, et al. (2005)
Psychotic features	True delusions or hallucinations occurring in the context of mood	Kowatch, Youngstrom, et al. (2005)
Episodic aggressive behavior (including parent reports of extreme externalizing behavior)	Not specific to bipolar disorder, but most bipolar youth show this; more episodic should trigger evaluation to rule out	Hodgins et al. (2002)
Family history of BD	Five-fold increase in risk for first-degree relative; 2.5-fold for second-degree or “fuzzy” bipolar	Hodgins et al. (2002)
Atypical depression	Associated with hypersomnia (vs. insomnia), increased appetite and weight gain (vs. decrease), decreased energy, and interpersonal rejection sensitivity	Benazzi & Rihmer (2000); Birmaher et al. (1996)

low scores on them generate highly accurate negative predictive values (e.g., the SnNOut rule, or very small likelihood ratios).

Methods for Confirming Diagnosis

Diagnostic Interviews

One of the most powerful tools available for establishing a diagnosis is diagnostic interviews. These run the gamut from unstructured clinical interviews guided by the intuition and experience of the clinician, all the way to fully structured interviews that provide a rigid framework and clear scripting of the questions and probes. There are advantages and drawbacks to either extreme. Unstructured clinical interviews provide the greatest flexibility to maintain rapport, to be culturally competent, and to concentrate on issues that appear related to the presenting problem, but the price is lower reliability (i.e., results are unlikely to be duplicated by another clinician's interview) and greater susceptibility to heuristics that undermine the validity of decisions (Garb, 1998). Fully structured interviews offer the mirror image of strengths and weaknesses: Interviews can be structured to the point that they are delivered via computer. Questions are always asked and probed exactly the same way, maximizing interrater reliability (i.e., it does not matter which computer does the interview), but minimizing the flexibility, cultural competence, or other advantages offered by involving clinical judgment in the process.

At present, no fully structured diagnostic interview has demonstrated good validity for diagnosing PBD. Some instruments have failed to detect any cases of PBD in epidemiological studies (Costello et al., 1996; Shaffer et al., 1996), raising concerns about their sensitivity to bipolar diagnoses even when used in clinical settings where PBD might be reasonably common. Most published research on PBD has relied on one of the several different versions of the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS), including the Epidemiological version (K-SADS-E; Orvaschel, 1995), the Present and Lifetime version (K-SADS-PL; Kaufman et al., 1997), or the Washington University version (WASH-UK-SADS; Geller, Zimmerman, et al., 2001). The K-SADS includes a mania module that has been validated down to at least age 5 (Nottelmann et al., 2001), and the WASH-U K-SADS includes

extensive additional items potentially related to depression and mania in children beyond the core list of DSM symptoms. However, reliable K-SADS administration requires considerable training and supervision, and groups may differ in their conceptualization of symptoms and behaviors (cf. Geller, Zimmerman, Williams, DelBello, Frazier et al., 2002; Wozniak et al., 1995). The K-SADS is also too cumbersome to use clinically. The core module of the PL version is nearly 200 pages long, with five additional supplements; and the WASH-U version is even more extensive. The complete KSADS interview with parent and child takes anywhere from 2 to 6 hours. Thus, training, expense, and burden on the family all mitigate against routine clinical use of the K-SADS.

The Children's Interview for Psychiatric Syndromes (ChIPS; Weller, Weller, Fristad, Rooney, & Schecter, 2000), a much briefer semistructured diagnostic interview, has shown promising validity for mood disorders (Fristad, Cummins, et al., 1998; Fristad, Glickman, et al., 1998). It is more likely to be viable for clinical use than the K-SADS due to lower training demands and briefer administration time. The ChiPS includes neither sufficient probes to capture cyclothymia nor some other variants of BD NOS; and its validity needs to be demonstrated in the hands of research groups other than its developers. Still, the combination of available validity data and the much more streamlined format makes ChiPS an attractive candidate, if a semistructured diagnostic interview is desired.

Concentrate on "Handle" Symptoms

Realistically, most practicing clinicians conduct unstructured diagnostic interviews rather than adopt one of the structured or semistructured interviews described earlier. To establish whether BD is present, it is essential to ask about all of the DSM symptoms of mania or hypomania. However, the symptoms are not equally useful indicators of potential BD (see Table 6.7). Many symptoms commonly seen in mania or hypomania (Kowatch, Youngstrom, et al., 2005) are frequently present in conditions other than BD (Carlson, 1998, 2002; Klein et al., 1998). Irritable mood, poor concentration, and high levels of motor activity are examples of symptoms that are highly sensitive but not specific to BD. Their high sensitivity means that the *absence* of the symptom may be

helpful in ruling out a BD (SnNOut at the symptom level), but the presence of such symptoms is by itself ambiguous. Irritability is analogous to the “fever” or “pain” of child mental health: It indicates that something is wrong but does not provide much guidance in deciding what is wrong.

Other symptoms are more helpful in getting a “handle” on whether BD is present. Episodes of abnormally elated, expansive mood are one such symptom. Although elated mood is not the most impairing symptom associated with BD and is rarely high on the list of presenting problems, it is present in more than 80% of cases with PBD (Kowatch, Youngstrom, et al., 2005). Furthermore, elated mood that is noticeably more frequent, more intense, or longer in duration than would be developmentally appropriate rarely occurs in other child mental health syndromes (Kowatch, Fristad, et al., 2005). Grandiosity also appears fairly common in BD but less frequent in ADHD (Geller, Zimmerman, Williams, DelBello, Bolhofner, et al., 2002). However, chronic grandiosity or an inflated but brittle sense of self-esteem is associated with CD (which was excluded from earlier studies of PBD), undermining the specificity of this symptom in settings in which antisocial behavior might occur.

Decreased need for sleep, which is not present in all cases, is highly specific to PBD and may be challenging to assess clinically for many reasons: Self-report is not very accurate about the onset and offset of sleep periods; parents may not know when the child is falling asleep or waking (especially if the parent is asleep at the time); and children often have televisions or computers in their room that contribute to poor sleep hygiene even when mood dysregulation is not a factor. In addition, sleep disturbance is more suggestive of BD when individuals are not sleeping because they have too much energy, or when they get less sleep than usual yet still feel energetic the following day. This should be distinguished from the insomnia often seen with unipolar depression, in which a person wants to sleep but has difficulty falling asleep despite low energy, due to stress and rumination about problems.

Hypersexuality is another symptom that deserves comment. Most children with PBD do not show hypersexuality (see Table 6.7). Indeed, hypersexuality is rarely present in prepubertal children outside of the context of either sexual abuse or mood disorder. Thus,

hypersexual behavior should trigger careful assessment of both possibilities.

Many other features that clinicians have noticed tend to occur with mood episodes. Table 6.7 (adapted from Youngstrom, Birmaher, & Findling, under review) lists the DSM-IV-TR and ICD-10 symptoms of mania, along with some clinically associated features. Where available, sensitivity estimates for the symptom or sign are provided. Quantitative estimates of specificity are more rare, and the few published estimates are unlikely to be clinically generalizable because of the inclusion and exclusion criteria used. Table 6.7 also offers brief comments about aspects of clinical presentation that would be more indicative of bipolar than of nonbipolar diagnoses.

For all of these symptoms, the case for BD is most compelling when the symptoms occur together in episodes that are a distinct shift from the person’s typical functioning. Although not all authorities agree about the importance of distinct episodes, episodicity increases confidence in the diagnosis of mood disorders, particularly when mood episodes have recurred. The presence of episodes even when symptoms are prodromal or subthreshold also predicts later BD (Egeland, Hostetter, Pauls, & Sussex, 2000). Careful assessment of episodicity or fluctuations in symptom presentation also may help to clarify otherwise ambiguous symptoms. ADHD is associated with chronically high energy and poor concentration, for example. Hearing about a person suddenly having more energy than usual for periods of 1–2 weeks at a time and also difficulty staying focused on tasks sounds more like a mood disorder and less like ADHD. Careful evaluation of temperament and developmental history is vital to establish the backdrop against which these changes in functioning can be detected (Quinn & Fristad, 2004).

Mood and Energy Checkups

Prospectively gathering data about mood and energy over the course of treatment is a valuable tool for clarifying whether there are fluctuations suggestive of a mood disorder. This is a departure from the traditional model of bunching psychological assessment at the beginning of treatment. Instead, a more “dental model” of scheduling regular checkups to monitor mood and energy clarifies mood diagnosis in a way that a single panel of assessment can-

TABLE 6.7. Symptoms and Associated Features of BD

Symptom	Sensitivity to PBD ^a	Specificity to PBD	Features suggesting PBD	Features suggesting other diagnoses	Recommendation
Handle symptoms (high specificity)					
A.1. Elated, expansive, euphoric mood	70% (45–87%)	High	Extreme, causes impairment, situationally inappropriate, extreme duration	Transient, more responsive to redirection, more situationally driven; substance abuse, use of meds (e.g., corticosteroids)	Highly specific feature; its presence helps rule in diagnosis. Assess even though family may not consider it part of presenting problem.
A.2. Irritable mood	81% (55–94%)	Low	Irritability in context of other mood symptoms; high versus low energy irritability	Chronic oppositionality in absence of changes in mood or energy; it can be unipolar depression	Assess via collateral informant; self-report underestimates. If collaterals deny irritability, effectively rule out PBD because of high sensitivity. Embed in context of changes in mood and energy.
B.1. Grandiosity	78% (67–85%)	Moderately high; much lower if CD is included	Episodic quality, and should fluctuate with mood. Periods of grandiosity contrasted with low self-esteem, feeling worthless	More chronic, arrogant, not associated with mood is suggestive of CD/APD (antisocial personality disorder) or adolescent overconfidence; substance abuse	Worth emphasizing, but probably not specific enough to elevate to required feature. Fluctuations a key feature in discerning from CD/APD.
Increased energy	89% (76–96%); highest sensitivity in meta analysis	Low for “high energy,” which is also common in ADHD; <i>episodic periods</i> of high energy would be more specific to mood disorder	Higher, if asked about fluctuation or change; lower, if asked about chronic (common feature in ADHD)	Chronic high motor activity	Used to assess as change in functioning from youth’s typical behavior. Episodic quality is more specific to bipolar disorder. Focus on <i>energy</i> versus motor activity for self-report; <i>change</i> in motor activity for collaterals.
Nonspecific symptoms (in descending order of sensitivity to BD)					
Pressured speech	82% (69–90%)	Unclear. Carlson (2002) raises issue of expressive language problems; but not evaluated yet in published samples	Episodic quality, change from typical for youth; set against slowed or impoverished speech during depression	Chronically “chatty” or talkative, more suggestive of ADHD	Emphasize changes from typical functioning embedded in shifts of mood or energy.
Racing thoughts	74% (51–88%)	Good, if embedded in mood context	Ask about imagery as well as words (Youngstrom et al., under review)	Distinguish from expressive language disorder and effects of substance abuse, medications	
Decreased need	72%	High, if framed as	High energy, actively	Decreased sleep due to	Emphasize decreased need for sleep, as

for sleep	(53–86%)	decreased need, not insomnia; low, if just focus on trouble falling asleep	engaged in activities, does not miss sleep the next day	stimulant use (ADHD), use of substances or medications (e.g., asthma medications); difficulty falling asleep with unipolar depression (vs. decreased need for sleep). Depressed persons want to sleep but cannot	distinct from difficulty falling asleep (particularly due to stress or rumination). High energy, little diminution of energy despite decreased sleep.
Mood swings/lability	High	High, based on PGBI, CBCL, Conners items	Frequent, intense, with periods of long duration	May be induced by substance abuse, medications, medical/neurological illnesses, borderline personality traits, disruptive disorders	Parent report highly sensitive. PBD unlikely if parent denies. Specificity appears promising, based on multiple scales. Conceptualize as mixed state with volatile mood.
Hypersexuality	38% (31–45%)	High, typically either PBD or sexual abuse	Hypersexuality not characteristic, embedded in episodes of energy/mood; has pleasure-seeking quality	Sexual abuse linked to trauma, perhaps more seductive/reenacting quality than sensation-seeking; exposure to X-rated movies, actual sex	Insensitive to PBD, so absence not informative. Highly specific presence should trigger careful assessment of PBD and abuse (recognize that they could co-occur).
Distractibility	84% (71–92%)	Low, ADHD, unipolar, anxiety, PTSD, and low cognitive functioning all show this, too	Higher, if asked about change from typical; embedded in context of mood	Chronic problems much more suggestive of ADHD or neurological impairment	Probably important to assess via collateral instead of self-report. High sensitivity could make negative collateral report helpful in ruling out BD.
Poor judgment	69% (38–89%)	Moderate	Episodic, embedded in mood/energy, not a trait of youth	Impulsive or accident-prone, clumsy	Episodic, sensation seeking may be most specific presentation.
Flight of ideas	56% (46–66%)	Moderate		(Speech problems again) substance abuse, medication-induced effects	
Increased sense of well-being (ICD-10, p. 113)	Unknown	Unknown	Unknown, but theoretically likely to be low	Consistent with high positive affect model of mania	Needs investigation.
Increased sociability/people-seeking/overfamiliarity (ICD-10, p. 113); added to WASH-U K-SADS;	May be fairly sensitive	Unknown	Unknown		Needs investigation.

^a Sensitivity estimates are from Kowatch, Youngstrom, et al. (2005) meta-analysis unless otherwise noted.

not. These checkups may be as basic as asking about changes in mood and energy at each appointment, or they could use brief checklists. Brevity is crucial to minimize burden and increase cooperation. Many instruments that would be good choices for an initial assessment battery are poor options for the repetitions needed to get prospective information.

At the opposite extreme, the “life-charting method” boils down questions to a bare minimum of two or three items (one rating energy, another rating mood and possibly distinguishing irritability from “up” or “down” moods), then has the patient or parent rate the items several times a day for several weeks or months (Denicoff et al., 1997). The life-charting method provides extremely detailed information about shifts in mood and energy, and it can be a powerful tool for identifying triggers that exacerbate mood disturbance. Several excellent examples of life charts are available at no charge on the Internet (Google searches on the term “bipolar life chart” provide multiple hits). Some families take readily to the life-charting methodology. Others find it too burdensome.

Methods Not Yet Diagnostically Informative

Many widely used procedures have not yet demonstrated validity for the assessment of PBD. Some have not been systematically investigated yet; others have some preliminary data available, but nothing that adequately draws inferences about the diagnostic validity of the tool applied in clinical settings. There have been no published evaluations of projective techniques such as the Rorschach Inkblot Test, the Thematic Apperception Test, or kinetic family drawing, despite a clinical lore that PBD might be associated with gory content (Popper, 1990). There also are no published studies with objective personality inventories yet. Without rigorous research, it is impossible to tell how helpful assessment results on any of these instruments might be in determining a bipolar diagnosis. Even face-valid results might occur frequently enough in nonbipolar cases to undermine the diagnostic value, much as the ubiquity of irritable mood offsets its high sensitivity to PBD. Other tests have shown statistically significant differences between bipolar and nonbipolar groups, including some neuropsychological and affective processing tasks (Dickstein et al., 2004, 2005; Henin et al., 2006; Rich, Bhangoo, et al., 2005; Rich,

Schmajuk, et al., 2005). However, these studies typically obtain effect sizes smaller than would be needed to classify individuals accurately based on test results, and they have used tight inclusion and exclusion criteria that increase internal validity (which is important for these novel investigations). Thus, clinicians attempting to use the same tools in clinical settings with fewer inclusion and exclusion criteria obtain even more modest results, further weakening the chances of a test contributing accurately to diagnostic formulation. Given the current evidence base:

1. There is no value added by administering any of these tests to aid in the differential diagnosis of PBD. Although many of these tools might demonstrate validity in future studies, at present they can only be considered unproven.
2. If these tests already have been given as part of an assessment battery, they should not be interpreted as changing the diagnostic formulation with regard to PBD.
3. These tests should only be added to an assessment battery in youth diagnosed with BD if the test serves some other, additional clinical purpose, such as ascertaining appropriate educational placement.

Cross-Informant Agreement and Implications for Impairment

A common issue in child assessment occurs when a parent (often the mother) reports lots of concerns about the child's behavior that do not appear to be corroborated by other perspectives, such as youth self-report or ratings provided by teachers. Clinicians are frequently worried that the parent might be hypervigilant or have unrealistic expectations about appropriate behavior, that ineffective parenting styles might be creating behavior problems that otherwise are well managed in the classroom and other settings, or that the parent's anxiety or depression might be biasing reports about the child's behavior (Richters, 1992). When parent and youth perceptions differ, clinicians tend to give more weight to youth report about internalizing problems, because youth have direct access to their own feelings (Loeber et al., 1990). Discrepancies between parent, teacher, and youth descriptions of behavior problems in PBD tend to be large (Hazell et al., 1999; Kahana et al., 2003; Youngstrom, Findling,

Calabrese, et al., 2004), raising concerns about both the accuracy of parent report and stability of behavior across settings (Thuppal, Carlson, Sprafkin, & Gadow, 2002).

Importantly, results have consistently demonstrated that parent appraisals of mood and behavior identify bipolar cases significantly better than do self- or teacher reports (Findling et al., 2002; Hazell et al., 1999; Kahana et al., 2003; Wagner et al., 2006; Youngstrom, Findling, Calabrese, et al., 2004; Youngstrom, Meyers, et al., 2005), even when predicting research diagnoses made on the basis of direct interviews of both the parent and child, as well as clinical observation. The greater validity of parent report persists in spite of high rates of mood disorder in the reporting parent in many of these samples, and in spite of the high levels of their own distress reported by parents (Youngstrom, Findling, & Calabrese, 2004).

The lower validity of teacher compared to parent reports appears to be due partly to the tendency of teachers to focus on increased motor activity and poor concentration, then to attribute these behaviors to ADHD (Abikoff, Courtney, Pelham, & Koplewicz, 1993). In fact, teachers do no better than chance at distinguishing between children with BD and those with ADHD (Youngstrom, Findling, Calabrese, et al., 2004) when using the Achenbach Teacher's Report Form (TRF; 1991b). Teachers might do better identifying bipolar cases using instruments that include item content more specific to mania, although some important behaviors, such as decreased need for sleep, are unlikely to be observed at school.

At least three factors undermine the validity of youth self-report: (1) Children and adolescents are often less cognitively capable of completing questionnaires, and less psychologically minded than adults; (2) social desirability effects might make youth minimize endorsement of irritable mood or hypersexuality; and (3) mania and hypomania tend to be more distressing to people around the affected person, rather than to the person him- or herself, and mood symptoms often are associated with a reduction in insight into one's own behavior (Dell'Osso et al., 2002; Pini, Dell'Osso, & Amador, 2001; Youngstrom, Findling, & Calabrese, 2004).

Agreement among informants about cases with PBD is actually higher than typically believed. According to both themselves and their

teachers, affected youth experience more behavior problems than would be expected based on the level of problems described by the parent (Youngstrom, Meyers, Youngstrom, Calabrese, & Findling, 2006b). Interrater agreement appears to be even higher when focus is on mood symptoms in particular instead of behavior problems generally (Youngstrom, Findling, & Calabrese, 2004), so there is likely to be even more cross-situational consistency than current measures reveal. Even so, there appears to be a dose-response relationship, such that when manic symptoms are reported by more informants and in more settings, global functioning and objective measures of behavior on an inpatient unit all indicate progressively more severe impairment (Carlson & Youngstrom, 2003).

TREATMENT TARGETS: PROCESS AND OUTCOME MEASURES

Symptom Reduction

There are many rating instruments that measure symptoms during the course of treatment. Some are better suited for baseline and outcome evaluation; others are more suitable for monitoring progress during the course of treatment. It is worth bearing in mind that tools may play a valuable monitoring function without being top-tier outcome measures. The life-chart methodology or session-by-session checkups on mood and energy are cases in point. These are unlikely to be primary outcome measures, but they provide helpful weekly feedback about progress and setbacks in the course of treatment.

Clinician-Rated Measures of Symptom Severity

For clinical trials, the primary outcome measures are clinician-rated assessments of the severity of manic and depressive symptoms. The industry standards have been the Young Mania Rating Scale (YMRS; Young, Biggs, Ziegler, & Meyer, 1978) and the Child Depression Rating Scale—Revised (CDRS-R; Poznanski, Miller, Salguero, & Kelsh, 1984). The YMRS was originally designed for use with adults on an inpatient unit, with ratings completed by staff nurses based on direct observation of behavior over an 8-hour shift. With children and adolescents, YMRS ratings are typically based on clinician interviews with the child and the pri-

mary caregiver, and the reference period is usually extended to cover the past 2 weeks instead of 8 hours. Although the item anchors and weights were developed for use with inpatient adults, no adaptations have been made to make the anchors more developmentally appropriate for children or adolescents. The YMRS also includes some items covering behaviors that are not DSM symptoms of mania, and it omits other core symptoms (e.g., grandiosity or increased engagement in pleasurable but risky acts). In spite of these shortcomings, the YMRS has demonstrated considerable evidence of validity in youth (Fristad, Weller, & Weller, 1992, 1995; Youngstrom, Danielson, Findling, Gracious, & Calabrese, 2002). Even so, 2 of the 11 items on the YMRS are so weak as to lower the internal consistency of an already short scale. One of these is the “bizarre appearance” item, and the other is the item rating “lack of insight.” Both items are also problematic in parent-report versions of the YMRS (Gracious, Youngstrom, Findling, & Calabrese, 2002; Youngstrom, Gracious, Danielson, Findling, & Calabrese, 2003). The calibration of YMRS scores across sites may also be different, such that similar clinical presentations earn widely divergent scores (Youngstrom, Findling, et al., 2003).

In contrast, the CDRS-R was developed specifically for use with children and adolescents, and the initial validation samples comprised youth (Poznanski et al., 1984). The CDRS-R includes 17 items rated on either a 1- to 5-point or 1- to 7-point scale, with higher scores signaling greater severity. Ratings are based on interviews with both the caregiver and the youth, with three items rated entirely on the basis of direct observation during the course of the youth interview. Strengths of the CDRS-R include its being designed specifically for youths, with developmentally appropriate anchors and validation samples; its high internal consistency (alphas often exceed .90); and its demonstrated sensitivity to treatment effects. Limitations of the CDRS-R are that it does not cover all DSM symptoms of depression, that it fails to distinguish between psychomotor agitation and retardation, that it does not assess both hypersomnia and insomnia (particularly problematic inasmuch as hypersomnia may denote bipolar depression), and that its scores also might depend substantially on the rater rather than on the severity of depression.

The degree to which clinician ratings are sus-

ceptible to variations in clinical judgment poses a major challenge not only for multisite trials but also for independent clinicians attempting to use the measures in their own practice. Without using standardized videotapes or training vignettes, a clinician has no means of knowing whether his or her perceived sense of mood severity corresponds with other clinicians' perceptions. In a recent study using videotapes, large differences were found between the scores assigned by American, Indian, and British psychiatrists (in descending order of average ratings) (Mackin, Targum, Kalali, Rom, & Young, 2006). The fact that so much variance in scores depends on the rater and not the diagnosis or the severity of illness obscures potential similarities across sites and studies. This state of affairs also means that we should not put great faith in commonly used rules of thumb, such as a YMRS score of 13 or higher to connote hypomania, or 16 or higher to designate moderate mania.

Newer measures of mania and depression, such as the K-SADS Mania Rating Scale and K-SADS Depression Rating Scale (Axelson et al., 2003), are designed to provide more thorough coverage of mood content, more consistent anchors and item score ranges, and other psychometric advantages. They represent a definite improvement over the prior generation of rating scales, but have not yet reached the tipping point at which their technical merits outweigh the inertia of the backlog of publications using the more familiar instruments. No clinician-rated instrument will resolve the problems associated with rater effects (e.g., different calibration across sites or raters) without requiring calibration against a standard set of training tapes, as is done with measures such as the Psychopathy Checklist—Revised (Hare, 1991).

Parent-Rated Measures of Severity and Outcome

Parent checklists are much easier to deploy in a standardized fashion across sites and clinics than are clinician-rated instruments. Training costs are lower, and susceptibility to idiosyncratic clinical interpretations of behaviors is also lessened. As yet there is no established front-runner for parent-reported symptom outcome measures. The CBCL often shows little improvement over the course of treatment, possibly because ratings cover a 6-month window, and acute clinical trials tend to be much shorter in length. The CBCL may also be ham-

pered by the lack of scales with content specific to mood disorders. The MDQ focuses on symptoms of mania, but because it uses a simple present-absent format, it may not gather enough information about severity to be sensitive to treatment effects. The parent GBI has proven highly sensitive to treatment effects in open-label studies (Cooperberg, 2001; Youngstrom, Cooperberg, Findling, & Calabrese, 2003), showing large effects on both the manic-mixed and the depression scales. However, the reading level (roughly 12th grade) and the burden imposed by the GBI (10 pages of questions in 12-point font) hinder its utility as an outcome measure in clinical settings. Parent-rated YMRS scores appear less sensitive to treatment effects, in part due to the lower reliability of the instrument. Other parent-reported measures, such as the Child Bipolar Questionnaire (Papolos & Papolos, 2002) and the Child Mania Rating Scale (Pavuluri et al., 2006) (see Table 6.4) have not yet been evaluated as outcome measures.

Youth Self-Report Measures

As documented earlier, youth self-report, from a diagnostic perspective, does not efficiently identify BD. Youth might seek treatment for the depressed phase of illness, but they are very unlikely to self-refer for treatment during the manic, mixed, or hypomanic phases of illness. As a result, treatment referrals are often made by a concerned adult instead of the adolescent. It follows that the baseline levels of symptoms typically are lower when assessed via self-report than via collateral informants, because referrals are usually driven by the collateral perspective. The lack of initial insight and lower self-rated severity at baseline limit the room for improvement during therapy, ensuring that self-report will look like a relatively insensitive method for quantifying outcomes. Studies gathering both youth and parent report on the same measures have confirmed this expectation (Youngstrom, Cooperberg, et al., 2003).

Other Collateral Informants

Although there is a broad spectrum of possible informants about psychosocial functioning in youth, including siblings, peers, and teachers, among others, relatively little has been done to date in terms of collecting outcome data.

Outcome Benchmarks

“Social validation” provides an important set of methods for demonstrating meaningful clinical improvement (Kazdin, 1977). This involves confirming with parents, teachers, peers, or other significant individuals in the youth’s life that they see observable improvement in the symptoms or functioning. Social validation also emphasizes the use of ecologically valid indicators of functioning. For PBD, these indicators might include improved school attendance, better grades, fewer disciplinary incidents, increases in the number of friends, or similar social, educational, or vocational gains.

A complementary system for measuring clinically significant change developed by Jacobson, Roberts, Berns, and McGlinchey (1999; Jacobson & Truax, 1991) has gained popularity among research-oriented clinicians. This approach to clinical significance involves using a relevant psychometric measure, then showing (1) that the scores change enough for clinicians to be confident that an individual patient really is improving given the precision of the instrument, and (2) that the scores have moved past a benchmark compared to clinical and nonclinical score distributions. The advantages of this approach to clinical significance include its feasibility, its strong psychometric underpinnings, and its reliance on empirically defined benchmarks (Jacobson et al., 1999). It also clearly focuses on whether treatment is helping each individual patient rather than on the way that effect sizes describe the average outcome for an aggregate of cases. The big drawback to the Jacobson and colleagues approach is that it requires psychometric information that is typically not reported in technical manuals or articles. Specifically, determination of “reliable change” requires knowledge of the standard error of the difference score for the measure. With regard to the three benchmarks, setting the threshold for getting the patient away from the clinical distribution requires having norms for a clinical population, or at least a mean and standard deviation for a representative clinical sample. Similarly, it is only possible to determine whether a patient has moved back into the nonclinical range of functioning (defined here as scoring within two standard deviations of the nonclinical mean) by having nonclinical norms available. The third threshold, crossing closer to the nonclinical than to the clinical mean, requires information about both the

clinical and nonclinical distributions to calculate a weighted average.

To make it more practical for clinicians to apply the Jacobson and colleagues approach, Cooperberg (2001) meta-analyzed studies with relevant data on measures frequently used with PBD, generating pooled estimates of the mean and standard deviation for each measure in samples of youth with and without BD. The standard error of the difference was calculated with use of the standard error of the measure. Table 6.8 presents the standard error of the difference, allowing calculation of Jacobson's Reliable Change Index, but it also presents the number of change points needed to ensure 90 or 95% confidence (two-tailed) that the patient is improving. For most clinicians, the critical

scores are more useful, because they do not require computation. Table 6.8 also presents the benchmark values for moving away from the clinical distribution ("A"), back into the nonclinical range ("B"), or moving closer to the nonclinical than to the clinical average ("C").

In addition, Table 6.8 presents similar estimates for the CBCL and the Ohio Scales, based on the published standardization samples. These reference numbers are based on large and well-described samples. The "clinical" ranges for these measures are based on outpatient referrals, with or without a bipolar diagnosis, whereas the estimates for the mood-specific measures are based on an aggregate of multiple smaller samples with research diagnoses of mood disorder.

TABLE 6.8. Clinically Significant Change Benchmarks with Common Instruments and Mood Rating Scales

^a A, away from the clinical range; B, back into the nonclinical range; C, closer to the nonclinical than to the clinical mean.

Adherence

Nonadherence to treatment is a major issue when working with BD in children and adolescents, as well as adults. Patients frequently refuse to take medications, or they take them inconsistently due to attitudes about illness and treatment, concern about the side effects of the medications, or a lack of understanding about the recurrent nature of the illness. Consistent attendance at therapy appointments is also a difficulty, with the chaotic family environment often creating obstacles to compliance. It is crucial that practitioners monitor adherence to treatment recommendations. Psychoeducation about the nature of PBD, the potential benefits of medication and other treatment components, as well as potential side effects to monitor, has been demonstrated to improve adherence substantially, thus improving overall outcomes as well (Fristad, Gavazzi, et al., 2003; Fristad, Goldberg Arnold, & Gavazzi, 2003).

Quality of Life and Positive Aspects of Functioning

There is growing recognition that treatment should attend to improving quality of life and positive aspects of functioning versus focusing solely on symptom reduction. With children and adolescents, it is important to promote social and educational development, in addition to ameliorating problem behaviors. If a formal measure of quality of life is desired, then the two best-validated instruments currently available appear to be the KINDL (Ravens-Sieberer & Bullinger, 1998) and the Pediatric Quality of Life Scale (Varni, Seid, & Rode, 1999) based on a recent review (Harding, 2001). Whether or not a formal quality-of-life measure is used, clinicians should assess peer relationships, family functioning, and academic performance. Bipolar illness tends to have a detrimental effect on all of these areas of functioning, and interventions that address these deficits have a tremendous impact on both reducing the burden and improving the prognosis.

Differential Treatment Planning and Treatment Utility

Several factors deserve comment relative to how assessment may contribute to treatment planning. First, the distinction between unipo-

lar and bipolar depression is important to make. Although the symptoms and presenting complaints of bipolar depression may appear similar to unipolar depression, the treatment response can be quite different. Antidepressant medications may be overactivating in BD, triggering mania or possibly increasing suicide risk (Carlson, 2003; Geller et al., 1993; Kowatch, Fristad, et al., 2005). Similarly, cognitive or social activation strategies need to be qualified to avoid the risk of not only lifting the person's depression but also triggering a mania episode (Newman et al., 2002). Besides avoiding unintended harmful effects, recognition of bipolar depression also suggests positive strategies that may be effective, including improved sleep hygiene and avoidance of self-medication of symptoms (Danielson et al., 2004).

Repeated assessment of mood and energy, whether by brief "checkups" at the beginning of each session, repetitions of a brief mood checklist, or via the life-charting method, is a powerful tool to discern whether there is an ebb and flow suggestive of a mood disorder or a more chronic condition. Once the case conceptualization includes a mood disorder, these repeated assessments become a valuable means of monitoring progress and identifying "triggers" that can worsen mood and functioning. Although there are many generic triggers, such as stress or sleep disruption, others will be more subtle or unique to the individual. These assessments are also valuable in learning the signs that indicate potential "roughening" or relapse (Sachs, 2004).

Clinicians also need to be alert to the frequent lack of insight into behavior, and the frequent differences in perspective, between the parent and the youth in bipolar illness. Many youth are not self-referred for treatment, and if their behaviors are driven by manic or mixed states, then they may perceive the problem as being other people's, not their own. What appears to be irritable mood to observers seems more like parents and teachers are "hassling," "nagging," or otherwise provoking the youth. Sometimes it may be possible to increase insight, but this is more often accomplished after the mood states are stabilized.

A final issue to consider in case formulation revolves around the "classic," or episodic, versus "chronic" presentation. Although this is not currently recognized as a formal distinction in DSM-IV-TR or ICD-10, the episodic versus

chronic distinction is becoming a recurrent theme in the literature, both in youth and in adults. Youth with a more episodic presentation may have a better response to lithium and higher likelihood of a good prognosis (Ghaemi et al., 2002). Youth with the more chronic presentation, which may account for a large portion of youth diagnosed as “bipolar,” show a poorer response to lithium, more comorbidity, and equal or higher levels of impairment. It is unclear whether this presentation is on the bipolar spectrum, or whether it represents a distinct syndrome. Most people with this presentation appear to continue to show chronic mood lability, suggesting that this might be the juvenile presentation of BPD (see Shiner, Chapter 17, this volume) in at least some cases. Interestingly, there is debate about whether BPD itself might be on the bipolar spectrum, representing the extreme of mood cycling or instability (MacKinnon & Pies, 2006). Besides indicating changes in pharmacotherapeutic approach, the episodic–chronic distinction may prove important for psychotherapy as well, perhaps suggesting that techniques drawn from dialectical behavioral therapy (Linehan, 1993) might be helpful in addressing the affective instability in the more chronic presentation.

OTHER ISSUES IN CASE FORMULATION

Developmental Factors

Developmental factors influence the assessment process in important ways. The younger the individual, the more conservative practitioners should be about applying a diagnosis of BD. On the one hand, genetic and environmental risk factors promoting development of BD may have been present since before birth, so it would be an error to assume dogmatically that BD cannot occur until after onset of puberty, and the hormonal cascade involved in puberty itself may be starting at unexpectedly young ages in some cases. However, the evidence also points to BD being more rare prepubertally, and other conditions that are much more common in children may also account for mood lability. Normal development involves testing of limits, tantrums, and some aggression, and all these may interact powerfully with the family environment and parenting to produce coercive cycles of aggressive behavior (McMahon & Frick, 2005; Patterson, DeBaryshe, & Ramsey, 1989). Additionally, many

other childhood disorders, including anxiety disorders, pervasive developmental disorders, and unipolar depression, frequently have irritable mood and poor frustration tolerance as part of their presentation. The behavioral genetics literature sometimes described potential “phenocopies,” or processes that produce a similar looking set of behaviors, but for different etiological reasons. These potential “phenocopies” may be more common than “true” PBD in most clinical settings.

Comorbidity is another challenge in case formulation. It is not parsimonious to diagnose a child with both anxiety and explosive, irritable mood as having both disorders, unless it can be shown that the two appear at separate times in at least some of the person’s life (APA, 2000). Nor is it prudent from a risk management perspective to start simultaneously medications for both “comorbid” conditions; instead, the assessment process should clarify which problems are “primary”—in the sense of producing the biggest therapeutic gains and reductions in burden—and concentrate on alleviating them first. “Comorbidity” in the initial presentation might provide some useful distinctions about treatment selection in the future, but at present it seems to be more of a marker of severity. From a case formulation perspective, “comorbidity” may also provide a shorthand for a list of topics to revisit later in treatment, to “mop up” whatever has not resolved along with treatment of the primary problems.

Developmental stage changes the sources of information available for the assessment process, and also perhaps the weight that should be assigned to different perspectives. Younger children are able to fill out self-report questionnaires, and older youth may have difficulty depending on reading level. Youngsters also are less psychologically minded and often have difficulty both tolerating formal, semistructured diagnostic interviews and providing meaningful responses. Because referrals are usually driven by parental concerns, youth are frequently less motivated to cooperate in the interview. For all of these reasons, some groups and clinicians have not always interviewed youth under 12 years of age (e.g., Wozniak et al., 1995). Others have argued strongly that it is crucial to interview directly even young children, because they often provide different answers than their parents (Tillman et al., 2004). At a minimum, it seems like good practice to meet with children to understand their con-

cerns, to assess their motivation for treatment, and also to make behavioral observations that can (1) corroborate or disconfirm parent report about mood and energy, (2) provide a sense of whether deficits in cognitive ability, a pervasive developmental disorder, or some other medical factor might be contributing to the mood dysregulation, and (3) gather some initial information about how the child responds interpersonally.

With adolescents, parent reports still remain valuable, but self-reports become more viable. Clinicians need to be sensitive to different mechanisms that might underlie apparent disagreements, including low insight and motivation contributing to adolescent underreporting or parent stress leading to overreporting. With adolescents, more thorough assessment of substance use should be a prominent feature of case formulation, and it should be revisited over the course of treatment, because mood disorders are linked to greatly increased risk of alcohol and drug use. Discussions about sexual activity may also be necessary; the impulsivity and fluctuating self-esteem associated with mood disorder contribute to risk of pregnancy, sexually transmitted infection, and poorer choices of partners.

Ethical and Legal Issues

The assessment and treatment of PBD raises multiple ethical and legal issues, three of which are especially salient:

1. Who is responsible for seeking and accepting treatment?
2. How do we proceed when a parent report does not appear to agree with other sources of information?
3. How do we ethically treat a potentially lethal condition that is difficult to recognize, in the absence of clear data about the long-term risks and benefits of different interventions? Does it make sense to try to treat prodromal BD?

First, the issue of responsibility for seeking and adhering to treatment is particularly complicated in PBD. In addition to the routine complexity of working with child patients in the legal custody of a parent or other caregiver (who ultimately is responsible for seeking and approving of treatment), BD often compromises patients' insight into their behavior. Fur-

thermore, many symptoms of mania are not distressing to the patient, whereas they are annoying or threatening to people around the patient. Hypomania and mania often feel pleasant, or at least not pathological, to the affected individual, yet these mood states can cause considerable social disruption. Behavior that feels "spontaneous" and "alive" to the youth can be perceived as obnoxious or threatening by others. The consequence is that youth with mania usually do not recognize their own mood disturbance, and instead project the blame for interpersonal conflict onto others. This lessens their motivation to participate in therapy, and it raises ethical concerns about continuing to treat them even when they are actively opposed to therapy. It also challenges conventional definitions of "impairment" emphasizing that the symptoms are causing distress (Wakefield, 1997).

Cross-informant agreement raises a second, related set of issues. Clinicians are often unimpressed by the level of agreement between parents and other informants. Given the heritable nature of BD, affected youth run a high risk of having affected parents as well. Clinicians are justifiably concerned about the possibility that a parent's own mood state might bias his or her description of the child's behavior. This undoubtedly occurs. However, countervailing trends need to be considered as well. As described earlier, these include the tendency for lack of insight to undermine the validity of self-report for mania, and the fact that most teacher-rated instruments do not include mania scales. Clinicians also need to bear in mind that most referrals are initiated by a parent, which means that the parent will on average be the most concerned party ("regression to the mean" produced by selecting cases based on one informant that is imperfectly correlated with other informants) (Campbell & Kenny, 1999). Many legitimate cases of PBD are referred by parents who themselves experience epochs of substantial mood disturbance. Clinicians need to balance recognition that adult mood can influence ratings of child behavior and the fact that parent report appears to be one of the most valid indicators of PBD, even when the adult also is affected by mood disorder (Youngstrom, Findling, & Calabrese, 2004).

Finally, there is the issue of how early in the course of illness to treat BD. Arguments for early intervention include the potential for

better treatment response, possible neuroprotective effects that could lessen or avert the physiological and cognitive changes evident in recurrent illness, reduced risk of relapse, and the hope of better long-term functioning and quality of life (Chang, Steiner, et al., 2003). These potential benefits need to be weighed against the risks associated with early treatment, including the unknown long-term effects of medication, as well as the stigma of labeling people as having a mental illness and how this affects their relationships. Attempting to identify and treat BD at its earliest stages increases the challenge to differentiate between pathological mood states and typical functioning. Implicitly, arguments for early intervention lower the “treatment threshold” by accepting milder and fuzzier presentations as reasonable treatment targets. The case for prevention or early intervention is strengthened if there are low-cost or low-risk strategies that might help, such as changes in diet. Without more research about preventive techniques, as well as the long-term effects of more acute treatments, the best strategy might be “watchful waiting,” with at-risk families documenting the emotional and behavioral functioning of children periodically as they grow up. With younger children, disruptive and aggressive behavior may demand treatment, but neither a PBD label nor pharmacological interventions should be used lightly.

CONCLUSION

BD in adolescence and childhood remains a controversial topic. Practitioners should be agnostic about the possibility of diagnosing it. Agnosticism implies being somewhat skeptical but open to the possibility, and looking for convincing data. Families are not well served by misdiagnosis in either direction.

Assessment of BD presents numerous challenges, such as a fluctuating presentation, complicated diagnostic criteria, and high rates of comorbidity. The hurdles to accurate recognition only grow higher with younger cases. At the same time, rapid progress has been made in demonstrating the validity of the diagnosis, understanding the associated burden, and learning about the prognosis over at least 4 years of follow-up. The field has also made gains in the number and quality of assessment tools avail-

able for diagnosis and for measuring progress and outcomes with children and adolescents.

The assessment model I have advocated in this chapter is heavily influenced by the recommendations of evidence-based medicine (Guyatt & Rennie, 2002; Sackett et al., 2000) and represents a different perspective than traditional approaches to psychological assessment. The information about the relative performance of tests and the clinical features associated with BD is valuable regardless of whether practitioners adopt other, more novel procedures, such as using the nomogram for estimating risk. There also are clear take-home messages, including some that counteract conventional wisdom about assessment, such as the importance of involving a parent or other familiar adult in the assessment of manic symptoms, compared to the relatively lower validity of self- or teacher-report. However, employing the rest of the evidence-based methods I have described here will help to make the best use of the assessment tools available, and to strike the balance between being open to the possibility of PBD yet avoiding overdiagnosis of a rare yet popularized condition.

Adolescent Suicidal and Nonsuicidal Self-Harm Behaviors and Risk

David B. Goldston
Jill S. Compton

Suicidal and nonsuicidal self-harm behaviors are a serious public health problem among youth in the United States. Suicide is the third leading cause of death among 10- to 24-year-olds after accidents and homicide and accounts for a greater number of deaths than the next three leading causes of death (cancer, heart disease, congenital anomalies) combined within this age group (Centers for Disease Control and Prevention [CDC], 2006). Suicide also often leaves a traumatic toll on survivors (Jordan & McMenamy, 2004). In addition, about 1 in 12 high school students may be expected to attempt suicide yearly (Grunbaum et al., 2004). These nonlethal attempts result in a large proportion of adolescent psychiatric emergencies (Peterson, Zhang, Santa Lucia, King, & Lewis, 1996) and represent a significant burden on the health care system. Attempts are obviously associated with not only risk of physical injury, but also greater risk of repeat nonlethal suicidal behavior and eventual death by suicide (Goldston et al., 1999; Joiner et al., 2005; Leon, Friedman, Sweeney, Brown, & Mann, 1989; Lonqvist & Ostamo, 1991). Although suicide deaths are often thought to be a permanent solution to the transient problems faced in youth, with proper identification and treatment, suicide should be preventable.

Nonetheless, despite increasing knowledge about the prevalence, course, and risk factors for suicidal behaviors, clinicians' ability to predict precisely who (on an individual level) is at risk for suicide, and when they are at risk, often is limited. Careful assessment of suicidal and nonsuicidal self-harm behaviors and risk can help clinicians better recognize and minimize the chances of future self-harm behaviors, and evaluate efforts to prevent or reduce suicidal behaviors.

Nonsuicidal self-harm behavior may be differentiated from suicidal behavior in that the former is not associated with intent to die. Nonsuicidal self-harm behavior, such as self-mutilation, has also become increasingly prevalent in adolescent populations (Laye-Gindhu & Schonert-Reichl, 2005). Nonsuicidal self-harm behavior is especially concerning in school settings, where such behavior sometimes occurs among groups of peers. Teachers and counselors recognize increased rates of these behaviors but often are ill-equipped to deal effectively with self-harming youth. There also appears to be an overlap between nonsuicidal self-harming behavior and suicidal behavior in adolescents (Laye-Gindhu & Schonert-Reichl, 2005). We hope that better assessment of nonsuicidal self-harm behavior and its func-

tions (Nock & Prinstein, 2004, 2005) can improve our efforts at understanding the processes that are associated with and maintain this behavior, and ultimately help in prevention and treatment efforts.

PREVALENCE OF SUICIDAL AND NONSUICIDAL SELF-HARM

Prevalence estimates for suicide deaths across the lifespan, but especially in younger age groups, may be conservative given the likelihood that suicide deaths may be misclassified as accidental or undetermined causes of death (Mohler & Earls, 2001). The misclassification bias notwithstanding, the developmental trends in suicide rates are clear. Suicide deaths are very rare prior to age 15, increase between age 15 and 19, and are still more prevalent in young adulthood (CDC, 2007). For the year 2003, reported prevalence rates for suicide deaths in the United States were 1.3 per 100,000 for 10- to 14-year-olds, 8.2 per 100,000 for 15- to 19-year-olds, and 12.5 per 100,000 for 20- to 24-year-olds. Although the overall rates of youth suicide have decreased since 1995, contemporary rates of suicide among 15- to 24-year-olds continue to be considerably higher than estimates reported in the 1950s (National Center for Health Statistics [NCHS], 2002). Reports show that suicide among adolescents and young adults ages 15–24 declined substantially from 1995 to 2004 for young men (from 22.0 to 16.8 per 100,000) but not for young women (from 3.7 to 3.6 per 100,000) (CDC, 2006; NCHS, 2002). These trends for reduced suicide deaths among males have been viewed with cautious optimism, because the factors associated with decreasing suicide rates are not well understood. Hypotheses discussed in the literature include better recognition and treatment of depression in youth (especially in light of increased use of antidepressants, such as selective serotonin reuptake inhibitors), co-occurring decreases in substance use among younger cohorts, proportionately reduced use of firearms in suicide attempts, and a favorable socioeconomic climate in the United States during the period in question (Berman, 2003; Shaffer, Pfeffer, & the Workgroup on Quality Issues, 2001).

Prevalence rates of suicidal ideation, suicide attempts, and nonsuicidal self-harm vary as a function of assessment method (e.g., anonymous self-report questionnaires vs. face-to-face

psychiatric diagnostic interviews) and operational definitions of the terms (Meehan, Lamb, Saltzman, & O'Carroll, 1992). Nonetheless, it appears that suicide attempts are relatively uncommon before puberty, with rates of less than 1% for 5- to 11-year-olds (Lewinsohn, Rohde, Seeley, & Baldwin, 2001). Rates of suicide attempts increase rapidly with the onset of puberty, however. Anonymous self-report data from adolescents, collected as part of the Youth Risk Behavior Survey (YRBS) by the CDC, indicate that 8.4% of high school students in the United States endorsed having attempted suicide in the previous year, 2.3% reported making an attempt that required medical attention, 13.0% reported having made a specific plan to attempt suicide, and 16.9% reported seriously considering a suicide attempt in the same time frame (CDC, 2006).

Prevalence studies of nonsuicidal self-harm behavior among adolescents in the community are rare, and estimates vary considerably. For example, results from two studies with large representative samples of adolescents indicated nonsuicidal self-harm rates of 5.1 and 6.9% (Patton et al., 1997; Rodham, Hawton, & Evans, 2004). However, even these estimates are much lower than those in a recently published report showing that 15% of adolescents in a school-based sample of over 400 students reported engaging in self-harm behavior (Laye-Gindhu & Schonert-Reichl, 2005). Other research studies with slightly older samples of college undergraduates have yielded findings consistent with these higher figures and report prevalence estimates of 14 to 38% of students engaging in self-harm behavior (Favazza, 1992; Gratz, Conrad, & Roemer, 2002).

Adolescent and young adult males are more likely than females to die by suicide, whereas adolescent and young adult females report higher rates of nonsuicidal self-harm. According to data for the year 2004, there were 1.8 male suicide deaths for every female suicide death among children 10–14 years old, 3.6 male deaths for every female death in 15- to 19-year-olds, and 5.8 suicide deaths among males for every suicide death among females ages 20 to 24 (CDC, 2007). Moreover, the increase in suicide deaths among young people from the 1950s through the 1990s was also primarily attributable to increases in suicides among males. Specifically, the rate of suicide among 15- to 24-year-old males was 6.5/100,000 in 1950 and 18.4/100,000 in 1998 (NCHS, 2002). By contrast, the rate for fe-

males in the same age range was 2.6/100,000 in 1950 and 3.3/100,000 in 1998 (NCHS, 2002).

Gender differences emerge in the opposite direction when nonfatal suicide attempts and nonsuicidal self-harm behavior are examined among adolescents and young adults. In a longitudinal study of a community sample, Lewinsohn and colleagues (2001) found few gender differences in suicide attempters before age 12, but from age 12 through late adolescence, girls were more likely than boys to attempt suicide for the first time. At young adulthood, gender differences in incidence of suicide attempts dissipated, although females still tended to have higher rates than males (Lewinsohn et al., 2001). Higher rates of attempts among females also were found among high school students taking the YRBS (CDC, 2006) and in epidemiological studies with adults (Weissman et al., 1999). In a similar manner, data from a large study of high school students in Canada indicated that adolescent girls reported more nonsuicidal self-harm behavior than did adolescent boys (Laye-Gindu & Schonert-Reichl, 2005). Gender differences in adolescents' nonsuicidal self-harm behavior appear to be especially evident in clinical samples (Nixon, Cloutier, & Aggarwal, 2002).

Prevalence rates also differ among different ethnic and racial groups; such differences are presumed to reflect differences in culture and the socioenvironmental context of these behaviors (Goldston, Molock, et al., under review). For the years 1999 to 2004, the highest rates of suicide deaths for 10- to 24-year-olds were found among American Indian and Alaska Natives (19.3 and 5.5 per 100,000, for males and females, respectively; CDC, 2007). Among males, the lowest rate was found among Asian American and Pacific Islanders (6.5/100,000; CDC, 2007). Among females, the lowest rates were found among African Americans and Latinas (1.4 and 1.7 per 100,000, respectively; CDC, 2007).

Among nonlethal self-harm behaviors, YRBS data indicate that the highest rates of suicide attempts among females occur among American Indians, and Latinas (yearly rates of 21.8%¹ and 14.9%, respectively—Crosby, personal communication, January 2005; CDC, 2006). The highest rates of attempts for males were found for American Indians (13.9%;

Crosby, personal communication, January 2005). No comparable data regarding ethnic differences in nonsuicidal self-harm behavior were available.

METHODS AND MOTIVES OF SELF-HARM BEHAVIORS

The primary methods used for suicide for 10- to 24-year-olds in 2004 were firearms (47.0%), hanging or suffocation (37.4%), poisoning or overdose (8.2%), and falls or jumping (2.4%; CDC, 2007). Since 1990, there has been an increase in the proportion of suicides by hanging or suffocation (from 19.6%) and a decrease in the proportion of suicides by firearms (from 64.5%) among young people (CDC, 2007). Males accounted for 82% of the suicide deaths among people ages 10–24 in 2003, and compared to their female counterparts, used more firearms (51.3 vs. 27.4%) and less poisoning (6.1 vs. 18.0%; CDC, 2007).

Although the most common methods for attempting nonlethal suicide are ingestion and cutting, more than half of male adolescents' suicide attempts are by alternative means, such as guns, hanging, and other methods (Brent, 1987; Lewinsohn, Rohde, & Seeley, 1996; Spirito, Stark, Fristad, Hart, & Owens-Stively, 1987). By definition, suicide attempts are associated with at least some desire to die, but suicidal behavior often is associated with ambivalence and mixed motives. For many, suicide represents a way to get relief from difficult emotional states, to escape problems, to get back at others, or to make others feel sorry for their behavior (Boergers, Spirito, & Donaldson, 1998; Hawton, Cole, O'Grady, & Osborn, 1982; Kienhorst, DeWilde, Diekstra, & Wolters, 1995).

The most common method of nonsuicidal self-harm behavior is cutting with a sharp implement; other forms include burning, hitting, pinching, scratching, and biting (Ross & Heath, 2002). Teenagers engage in self-harm behavior for a variety of reasons: to cope with difficult feelings (e.g., depression and anxiety); to relieve unbearable tension, express frustration or anger, get revenge; to feel physical pain when other pain is unbearable; to distract attention away from unpleasant memories; to punish oneself, stop suicidal ideation, or avoid a suicide attempt; to stop feeling alone and empty; to gain control; and to stop feeling "numbed out" (Nixon et al., 2002). Additional

¹ Data for Native Americans were collected by the Bureau of Indian Affairs only for youth attending boarding schools.

findings suggest that nonsuicidal self-harm behavior among adolescents is typically an impulsive rather than well-planned act, and often occurs among adolescents whose friends engage in similar behavior patterns (Nock & Prinstein, 2005).

CO-OCCURRENCE WITH PSYCHIATRIC DISORDERS

Although there are rare instances in which suicide deaths occur without concurrent psychopathology, suicidal and nonsuicidal self-harm behaviors are thought to be so closely related to psychiatric illness that such behaviors are incorporated into the diagnostic criteria as symptoms of illness themselves (Brent, Perper, Moritz, & Allman, 1993). DSM-IV-TR (American Psychiatric Association [APA], 2000) criteria for major depressive disorder (MDD), for example, include recurring thoughts of death; suicidal ideation, with or without a plan; and suicide attempts as possible symptoms. Both suicidal and nonsuicidal self-harm behaviors are among the criteria accepted for borderline personality disorder (BPD; although the validity of diagnosing personality disorders in adolescents has been questioned; see Shiner, Chapter 17, this volume, for a discussion of personality disorders in adolescents). Despite the fact that suicidal and nonsuicidal self-harm behaviors often occur in the midst of mental health or substance use disorders, it is important to note that most adolescents with psychiatric disorders do not engage in suicidal or nonsuicidal self-harm behaviors.

Depressive and Anxiety Disorders

Studies in which the parents of adolescents who died by suicide (i.e., psychological autopsy studies) are interviewed have identified psychiatric disorders, especially depressive disorders, as primary risk factors for suicide (Shaffer, Gould, et al., 1996). These findings are consistent with data from longitudinal research with community-dwelling 9- to 16-year-olds in which depression with comorbid anxiety disorders or comorbid disruptive behavior disorders is strongly associated with suicidal thoughts and behavior (Foley, Goldston, Costello, & Angold, 2006). Similarly, in a longitudinal study of formerly psychiatrically hospitalized adolescents, Goldston, Daniel, and colleagues (under review) found that MDD and general-

ized anxiety disorder (GAD) are strongly related to suicide attempts, and that this relationship strengthens as individuals get older. When viewed prospectively, MDD is the psychiatric disorder that was most strongly predictive of repeat suicidal behaviors among hospitalized adolescents (Goldston et al., 1999). Finally, studies indicate that suicide risk is greater for adolescents with longer durations of illness (Brent, Kolko, Allan, & Brown, 1990) and shorter time to relapse compared to nonsuicidal adolescents (Lewinsohn, Clarke, Seeley, & Rhode, 1993).

Depression also appears to be related to nonsuicidal self-harm behaviors among adolescents (Garrison, Addy, McKeown, & Cuffe, 1993), and many teenagers report engaging in self-harm behaviors specifically to cope with their depression (Nixon et al., 2002). Adolescents with a history of both suicidal and nonsuicidal self-harm behavior have more depression than peers who have attempted suicide but have never engaged in nonsuicidal self-harm behavior (Guertin, Lloyd-Richardson, Spirito, Donaldson, & Boergers, 2001).

Substance Use Disorders

Among formerly psychiatrically hospitalized adolescents followed into young adulthood, the likelihood of suicide attempts was greater during episodes of substance use disorders, and the relationship between suicide attempts and substance use disorders strengthened as adolescents got older (Goldston, Daniel, et al., under review). Nonetheless, the relationship between substance abuse and suicidal self-harm behavior is complicated. The literature supports the notion that this relationship varies depending on age of onset, progression, severity or frequency, and level of substance use impairment, and that serious substance abuse is more likely to be associated with suicidal behavior (Goldston, 2004). For example, Esposito and Clum (2002) found that among high-risk youth in the schools, suicidal thoughts were related to the more severe drug and alcohol dependence disorders, but not significantly related to drug and alcohol abuse disorders. In addition, the relationship between substance abuse and suicidality is found more consistently in youth with more serious suicidal behaviors (Esposito-Smythers & Spirito, 2004; Goldston, 2004). For instance, Gould and colleagues (1998) found that suicide attempts, but not suicidal

ideation, were associated with substance use disorders in an epidemiological sample. Both substance abuse and suicidal behaviors are associated with significant psychiatric comorbidity (e.g., Armstrong & Costello, 2002), prompting researchers to consider whether an independent relationship exists between adolescent self-harm behavior and substance abuse in the presence of co-occurring disorders such as depression (e.g., Esposito & Clum, 2002; Gould et al., 1998). In a case-control study, Brent and colleagues (1993) found that substance use disorders without mood disorders increased the risk of suicide three-fold, but in the presence of depression, the risk of suicide increased 17-fold.

The relationship between substance abuse and nonsuicidal self-harm behavior is less well studied. In a recent study, self-harm behavior among adolescents was most commonly an impulsive act that did not include the use of alcohol or drugs (Nock & Prinstein, 2005).

Disruptive Behavior Disorders

Disruptive behavior disorders also have been found to be associated with suicidal behaviors. For example, in a psychological autopsy case-control study, Shaffer, Gould, and colleagues (1996) found that disruptive behavior disorders were present among 50% of the adolescents who died by suicide. For adolescent males, but not females, the rates of conduct and oppositional disorders were greater than those observed in matched control subjects. However, disruptive behavior disorders were often comorbid with other disorders and did not appear to be independently related to suicide among adolescent males after the researchers controlled for the presence of past attempts and other diagnoses, such as mood and substance use disorders. In another psychological autopsy study, Brent and colleagues (1988) found no significant difference in the rates of disruptive behavior disorders of adolescent suicide victims and hospitalized suicidal adolescents. However, the adolescents who died by suicide did have higher rates of affective disorders with nonaffective comorbidity, including conduct disorder. In a review of the literature, James, Lai, and Dahl (2004) found that attention-deficit/hyperactivity disorder (ADHD) appeared to be modestly related to increased rates of suicide, especially among young males; this relationship appeared to be partially attrib-

utable to commonly associated comorbid conditions, including mood and conduct disorders.

In terms of nonlethal suicidal behavior, Goldston, Daniel, and colleagues (1999; under review) found that ADHD and conduct disorder were proximal risk factors for suicide attempts, but disruptive behavior disorders by themselves were not predictive of subsequent suicide attempts among formerly hospitalized adolescents. In addition, in a community sample, Gould and colleagues (1998) found that oppositional defiant disorder and conduct disorder were more common among youth who reported suicidal thoughts or attempts than among nonsuicidal adolescents. In another community study, Foley and colleagues (2006) found that disruptive behavior disorders were proximally related to suicidal thoughts and behaviors but primarily associated with risk when comorbid with depressive disorders.

In a follow-up study, Barkley and Fischer (2005) found that young adults diagnosed as hyperactive during childhood were more likely than comparison young adults to have considered suicide, to have made a suicide attempt, to have been hospitalized for suicidal behavior during their high school years, and to have considered suicide as an option after high school. Among the "grownup" hyperactive children, Barkley and Fischer found that the increased risk for suicide attempts was associated with lifetime histories of MDD, conduct disorder, and greater severity of ADHD.

RISK AND PROTECTIVE FACTORS

Aside from psychiatric and substance use disorders, a number of other factors have been found to be associated with risk for suicidal and nonsuicidal self-harm behaviors. Most of the research regarding risk and protective factors has been cross-sectional in nature. Although informative about associations with self-harm behavior, these studies do not necessarily shed light on the degree to which these factors are associated with risk for subsequent self-harm. Given the low base rate of suicide even among those at high risk, it is difficult to predict suicide accurately as an outcome. Moreover, risk and protective factors may differ in different risk or population groups because of different base rates of self-harm and risk factors. Risk and protective factors also may differ over time, or over the course of de-

velopment, though research on these possibilities has been limited. Research on risk and protective factors also has often not differentiated between factors associated with short- and long-term risk for suicidal behavior (Hawton, 1987).

Both suicidal and nonsuicidal self-harm behaviors often occur in the context of immediate triggers or precipitants (proximal risk factors) and factors that may be associated with longer term risk (distal risk factors) (Moscicki, 1999). Although knowledge of proximal risk factors provides information about when individuals are at risk for suicidal or self-harm behavior, such knowledge does not necessarily provide information about who is at risk. Alternatively, distal risk factors may provide information about who is at risk for suicidal or nonsuicidal self-harm behavior, but not about when those individuals are at risk. In the following section, we review several groups of proximal and distal risk factors associated with suicidal and nonsuicidal self-harm behavior.

Previous Self-Harm Behavior

One obvious and pervasive concern for parents and providers of adolescents who engage in suicidal behavior is whether these acts will be repeated and ultimately lead to serious injury or death. Similar to other human behavior, a history of engaging in suicidal behavior is the best predictor of future suicide behavior, even after considering the effects of multiple risk factors (Joiner et al., 2005). Among adolescents, for instance, the number of prior suicide attempts has been found to be a strong predictor of future suicidal behavior (Goldston et al., 1999). Similarly, previous suicide attempts have been associated with significantly higher risk for repeated behavior among adults, with a suicide attempt increasing future risk by about 32% (Leon et al., 1989).

Some have argued that sensitization processes may account for increased risk associated with past suicidal behavior (Beck, 1996; Joiner, 2002). For example, previous experience with self-harm behavior may affect the capacity to participate in that behavior again in the future or sensitivity to cues associated with suicidal behavior. Alternatively, it is possible that the increased risk is associated with behavioral processes; for example, self-harm behavior may be associated with reinforcing consequences, such as reduction of painful affect,

that may increase the likelihood of its recurrence when in the presence of similar cues (Goldston, 2004; Goldston et al., 1999). Another possibility, which is not mutually exclusive, is that a subset of individuals is at risk for recurrent suicidal behaviors by virtue of historical, psychopathological, biological, environmental, or temperamental characteristics. Such individuals may simply be qualitatively different, or have different developmental trajectories, than individuals who engage in single attempts. In this regard, it is notable that outpatient children and adolescents with repeated suicide attempts had higher rates of sexual abuse, run-away behavior, and drug and alcohol use than first-time attempters (Mandell, Walrath, & Goldston, 2006; Walrath et al., 2001). In a similar manner, Esposito, Spirito, Boergers, and Donaldson (2003) found that adolescents presenting for emergency care after a repeat suicide attempt had more affective disorders, severe depressive symptoms, anger, disruptive behavior disorders, hopelessness, and self-mutilation than did adolescents with single attempts.

Although some researchers have noted that nonsuicidal self-harm behavior has addictive qualities (Nixon et al., 2002), the degree to which this behavior portends risk for future nonsuicidal self-harm or suicidal behaviors among adolescents has not been evaluated in prospective studies.

Impulsivity

Suicides among children and adolescents often are impulsive acts that correspond to recent stressors or crises (Hoberman & Garfinkel, 1988), and suicidal children have been found to have poorer impulse control than their nonsuicidal peers (Pfeffer, Hurt, Peskin, & Siefker, 1995). Impulsivity may be a relatively stable attribute of individuals, or it may reflect changes in cognitive or emotional states that result in a decreased ability to show restraint (Corruble, Damy, & Guelfi, 1999; Tice, Bratslavsky, & Baumeister, 2001; Weyrauch, Roy-Byrne, Katon, & Wilson, 2001). Nock and Prinstein (2005) have demonstrated that nonsuicidal self-mutilation among adolescents is typically an impulsive act. The degree to which impulsivity portends risk for future self-harm behavior is unclear.

Dougherty and colleagues (2004) have demonstrated that laboratory methods may be used

to quantify different facets of impulsivity and their relationship to suicidality. For example, stop tasks may be used to assess aspects of impulsivity related to the ability to inhibit ongoing behavior. These tasks reveal increased impulsivity among adolescents with suicidal ideation (Dougherty, Mathias, Marsh, Moeller, & Swann, 2004; Mathias, Dougherty, Carrizal, & Marsh, 2003) and repeated suicide attempts (Prevette, Mathias, Marsh, & Dougherty, 2005). Continuous performance tasks may be used to assess aspects of impulsivity related to the accurate initiation of behavior. Adult suicide attempters show increased impulsivity on this task (Dougherty, Mathias, Marsh, Papageorgiou, et al., 2004; Horesh, 2001). Finally, delay-discounting procedures may be used to assess the ability to tolerate delay for a larger reward. On these tasks, adolescents with suicidal thoughts evidence increased impulsivity (Mathias et al., 2003).

Hopelessness

Hopelessness is a sense of extreme pessimism about the future. In his eloquent writings on the phenomenology of suicide, Shneidman (1996) has suggested that hopelessness is the common cognitive state among individuals who engage in suicidal behaviors. Hopelessness typically is associated with a sense of futility about life, or a viewpoint that problems will never be solved, or that life circumstances will never change. The negative view of the future is also a central tenet of the cognitive model of depression (Beck, Rush, Shaw, & Emery, 1979). Hopelessness has been found to predict repeat suicide attempts among adolescents following psychiatric hospitalization (Goldston et al., 2001), and it also appears to be associated with suicide intent (Nock & Kazdin, 2002; Spirito, Sterling, Donaldson, & Arrigan, 1996). Nonetheless, some researchers question the degree to which hopelessness is associated with suicidal ideation or behavior after controlling for depression (Asarnow & Guthrie, 1989; Goldston et al., 2001; Nock & Kazdin, 2002).

Adolescent suicide attempters with a history of nonsuicidal self-mutilation have been noted to have more hopelessness than adolescent attempters without self-mutilation (Guertin et al., 2001). In addition, hopelessness has been found to be associated with the negative reinforcement function of nonsuicidal self-

mutilation (i.e., the degree to which such behavior is engaged in to relieve negative moods or affect) (Nock & Prinstein, 2005).

Reasons for Living

Clinicians working with suicidal patients often focus on helping patients recognize or develop new reasons for living. In one sense, it is intuitive that patients who have adequate reasons to continue living or have faith in their ability to cope generally do not take steps to end their lives. Indeed, there is evidence among previously hospitalized adolescents that individuals who endorse more reasons for living and, particularly, greater survival and coping beliefs, make fewer repeat suicide attempts over time (Goldston et al., 2001). Survival and coping beliefs also have been found to be negatively associated with hopelessness, dysfunctional attitudes, and suicidal thoughts, as well as estimates of future suicidal behavior (Cole, 1989b; Goldston et al., 2001). Jobes and Mann (1999) have suggested that the balance between reasons for living and reasons for dying is an important consideration in understanding risk for suicidality.

Problem-Solving Ability

Shneidman (1996) stated, "The common purpose of suicide is to seek a solution. Suicide is not a random act. It is never done without purpose. It is a way out of a problem, a dilemma, a bind, a difficulty, a crisis, an unbearable situation" (p. 130). This observation underscores the importance of problem-solving ability in the understanding of suicide and suicide risk. Shneidman also described the common perceptual state associated with suicide to be one of constriction, in which suicidal individuals often see suicide as their only option and are unable to identify other alternatives to this course of action. It is unclear whether the problem-solving deficits commonly observed among suicidal individuals are transient (state-like) or more stable over time (trait-like; Schotte, Cools, & Payvar, 1990). In addition, problem-solving difficulties may also be associated with hopelessness. For example, in the World Health Organization European (WHO/EURO) multicenter study on suicidal behavior, it was noted that passive-avoidant problem solving, characterized by "taking a gloomy view of the situation," a feeling of being "unable to do any-

thing,” and “the tendency to resign oneself to the situation,” was associated with repetitive instances of self-harm behavior (McAuliffe et al., 2006). In a review of adolescent studies, Speckens and Hawton (2005) noted that in many studies, suicidal adolescents have more social problem-solving deficits than do nonsuicidal adolescents, but many of these differences appear to be accounted for (mediated) by depression and hopelessness.

Childhood Sexual Abuse

Childhood sexual abuse is a well-documented risk factor for many negative short- and long-term outcomes, and suicidal ideation and behavior are not exceptions. For example, in one study, adolescents and young adults who made medically serious suicide attempts were 6.5 times more likely to have histories of sexual abuse than case-control subjects in the community (Beautrais, Joyce, & Mulder, 1996). In a study of hospitalized youth, physical (non-sexual) and sexual abuse were associated with a higher number of past suicide attempts (Shaunese, Cohen, Plummer, & Berman, 1993). In the National Comorbidity Study (NCS) sexual abuse was associated with histories of suicide attempts, even after considering other risk factors (Molnar, Berkman, & Buka, 2001). Moreover, concordance between parent and child in suicide attempts has been found to be more likely in the presence of parent and child sexual abuse (Brent et al., 2002).

There also is strong evidence of a relationship between childhood sexual abuse and nonsuicidal self-harm behavior (Briere & Gil, 1998; Santa Mina & Gallop, 1998; Zlotnick et al., 1996). In a study of adults, van der Kolk, Perry, and Herman (1991) found that earlier histories of trauma were associated with more cutting behavior. In a review focusing on self-injury among adults, Gratz (2003) suggested that there is much stronger evidence for an independent relationship between nonsuicidal self-harm behaviors and sexual abuse than for other forms of abuse.

Sexual Orientation

Young people who identify as gay, lesbian, or bisexual (GLB) appear to be at increased risk for suicidal behavior compared to heterosexual youth. Data from the YRBS indicated that GLB adolescents, or those unsure of their sexual ori-

entation, were more likely than heterosexual youth to attempt suicide (Garofalo, Wolf, Wissow, Woods, & Goodman, 1999). Similarly, data from the National Longitudinal Study of Adolescent Health indicated that homosexual adolescents were at higher risk for suicidality, although this risk may have been mediated by common risk factors such as depression and hopelessness (Russell & Joyner, 2001). In a recent study, D’Augelli and colleagues (2005) found that in a sample of GLB adolescents, over half of the suicide attempts were related to sexual orientation. Factors associated with higher likelihood of attempts included parental psychological abuse, being considered gender-atypical in childhood by parents, and parental efforts to discourage GLB behaviors. Suicide attempts also were related to sexual victimization and loss of friends due to sexual orientation, and tended to occur after recognition of homosexual feelings but before disclosure to parents (D’Augelli, Hershberger, & Pilkington, 2001; Hershberger, Pilkington, & D’Augelli, 1997). Nonetheless, in one psychological autopsy study, adolescents who died by suicide did not appear to have increased minority sexual orientation (Shaffer, Fisher, Parides, & Gould, 1995), although it could be simply the case that informants were unaware of victims’ sexual orientation or feelings.

Accessibility to Firearms

Presence of firearms in the home has been found to be more common among adolescents who die by suicide than by adolescents hospitalized for suicidality (Brent et al., 1988). In a recent case-control study, Grossman and colleagues (2005) found that the practices of locking up guns and ammunition, and storing guns unloaded, separately from ammunition, were associated with reduced firearm injuries and suicide attempts among children and adolescents. Parents, however, are often reluctant to remove guns from the homes to protect suicidal youth, even after counseling in this regard (Brent, Baugher, Birmaher, Kolko, & Bridge, 2000).

Family Psychiatric History

Suicidal behavior tends to run in families. Relatives of individuals who have engaged in suicidal behavior or died by suicide are themselves

at higher risk for suicidal behavior (Brent, Bridge, Johnson, & Connolly, 1996), and there is greater concordance among monozygotic than among dizygotic twins for suicidal behavior (Roy & Segal, 2001; Roy, Segal, Centerwall, & Robinette, 1991). The children of adult suicide attempters are approximately six times more likely to engage in suicidal behavior than the children of adults who have not made suicide attempts (Brent et al., 2002). Although there is evidence that relatives of adolescents who have attempted or died by suicide have higher rates of psychiatric disorders than relatives of nonsuicidal adolescents (Wagner, 1997), the rates of family psychiatric disorders are comparable to those for similar-age peers in treatment settings. In contrast to what is known about familial risk of suicidal behavior, little research has documented associations between nonsuicidal self-harm behaviors and family psychiatric history.

Life Stress

Clearly, life stress is an obvious and overarching proximal risk factor for suicide. One study found that the great majority (80%) of adolescents who attempted suicide had experienced a major life stress in the prior 3 months (Heikkinen, Aro, & Lonnqvist, 1994). These findings have been replicated by research showing increased rates of stressful life events among adolescents and young adults in the 3 months prior to death by suicide, and more specifically, in the week prior to death (Cooper, Appleby, & Amos, 2002). Life events associated with increased risk for suicidal behaviors often include interpersonal difficulties, conflicts, or losses, and environmental consequences such as disciplinary action or legal problems (Adams, Overholser, & Spirito, 1994; Beautrais, Joyce, & Mulder, 1997; Gould, Fisher, Parides, Flory, & Shaffer, 1996). Some adolescents, however, do not report precipitants for their suicidal behavior (Beautrais et al., 1997), and the occurrence of life events may be related to young people's poor problem-solving skills or psychiatric difficulties.

The relationship between stressful life events and nonsuicidal self-harm behavior is less well documented. Garrison and colleagues (1993) found that nonsuicidal self-harm behaviors are also significantly correlated with the presence of undesirable life events. In clinical settings,

interpersonal precipitants often appear to be associated with nonsuicidal self-harm behaviors.

Social Support

Shneidman (1996) has stated, "Suffering is half pain and half being alone with that pain. For some people, suicide is feeling entirely alone" (p. 119). In this regard, among high-risk adolescents in school, suicidal youth were found to have lower perceived social support from families, teachers, or friends than their nonsuicidal peers (Esposito & Clum, 2003). In particular, suicide attempters in one study were more likely than nonattempters to report that they would not go to a family member for assistance (O'Donnell, Stueve, Wardlaw, & O'Donnell, 2003). The relationship between social support and suicidality may differ by gender. For instance, peer support tends to increase as youth get older, and girls report more peer support than do boys. However, among girls in a hospitalized sample, perceived family support was related to hopelessness, depression, and suicidal thoughts, whereas among boys, peer support was most strongly related to depression and suicidal thoughts (Keer, Preuss, & King, 2006).

FUNCTIONAL IMPAIRMENT AND OUTCOMES

Suicidal adolescents evidence functional impairment in a variety of areas. For example, as assessed with the Child and Adolescent Functional Assessment Scale (CAFAS; Hodges & Wong, 1996), youth suicide attempters in outpatient settings showed greater impairment than their peers in home and school role performance, behavior toward others, and moods and emotions (Mandell et al., 2006). Repeat suicide attempters had the most impairment in moods and emotions, behavior toward others, and thinking.

Six months after entering treatment, suicidal youth continued to have difficulties in a number of areas of functioning (Mandell et al., 2006). For example, repeat suicide attempters were at higher risk than other youth for continuing to have problems in thinking and in behavior toward others, and first-time suicide attempters were at risk for continuing impairment in the home and substance use problems 6 months later. Repeat suicide attempters also

were at increased risk for developing severe functional impairment in the areas of behavior toward others, moods and emotions, and self-harm. First-time attempters were primarily at risk for greater impairment in the area of self-harm 6 months later.

These varied areas of impairment dovetail with results from a review by Spirito, Boergers, and Donaldson (2002), indicating that youth often continue to have relational problems, difficulties with parents, and substance abuse, behavioral, and school problems following suicidal behavior. With particular reference to school impairment, youth who died by suicide were noted to have more school suspensions and failing grades than comparison youth in the community (Gould et al., 1996). Moreover, Daniel and colleagues (2006) found that suicidal ideation and attempts were related to reading disabilities and eventual dropout from school. In contrast to suicidal behavior, little is known about the various areas of impairment or of the prognosis for adolescents with non-suicidal self-harm behaviors.

Summary

In this section, we have reviewed many factors associated with suicidal ideation and self-harm behavior among youth, including psychiatric factors (e.g., depressive disorders), cognitive factors (e.g., problem-solving ability, hopelessness), temperament (e.g., impulsivity), familial factors (e.g., family history of suicidal behavior), historical factors (e.g., history of suicide attempts, history of abuse), and facets of the environment (e.g., stressful life events, accessibility of firearms). We also have reviewed factors that may protect youth against suicidal behavior, such as perceived reasons for living. The large number of potential risk and protective factors may be daunting for clinicians working with multiproblem youth and trying to gauge or monitor both immediate and long-term risk. The large number of risk factors is partially a reflection of the current state of research in this area; most studies have focused on univariate relationships between risk or protective factors and self-harm behaviors. This univariate view of risk factors underscores that there are likely many interventions that prevent suicide and nonsuicidal self-harm behavior, but this approach provides limited information about which factor(s) are most important, for whom, and in what context. The factors often overlap; it is possible that some

may simply be correlates of others (e.g., hopelessness may be an indicator of depression), and some combinations of risk factors may be particularly important in portending later risk, or may portend risk for some, but not all, youth. Integrative models of risk and multivariate models regarding the evolution of risk over time are needed to help guide clinical practice, to help identify the most robust risk factors for particular individuals, and to guide assessment with more precision. In studies that have taken a multivariate approach, some of the strongest risk factors for future suicidal behavior across samples include diagnosis of depression (Goldston et al., 1999; Lewinsohn, Rohde, & Seeley, 1994) and past suicide attempts (Goldston et al., 1999; Joiner et al., 2005; Lewinsohn et al., 1994). Past suicidal behavior may also interact with other risk factors in contributing to risk. For example, in a clinically ascertained sample, Goldston and colleagues (1999, 2001) found that risk factors such as hopelessness and diagnosis of depression are more highly predictive of repeat than of first-time suicide attempts. As we describe in the next section, there are multiple approaches to assessment, and factors to be assessed depend in part on the intended purpose of an assessment.

PURPOSES OF ASSESSMENT OF SELF-HARM BEHAVIOR AND RISK

There are several purposes for assessing suicidal and nonsuicidal self-harm and risk, but the end goal is always the prevention of future suicidality and self-harm behavior. The first goal in suicide assessment is to identify imminent risk for self-harm behavior. Assessment of imminent risk helps to facilitate adequate monitoring and clinical intervention to diffuse crises and ensure immediate safety. Many suicidal crises are short-lived (Simon et al., 2001); hence, the importance of taking steps to diffuse such crises and ensure safety in the short run cannot be underestimated.

A second purpose of assessment is to predict future self-harm behaviors. Several approaches have been developed for estimating risk of future self-harm behavior. Unfortunately, however, despite cross-sectional correlations with histories of self-harm behaviors, it is still not clear that most assessments of "risk" actually predict (in a temporal or longitudinal sense) future self-harm behaviors. The prediction of

self-harm behavior is an important part of many suicide prevention and treatment efforts with at-risk populations.

A third purpose of assessment related to suicidality and self-harm is that of treatment planning. In this regard, it is important to understand the functional context in which self-harm behavior occurs, including the precipitants or triggers for the behavior, the associated vulnerability and protective factors, the nature of the self-harm behavior itself, and the intrapersonal and environmental consequences of self-harm behavior. Functional analyses of suicidal and nonsuicidal self-harm behavior provide very useful information about possible targets for intervention. It is also important to identify whether the self-harm behavior occurs in the context of a psychiatric or substance use disorder, and to examine whether functional commonalities exist among self-harm and other problem behaviors, so that one can develop integrated treatment approaches. Furthermore, in recognition of the broader cultural context of self-harm behavior, it is important to assess the cultural nuances related to the specific precipitants, vulnerability and protective factors, expression, and consequences of suicidal and nonsuicidal self-harm behaviors for any given patient.

The last purpose of self-harm assessment is treatment monitoring. Ongoing assessment of suicidal and nonsuicidal self-harm ideation and behavior, and of risk and protective factors, provides information about the effectiveness of current interventions. Pharmacotherapy with antidepressant medications, for example, has been linked to small increases (about 2%) in self-harm adverse events for some youth (U.S. Food and Drug Administration [FDA], 2004; Treatment of Adolescent Depression Study [TADS] Team, 2004). Hence, it is particularly important to monitor self-harm behavior continuously when medications have been prescribed for emotional or behavioral problems.

USING A COMMON LANGUAGE

Professionals dealing with suicidal and nonsuicidal self-harm behavior have often used varied and inconsistent language to refer to key terms. As a result, it has been difficult for clinicians to compare findings across studies or even to communicate effectively (e.g., Garrison, Jackson, Addy, McKeown, & Waller, 1991; Goldston, 2003; Lewinsohn, Garrison,

Langhinrichsen, & Marsteller, 1989). For example, many studies in the literature have focused only on suicidal behavior associated with medical consequences (e.g., Beautrais, 2003). Nonetheless, in the college sample of Meehan and colleagues (1992), 10% of students stated that they had attempted suicide sometime in their life, 5% said that they had experienced illness or injury because of a suicide attempt, and 3% stated that they had received medical attention because of suicidal behavior. Hence, studies that focus exclusively on suicidal behavior resulting in serious medical consequences may be very informative in their own right, but they may not adequately characterize the entire population of individuals engaging in suicidal behaviors. Additionally, most studies examining the predictive validity of clinical characteristics of suicidal behavior among adolescents have not found factors such as stated intent to be predictive of future suicidal behavior (Spirito, Lewander, Levy, Kurkjian, & Fritz, 1994).

In an article likening inconsistencies in the use of terms to describe suicidal behaviors to a “Tower of Babel,” O’Carroll, Berman, Maris, and Moscicki (1996) summarized the findings of a workshop whose task it was to provide recommendations about the ways suicidal terms are operationally defined. In this recommended nomenclature, *suicide* was defined as “death from injury, poisoning or suffocation where there is evidence (either explicit or implicit) that the injury was self-inflicted and that the decedent intended to kill himself/herself” (pp. 246–247). A *suicide attempt* was operationally defined as “a potentially self-injurious behavior with a non-fatal outcome, for which there is evidence (either explicit or implicit) that the person intended at some (non-zero) level to kill himself/herself. A suicide attempt may or may not result in injuries” (O’Carroll et al., 1996, p. 247). The phrase “some (non-zero) level to kill himself/herself” is an implicit acknowledgment of the ambivalence that accompanies much suicidal behavior (Shneidman, 1996). *Suicidal ideation* was defined as “any self-reported thoughts of engaging in suicide-related behavior” (O’Carroll et al., 1996, p. 247).

Beyond this recommended nomenclature, several self-harm behaviors may be difficult to classify or characterize (Goldston, 2004). For example, adolescents sometimes make “aborted suicide attempts.” The term “aborted suicide attempts” refers to occasions in which

adolescents make preparations for suicide but decide not to follow through with their intentions (Barber, Marzuk, Leon, & Portera, 1998). For example, an adolescent may start to make an attempt by putting a noose around his neck and preparing to jump, but then at the last minute, decide that he is scared, or that the problem is not worth dying over. As described by Barber and colleagues (1998), "The essential characteristics of an aborted attempt are 1) intent to kill oneself, 2) a change of mind immediately before the actual attempt, and 3) absence of injury" (p. 385). Among adults, aborted suicide attempts appear to be more common among patients who have histories of actual suicide attempts than among patients without such histories (Barber et al., 1998).

Another example of suicidal behavior that does not fall neatly into the nomenclature of O'Carroll and colleagues (1996) is the "interrupted suicide attempt." In contrast to aborted suicide attempts, interrupted suicide attempts occur when an individual starts to attempt suicide, but the attempt is interrupted or prevented by others, or by external circumstances (Steer, Beck, Garrison, & Lester, 1988). For example, a suicidal adolescent may be getting ready to attempt suicide by holding a knife against her wrist, when a parent or friend arrives and takes the knife away. As noted previously (Goldston, 2004), interrupted suicide attempts may be particularly common among adolescents who still live in their parents' homes, where their suicide attempts have a high likelihood of being discovered. In adult patient samples, individuals whose suicide attempts have been interrupted are at increased risk for eventually dying by suicide compared to patients whose suicide attempts were not interrupted (Steer et al., 1988). It is not clear why individuals whose attempts are discovered should be at higher risk, but it may be that clinicians do not consider their behaviors to be as serious as those of individuals whose attempts are uninterrupted (Steer et al., 1988).

Passive suicide attempts represent another form of suicidal behavior. In passive suicidal behavior, adolescents may not take adequate precautions to save themselves when their lives are in danger, or necessary steps to prevent their demise. Adolescents with diabetes, for example, sometimes are persistently noncompliant with their medical regimen, despite health consequences. Although not all lack of adherence to the medical regimen is associated with

suicidality, Goldston, Kovacs, Ho, Parrone, and Stiffler (1994; Goldston et al., 1997) have noted an association between serious noncompliance and suicidal ideation and attempts.

Other suicidal youth may try to provoke peers, adversaries, or authorities to inflict harm upon them. Such behaviors, first described by Wolfgang (1959), are referred to as "victim-precipitated homicide." In contemporary society, such provocations may occur in the context of gang-related activity in urban areas or involve provocations of law enforcement officials. Such behaviors may be more common among groups in which suicide is associated with stigma.

Often confused with suicidal behaviors are nonsuicidal self-harm behaviors. There may be some similarities in the motives for nonsuicidal and suicidal self-harm behaviors, and certainly some youth engage in both forms of self-harm behaviors (Boergers et al., 1998; Nixon et al., 2002). Nonetheless, nonsuicidal self-harm behavior is not meant to end one's life. There have been suggestions, particularly by researchers studying adult clinical samples, that suicidal and nonsuicidal self-harm behaviors may sometimes be difficult to distinguish or classify (Isometsa & Lonnqvist, 1999). However, in most cases, nonsuicidal and suicidal self-harm behavior can be distinguished by asking respondents whether "any part of them" wanted to die when they engaged in this behavior.

WEIGHING DIFFERENT SOURCES OF INFORMATION

Given that suicidal behaviors are prevalent among adolescents and associated with a number of psychiatric disorders, it is important to inquire about the history of suicidal behavior, even when suicidal behavior is not the immediate referring problem. Likewise, in schools and other settings in which "gatekeepers" such as schoolteachers, coaches, or clergy may have contact with distressed youth, it is important for there to be recognition of the problem of suicide among young people. Gatekeepers who work with youth need to be comfortable asking about suicidality if they suspect that an individual is either considering or may already have attempted suicide. Direct inquiry (interviewing) is an appropriate method for asking about history of suicidal thoughts and behavior, and is the most commonly used approach. None-

theless, it is striking that even trained mental health professionals are sometimes reluctant to ask a youth about suicidality. Professionals may not ask direct questions because of their own anxiety and apprehension about what they might need to do should they find out that someone is suicidal. Clinicians may also fear that by asking about suicide, they communicate an idea that the young person has not already had and may now consider and act upon. As a recent study pointed out, however, presenting suicidal adolescents with screening questions about suicidality does not increase rates of suicidal ideation or distress (Gould et al., 2005). In fact, the most vulnerable adolescents actually experienced some diminution in level of distress after being asked suicide-related questions (Gould et al., 2005). Moreover, as Fremouw, Perczel, and Ellis (1990) have pointed out, suicidal thoughts and behavior are common among individuals who are depressed, and queries about suicidality may communicate that clinicians recognize and understand the experience. Clinicians may actually run a greater risk when they do not ask about suicidal thoughts and behavior, because this omission may inadvertently reinforce adolescents' sense of alienation or the perception that no one really understands their experience.

For inquiries about suicidal behavior, adolescents should generally be relied upon more heavily than their parents or other adult informants. Suicidal behaviors, and certainly suicidal thoughts, are often not discussed with others, and several studies have found that youth tend to report suicidal behaviors that their parents know nothing about (Breton, Tousignant, Bergeron, & Berthiaume, 2002; Foley et al., 2006; Klimes-Dougan, 1998; Velez & Cohen, 1988; Walker, Moreau, & Weissman, 1990). For example, in a community survey, parents only correctly identified 6 of 59 adolescents who had reported suicidal thoughts, and 2 of the 36 adolescents who had attempted suicide (Breton et al., 2002). Similarly, in the Great Smoky Mountains epidemiological study (Foley et al., 2006), 69% of reports of suicidality consisted of positive reports by youths and negative reports by adults. It is sometimes the case that parents "miss" or misinterpret their child's suicidal behaviors either by not taking these behaviors seriously, believing that suicidal behaviors (or threats) are merely intended for instrumental purposes (e.g., to avoid punishment), failing to believe

that their child would want to kill him- or herself, or by simply being unaware of the behaviors (Goldston, 2003). Parental inaccuracies in perception of suicidal behavior also may be related to a lack of understanding of the fact that much adolescent suicidal behavior is associated with ambivalence and mixed motives. For example, it may be the case that adolescents simultaneously "want their way" in an argument with parents, want to avoid discipline, and also want to die because they feel so miserable.

Occasionally, reports of suicidality may not accurately reflect the level of distress experienced by an adolescent (Goldston, 2003). For example, an adolescent may deny feeling suicidal (and minimize other signs of distress) in an emergency room setting to avoid uncomfortable feelings or being hospitalized. Therefore, it is important for clinicians to consider alternative data sources, in addition to verbal reports, when evaluating suicide risk, particularly in an emergency setting. Similarly, adolescents may deny suicidality because they wish to be secretive about their intent or may desire to avoid unwanted attention or embarrassment. Thus, rapport with adolescents is especially important in eliciting accurate reports of suicidal behavior.

In contrast, sometimes there are occasions in which adolescents overreport suicidality. Communication of high suicide intent when it does not accurately reflect the feelings experienced by the adolescent may be associated with his or her desire to "mend" relationships (e.g., avoid breaking up), to be hospitalized, or to be taken out of a home environment that is experienced as intolerable (Goldston, 2003). Nonetheless, as pointed out by Goldston, Daniel, and Arnold (2006), "Child and adolescent report is certainly very important, but it should never preempt the judgment of a clinician. Clinicians should always err on the side of caution in making judgments about the risk of suicidal behavior; conversely, clinicians should be extraordinarily careful to not be dismissive of adolescent self-reports of suicidal ideation or behavior" (pp. 360–361).

STRATEGIES FOR ELICITING INFORMATION ABOUT SELF-HARM IN INTERVIEW

Shea (1999) has described several useful interviewing techniques that elicit information

about suicidality. For example, individuals sometimes deny having a history of suicidality at first, but report suicidal behavior when asked follow-up questions about specific methods. In one example with adults, Barber, Marzuk, Leon, and Portera (2001) asked psychiatric inpatients about their past suicidal behavior, including aborted suicide attempts. When following up with the same patients after the initial assessment, Barber and colleagues found that 44% of adults who previously denied a history of aborted suicide attempts eventually reported such an attempt in response to specific queries.

In this regard, it also is very important to ask for concrete information or examples of suicidal behavior. For example, if a patient reports that he or she has attempted suicide “three or four times” in the past, it is useful to elicit as much information as possible about each suicide attempt, including approximate date, the method used, and the precipitants and consequences. This provides contextual information about the patterns of suicidal behavior that the clinician can use for treatment planning and understanding the current episode of suicidal behavior.

Normalization is another interviewing technique that is sometimes useful in the interview with suicidal patients (Shea, 1999). Although suicidality is often thought of as a difficult subject to discuss, framing questions about self-harm behavior in ways that minimize shame or embarrassment may help to “normalize” the topic. For example, the clinician may ask about suicidal behavior by prefacing the inquiry with a statement, such as “A lot of times when people are very upset, depressed, or feeling hopeless, they will think about wanting to attempt suicide. In the last week, how often have you had thoughts like that?”

Other useful techniques that elicit information about self-harm behavior include the gentle assumption and the amplification assumption (Shea, 1999). With the gentle assumption, the clinician implicitly makes an assumption that the patient has either thought about self-harm or has engaged in self-harm behavior (rather than asking the individual “whether” he or she has thought about or engaged in self-harm). For example, rather than asking a depressed adolescent, “Have you ever thought about suicide?”, the clinician might ask, “When was the last time that you thought about killing yourself?” Similarly, rather than

asking an adolescent whether he or she has made a suicide attempt in the past, the clinician might ask how many suicide attempts he or she has made.

Using the amplification assumption, the clinician may try to make the adolescent feel more comfortable reporting self-harm behavior by assuming a degree of self-harm behavior that probably exceeds what the adolescent has experienced. For example, in assessing non-suicidal self-harm, rather than asking the adolescent how often he or she cuts him- or herself, the clinician might ask, “In the last week, how many days have you cut on yourself at least five separate times?” Most self-harming adolescents do not engage in self-harm behavior at this frequency, so they may then feel more comfortable reporting rates that more closely resemble the actual frequency of their self-harm.

ASSESSMENT OF IMMINENT SUICIDALITY

One of the most important clinician tasks is to evaluate whether a patient is at imminent risk for suicidal behavior. Youth are generally considered to be at imminent risk when they state that they intend to kill themselves, feel that they can no longer keep themselves safe, or unable to say that they will refrain from attempting suicide, or cannot agree to a collaboratively developed safety plan.

Alternatively, the same conclusion may be reached by a clinician who thinks that despite what the adolescent says, his or her past behavior, history, and the nature of the current crisis suggest that the individual is at extraordinarily high risk of attempting suicide in the near future. When someone is thought to be at imminent risk for suicide, the clinician should first take immediate therapeutic steps to reduce this risk. However, if such efforts are not successful, the clinician may recommend hospitalization or another form of treatment that provides the monitoring necessary to ensure safety and prevent suicidal behavior.

Safety Plans as a Form of Assessment

Clinicians sometimes use various forms of no-suicide contracts in the hope that these will reduce immediate risk of self-harm behavior. Such contracts typically entail an explicit verbal or written statement that patients will not attempt to harm themselves within a specified

period of time, or will tell someone if they feel that they cannot keep themselves safe. In theory, no-suicide contracts may have several advantages, including the fact that they represent a collaboration for safety between patient and clinician, encourage the patient to take responsibility for his or her own safety, entail a formal commitment not to engage in self-harm, and emphasize the clinician's concern about the patient's safety (Lee & Bartlett, 2005; Range et al., 2002). Nonetheless, the therapeutic value of no-suicide contracts has not been established. In fact, in the state of Minnesota, a "no-harm contract" was in place in almost every completed suicide occurring in an acute care facility" (Office of the Ombudsman for Mental Health and Mental Retardation, State of Minnesota, 2002). In addition, questions have been raised about whether no-suicide contracts may discourage patients from talking about suicidality, and encourage clinicians to become less vigilant in ongoing risk monitoring (Lee & Bartlett, 2005; Range et al., 2002). For these reasons, it is recommended that patients and therapists develop a collaborative safety plan in lieu of written or formal contracts. A safety plan differs from a no-suicide contract in that it outlines the steps agreed upon to ensure the safety of the patient in a suicidal crisis.

It is instructive that no-suicide contracts were originally developed as a method to assess suicide risk (Drye, Goulding, & Goulding, 1973). To the extent that patients cannot collaboratively develop a plan for safety and agree to refrain from efforts to kill themselves, they are by definition at imminent risk for suicidal behavior. Hence, regardless of whether clinicians use formal no-suicide contracts or develop safety plans, the fact that patients can or cannot agree to such terms provides important information about whether they are able to keep themselves safe.

Tasks for Assessing Imminent Suicidality

Bradley and Rotheram-Borus (1990) outlined five specific tasks (typically taking 20–30 minutes) to evaluate imminent danger of suicide among adolescents. The first task of the imminent danger assessment is to ascertain whether the adolescent is able to make positive statements about him- or herself; that is, adolescents should be able to recognize at least three positive attributes about themselves, their world, or at least about their interactions with

their therapist. Because most suicidal individuals tend to be entrenched in a negative and hopeless style of thinking, this task helps the clinician to evaluate the degree to which adolescents are in this negative mindset.

The second task in the assessment of imminent risk is to assess adolescents' capacity to assess their own feelings. In this regard, Rotheram (1987) suggests using a "feelings thermometer," wherein the adolescent can rate his or her feelings on a 0- to 100-point scale. The adolescent should be able to label both comfortable and uncomfortable feelings, and, specifically, should be able to label situations in which he or she has felt suicidal. To the degree that adolescents are able to recognize how they feel when they are becoming suicidal, they presumably will be better able to tell someone or take appropriate precautions to avoid acting on suicidal thoughts.

The third task used by Rotheram (1987) to assess current risk for suicide is to observe whether the adolescent is able to develop plans for coping with situations that have previously been (or might potentially be) associated with suicidal thoughts and feelings. This task is particularly useful in an emergency setting in which adolescents may state that they are no longer suicidal to avoid hospitalization or to stop further talk about the incident in front of family members. In their immediate desire to escape the situation, many adolescents may say that they are no longer suicidal, without having developed viable plans for dealing effectively with the situations that precipitated their suicidal behavior.

The fourth important task in the imminent danger assessment is the identification of three support individuals (Bradley & Rotheram-Borus, 1990). In this task, adolescents should be able to identify at least three individuals they can contact or speak with in the event that they are feeling suicidal or cannot keep themselves safe. The identification of support individuals is not only an assessment in and of itself (e.g., it is informative when individuals have so little perceived support that they cannot name three support people), but it also helps in the development of the therapeutic safety plan.

The fifth task in the evaluation of imminent danger is, of course, the solicitation of an agreement from the adolescent not to kill him- or herself, and an agreement to tell someone if he or she feels unable to stay safe. Rotheram (1987) suggests that "failure to perform these tasks is a behavioral indication of imminent

danger; coping skills to ward off suicidal tendencies are not available” (p. 108).

Although these tasks are extremely useful in assessing risk, the clinician should consider other factors as well in evaluating whether someone is at imminent risk of self-harm. These factors include the youth’s history, in particular, his or her history of suicidal behavior and adherence to safety agreements (e.g., reliability in letting others know when he or she feels suicidal), as well as parental history and capability of monitoring the adolescent and maintaining a safe environment in the home (e.g., making sure the adolescent does not have access to firearms when he or she is acutely suicidal). The final judgment of the clinician in assessing imminent danger to self should be made on the basis of all available information.

STANDARDIZED INSTRUMENTS FOR ASSESSING SELF-HARM BEHAVIORS AND RISK

There are a variety of instruments to screen and assess for suicidal or self-harm behavior among youths. Nonetheless, Prinstein, Nock, Spirito, and Grapentine (2001) have demonstrated that the agreement between different assessment instruments, methods, and sources of information in the assessment of suicidality is not always good. Hence, it behooves the clinician or researcher to obtain information from multiple sources, or to use multiple methods, basing final determination of clinical status on all available information.

One advantage to the use of standardized instruments is that they might help offset the unreliability of clinician judgment. For example, in a review of psychiatric assessments in an emergency setting, Way, Allen, Mumpower, Stewart, and Banks (1998) found that judgments about whether patients represented a “danger to themselves” were only modestly consistent among different clinicians (intraclass correlation coefficient = .44). Use of standardized instruments also may aid in the identification of suicidality that might otherwise not be detected (Malone, Szanto, Corbitt, & Mann, 1995). For example, hospital records of an adult sample indicated that clinicians failed to identify or document 12 of 50 instances in which patients were found to be depressed and to have histories of suicide attempts according to research assessments (Malone et al., 1995).

In considering instruments for assessing suicidality and risk among young people, Goldston (2003) recommended that four sets of question be asked. First, what is the level of precision in the definitions of suicidality? For example, are questions about suicidal thoughts separate from questions about thoughts of wanting to die or thoughts about death? Similarly, are there separate questions regarding suicidal and nonsuicidal self-harm behavior? Second, are items that assess whether the adolescent has engaged in suicidal behavior different or confounded by questions of degree of intent or the clinical characteristics of suicidal behavior? Instruments sometimes are designed to identify only suicidal behavior associated with “serious intent,” despite the fact that findings regarding the relationship between intent and lethality among youth have not been consistent (DeMaso, Ross, & Beardslee, 1994; Lewinsohn et al., 1996; Nasser & Overholser, 1999; Plutchik, van Praag, Picard, Conte, & Korn, 1989). Third, is it clear from the queries that suicidal behavior is associated with “non-zero” intent to kill oneself? In this regard, queries assessing suicidality are sometimes worded so broadly (e.g., “Have you ever tried to hurt or harm yourself?”) that they can elicit information about both suicidal and nonsuicidal self-harm. Finally, do questions about suicide attempt focus only on suicidal behavior that results in injury or requires medical attention? In the O’Carroll and colleagues (1996) recommended nomenclature, a suicide attempt by definition, does not have to result in injury; rather, it simply needs to be associated with the potential of injury. Restricting the focus to suicide attempts with injury excludes a subset of suicidal behavior, and the differences between suicide attempts that do and do not result in injury are not clear.

Detection Instruments

Detection instruments specifically assess current suicidality or self-harm behaviors, or one’s history of such behavior. Some detection instruments focus on the assessment of suicidal behavior or thoughts but not on nonsuicidal self-harm or vice versa. In addition, some instruments focus on a continuum of severity of suicidality, whereas others focus on the presence or absence of self-harm behaviors or thoughts. Among the instruments used for detecting self-harm behaviors or thoughts are

semistructured and structured psychiatric diagnostic instruments that have queries about self-harm, interviews developed specifically for assessing self-harm, self-report questionnaires or behavior checklists that include items assessing suicidality, or self-report questionnaires that focus solely on thoughts of self-harm or self-harm behaviors.

Although most psychiatric diagnostic interviews contain questions about suicidal ideation and attempts, two instruments in particular stand out because of the extent of their use and the amount of data available regarding their psychometric characteristics, the Schedule for Affective Disorders and Schizophrenia for School-Age Children—Epidemiological version (K-SADS-E) and the Diagnostic Interview Schedule for Children (DISC; see Goldston, 2003, for a comprehensive review of instruments for assessing suicidal behaviors and risk among children and adolescents).

The K-SADS-E (Orvaschel, 1994), a semistructured diagnostic interview for children and adolescents, provides interviewers the flexibility to clarify answers or ask questions beyond the required queries (Ambrosini, 2000). Interviewers for the K-SADS-E and other versions of the K-SADS are typically trained clinicians (Ambrosini, 2000). Because of the flexibility for additional questioning and clarification, and the use of clinicians as interviewers, the K-SADS-E can provide a systematic approach to assessment of psychiatric history in initial evaluations in clinical as well as research settings. The K-SADS-E typically takes between 2.5 and 3 hours to administer (Ambrosini, 2000) and has been used with youth in clinical (Brent et al., 1998), incarcerated (Rohde, Mace, & Seeley, 1997), and community (Lewinsohn et al., 1996) samples. The latest version of the K-SADS-E includes separate questions about recurrent thoughts of death, suicidal thoughts, suicide attempts, total number of past attempts, and nonsuicidal self-harm behavior. The query regarding suicide attempts (“Did you try to kill yourself?”) is straightforward and implies a non-zero intent to kill oneself, without any reference to a requirement that the behavior results in injury. The question about suicidal ideation (thoughts about hurting or killing oneself) is so general that it likely elicits reports of thoughts of both suicidal and nonsuicidal self-harm.

The items regarding current thoughts of death and suicidal ideation, and past suicide at-

tempt have high levels of interrater reliability (Lewinsohn, personal communication, September 1999). The suicidality items of the K-SADS-E have demonstrated concurrent validity, as reflected in associations with depression, poor coping skills, pessimism, and higher levels of suicidal ideation (Lewinsohn, Rohde, & Seeley, 1993; Rohde et al., 1997). In addition, these items have been found to be predictive of future suicidal behavior (Lewinsohn et al., 1994).

The DISC (Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000), a highly structured psychiatric diagnostic interview, has been used to evaluate suicidality in community- and school-based samples (Gould et al., 1998), clinical samples (Brent et al., 1986; Campbell, Milling, Laughlin, & Bush, 1993; King et al., 1997), and incarcerated samples (Kempton & Forehand, 1992) of youth. Although the structured format of the DISC makes possible its administration by individuals who do not necessarily have a clinical background, some training is required. The DISC takes approximately 1.5 to 2 hours for assessment of youth and approximately 1 hour for each informant (Shaffer et al., 2000).

The DISC has queries about thoughts of death, suicidal ideation, suicide plans, the association of suicidal thoughts with dysphoria, and lifetime number of suicide attempts. The DISC does not have queries about nonsuicidal self-harm behaviors, and the question asking the respondent whether he or she has “seriously” thought about suicide may yield conservative rates of suicidal thoughts. Although there is a separate question about suicide attempts requiring medical attention, the definition of “suicide attempts” is not confounded with a requisite degree of medical lethality or a requirement of injury. Moreover, the test-retest reliability of questions about suicide attempts is good to very good (Shaffer, personal communication, October 1999). In addition, DISC queries about suicidality have good concurrent validity, as evidenced by associations with “caseness” defined by cutoff scores on scales of suicidal ideation (King et al., 1997; Prinstein et al., 2001). Reports of current suicidal ideation and lifetime history of attempts were found to be related to subsequent suicidal behavior (Shaffer, personal communication, October 1999).

Interviews focused solely on assessment of suicidality or self-harm behaviors include the

Lifetime Parasuicide Count (LPC; Linehan & Comtois, 1997) and the Suicidal Behaviors Interview (SBI; Reynolds, 1989, 1990). The LPC was developed for adults and may be used to assess number of discrete episodes of both suicidal and nonsuicidal self-harm behaviors, although the instrument does not assess thoughts associated with self-harm. For most respondents, the LPC probably takes approximately 15 minutes or less (although administration time may vary with how well respondents remember the episodes and the number of self-harm episodes). Self-harm behaviors assessed with the LPC are classified as being associated with no intent to die (nonsuicidal self-harm), or with ambivalence and/or intent to die (both of the latter are considered to be suicide attempts). Relatively little psychometric information is available regarding the LPC, but it has been used in clinical settings, and adolescents with MDD, borderline personality disorder, and/or three or more Axis I psychiatric disorders were found to have more suicidal behaviors, as assessed with the LPC, than youth without these conditions (Velting & Miller, 1998).

The SBI, a 20-question semistructured interview, has been used with high-risk youth identified through screening evaluations in both school and clinical settings (Reynolds & Mazza, 1999). There are separate questions in the SBI about thoughts of wishing to be dead, thoughts of wanting to kill oneself, suicide attempts, and nonsuicidal self-harm behavior. The items regarding suicide attempts are consistent with the O'Carroll and colleagues (1996) nomenclature. The SBI has been found to have very high interrater reliability and internal consistency (Reynolds, 1990; Reynolds & Mazza, 1993), as well as considerable concurrent validity, as reflected in associations with number of past attempts, distress, and measures of depression (Champion, Carey, & Hodges, 1994; Reynolds, 1990; Reynolds & Mazza, 1999).

Depression questionnaires also often have items about suicidal thoughts that can be used as screens for the presence of suicidal ideation. For example, both the Beck Depression Inventory (BDI; Beck & Steer, 1987), which is appropriate for adolescents, and the Children's Depression Inventory (CDI), which is appropriate for children, have items assessing suicidal thoughts in the last 2 weeks. Both items assess severity of suicidal ideation, from no suicide

ideation to thoughts of wanting to kill oneself (with no intent to do so), to a desire to kill oneself, if given the chance. These scales have been used in both community and clinical settings (Ivarsson, Gillbert, Arvidsson, & Broberg, 2002; Joiner, Rudd, Rouleau, & Wagner, 2000; Overholser, Adams, Lehnert, & Brinkman, 1995; Steer, Kumar, Ranieri, & Beck, 1998). Overholser and colleagues (1995) developed items that can be appended to the copyrighted version of the CDI to assess for previous suicidal behavior as well. This is particularly important, because suicidal thoughts may wax and wane over time, but past history of suicide attempts is one of the best predictors of future suicidal behavior (Joiner et al., 2005).

Several questionnaires of note have been developed specifically to assess severity of suicidal ideation or suicidal behaviors. The 14-item Suicidal Behaviors Questionnaire (SBQ-14) was developed to assess suicidal thoughts and behavior in adults (Linehan, 1996). A very brief, four-item version of the SBQ, the Suicidal Behaviors Questionnaire for Children (SBQ-C), was developed for use with children (Cotton & Range, 1993). Questions from the SBQ have been used with student (Cole, 1989a, 1989b; Osman et al., 1998), incarcerated (Cole, 1989b), and clinically ascertained samples (Kashden, Fremouw, Callahan, & Franzen, 1993; Osman et al., 1996). The SBQ-C has been used with children from both community and clinical settings (Payne & Billie, 1996). The SBQ-14 includes questions about frequency and intensity of suicidal ideation, suicide threats, suicide attempts and nonsuicidal self-harm behavior, and expectations about suicidal behavior. However, the initial question about suicidal ideation treats suicidal thoughts and suicide attempts as a continuum; one of the choices on this rating scale ("I attempted to kill myself, but I do not think I really meant to die") may be confusing in that suicide attempts are by definition considered to be associated with some intent to die. Items from the SBQ-14 have been shown to have concurrent validity, as reflected in correlations with rated reasons for living, depression, hopelessness, and impulsivity scales (Cole, 1989a, 1989b; Kashden et al., 1993; Osman et al., 1996, 1998). The four SBQ-C items are very similar to the items in the SBQ-14 that are used to assess suicidal thoughts and attempts, frequency of suicidal thoughts, telling others about suicidal thoughts, and expect-

tations of suicide. However, the SBQ-C also includes the aforementioned potentially confusing query (from the SBQ-14) about suicide attempts without intent to die. The SBQ-C has been found to be internally consistent and scores on the SBQ-C have been found to be associated with depression and hopelessness scores (Payne & Billie, 1996).

The Beck Scale for Suicide Ideation (BSS; Beck & Steer, 1991), a questionnaire based on the interview-format Scale for Suicide Ideation (Beck, Kovacs, & Weissman, 1979), is one of the most widely used measures of suicidal ideation and includes items assessing passive suicidal ideation (when respondents state that they do not think they would take steps to save themselves if in harm's way). The scale also has one item assessing history of attempts. The BSS has been found to be internally consistent in clinical samples of adolescents (Kumar & Steer, 1995; Steer, Kumar, & Beck, 1993), but it is not clear whether it has been used with community samples. Severity scores on the BSS are predictably related to constructs such as depression, hopelessness, and another measure of suicidal thoughts (Kumar & Steer, 1995; Reinecke, DuBois, & Schultz, 2001; Steer et al., 1993).

The Suicidal Ideation Questionnaire (SIQ) was developed for use with high school youth, and the Suicidal Ideation Questionnaire—Junior (SIQ-JR), for use with junior high school (grades 7, 8, and 9) youth (Reynolds, 1988). Both scales assess a continuum of severity of thoughts of death to active suicidal ideation. Cutoffs on these scales denote clinically suicidal thoughts. One limitation of the scales when used as stand-alone screeners is that they do not include any items assessing suicidal or nonsuicidal self-harm behaviors. These reliable, highly internally consistent scales have been used in multiple clinical and nonclinical (primarily school) settings (Dick, Beals, Manson, & Bechtold, 1994; Hewitt, Newton, Flet, & Callander, 1997; Pinto, Whisman, & McCoy, 1997; Reynolds, 1988; Reynolds & Mazza, 1999). The scales have been well validated, as exemplified by correlations with depression, hopelessness, reasons for living, suicide attempts, and scores on other suicidality measures (Hewitt et al., 1997; King, Raskin, Gdowski, Butkus, & Opiari, 1990; Mazza, 2000; Pinto & Whisman, 1996; Pinto, Whisman, & Conwell, 1998; Reinecke et al., 2001; Reynolds, 1988). SIQ-JR scores also

have been found to predict later suicide attempts (King et al., 1995).

The Functional Assessment of Self-Harm (FASM; Lloyd, Kelley, & Hope, 1997) is a self-report instrument used to assess types and frequency of self-harm behavior (e.g., cutting and carving on oneself, pulling hair, biting self, “erasing skin,” picking at wound, hitting self on purpose) during the past year. Questions on this instrument assess whether the self-harm behaviors are nonsuicidal or suicidal in nature, whether the respondent was using alcohol or drugs while engaging in self-harm, whether the self-harm was impulsive, and age of first self-harm. For treatment planning purposes, the scale additionally includes questions about the different anticipated functions of the self-harm behavior. The FASM has been used both with clinical and nonclinical samples of adolescents, and its scales have adequate internal consistency (Guertin et al., 2001; Lloyd et al., 1997; Nock & Prinstein, 2004, 2005).

Assessment in Prediction of Suicidality

Assessment of risk for future suicidality is also an important task for the practicing clinician. Risk assessment instruments are developed primarily to assess risk of future suicidality or to screen for individuals who may be at risk for suicidality. Despite the availability of a number of risk assessment instruments to assist clinicians in assessing risk, it is notable that many clinicians who work with suicidal clients do not routinely incorporate assessment instruments into their practice (Jobs, Eyman, & Yufit, 1995). Perhaps the most important function of a risk assessment instrument is the degree to which it is actually predictive of later suicidal behavior (i.e., has established predictive validity; Goldston, 2003). Many available risk assessment instruments have been shown to have only cross-sectional, rather than predictive, associations with suicidal behaviors. Nonetheless, not every factor associated with suicidal thoughts or behavior at a single point in time is related to later suicidal behavior.

Risk assessment instruments include several self-report questionnaires. Some of these focus on specific constructs associated with vulnerability and protective factors for suicidal behavior, whereas others include combinations of different risk and protective factors. With regard to self-report questionnaires, some of the most promising instruments focus on the as-

assessment of cognitive states associated with suicidality. For example, the Beck Hopelessness Scale (BHS; Beck & Steer, 1988; Beck, Weissman, Lester, & Trexler, 1974; Steer & Beck, 1988), which was developed for adults, has also been used with adolescents in school and clinical settings for the assessment of pessimism or hopeless attitudes about the future (Brent et al., 1997, 1998; Goldston et al., 2001; Osman et al., 1998; Rotheram-Borus & Trautman, 1988). The BHS has been found to be internally consistent in samples of clinically ascertained suicidal adolescents (Steer et al., 1993), and to have a wealth of concurrent validity, as reflected in associations with assessments of depression, fewer reasons for living, and history of suicide attempts (Goldston et al., 2001; Osman et al., 1998; Reinecke et al., 2001). Most importantly, among outpatient adults, the BHS has been found to predict later suicide over a 20-year period of time (Brown, Beck, Steer, & Grisham, 2000), and in formerly hospitalized adolescents and adults in clinical settings, higher BHS scores have been found to predict repeat suicide attempts (Brittlebank et al., 1990; Goldston et al., 2001; Scott, House, Yates, & Harrington, 1997). Higher BHS scores also have been found to be associated with earlier discontinuation of treatment for depression among adolescents (Brent et al., 1997).

A child version of the BHS for youth as young as ages 6–13, the Hopelessness Scale for Children (HSC), has been developed (Kazdin, Rodgers, & Colbus, 1986) for assessments with children and adolescents in school and clinical settings (Asarnow & Guthrie, 1989; Cole, 1989a, 1989b; Hewitt et al., 1997; Kashani, Suarez, Allan, & Reid, 1997; Nock & Kazdin, 2002; Reifman & Windle, 1995). Particularly in clinical samples, the HSC has been found to be highly internally consistent (Kazdin et al., 1986; Spirito, Williams, Stark, & Hart, 1988). Similar to the BHS, a number of studies have documented the relationship between hopelessness assessed with the HSC and depression and fewer reasons for living (Asarnow & Guthrie, 1989; Cole, 1989a, 1989b; Pinto et al., 1998). However, findings are mixed pertaining to whether HSC scores are related to indices of suicidality cross-sectionally after controlling for depression (Asarnow & Guthrie, 1989; Cole, 1989a; Myers, McCauley, Calderon, Mitchell, et al., 1991; Nock & Kazdin, 2002). In one study of

hospitalized adolescents, HSC scores were found to predict suicide attempts within 18 months (Brinkman-Sull, Overholser, & Silverman, 2000). However, HSC scores were not related to subsequent suicidality in another study (Myers, McCauley, Calderon, & Treder, 1991).

As mentioned earlier, perceived reasons for living have been found to be a protective factor against suicide. The 48-item Reasons for Living Inventory (RFL-48), originally developed for assessing perceptions of reasons for not killing oneself in adult populations (Linehan, Goodstein, Nielsen, & Chiles, 1983), has also been used with adolescents (Goldston et al., 2001). Additional versions of this scale have been developed, including two versions specifically for use with adolescents: the Reasons for Living Inventory for Adolescents (RFL-A; Osman et al., 1998), and the Brief Reasons for Living Inventory for Adolescents (BRFL-A; Osman et al., 1996). Each version of the RFL has different subscales. However, on the RFL-48, the items on the Survival and Coping Beliefs subscale have the highest internal consistency (Pinto et al., 1998), and seem to be most highly related (in cross-sectional analyses) to suicidality, after controlling for severity of depression and hopelessness (Cole, 1989b). In a longitudinal study of formerly psychiatrically hospitalized adolescents, higher RFL-48 Survival and Coping Beliefs subscale scores were associated with fewer repeat suicide attempts over the course of the follow-up (Goldston et al., 2001). In cross-sectional studies, many of the subscales of the RFL-A and the BRFL-A were also predictably associated with constructs such as estimated suicide probability, suicidal ideation, and hopelessness (Gutierrez, Osman, Kopper, & Barrios, 2000; Osman et al., 1996, 1998). However, these latter RFL versions have not been demonstrated to be predictive of future suicidality (Goldston, 2003).

The BHS, HSC, and various versions of the RFL questionnaires are but a few of myriad risk assessment instruments available (Goldston, 2003). However, these questionnaires are among the very few that have demonstrated predictive validity, and, in at least some samples, scores on these questionnaires have been shown to predict later suicidal behavior. In addition, these questionnaires are brief and can be administered easily in school or clinical settings, typically taking 5–10 minutes for completion. Importantly, hopelessness and reasons

for living in particular have the additional advantage of being easily targeted in treatments for suicidality. For example, a clinician may use cognitive therapy to help modify the maladaptive negative thoughts associated with hopelessness, and a variety of clinical approaches to strengthen existing reasons for living or develop new reasons for living.

A number of multistage screening procedures have been developed to assess suicide risk. Multistage approaches are advantageous insofar as screening with single instruments often results in unacceptable numbers of false positives (individuals identified as being “at risk” who are not at serious risk). Screening assessments are an integral part of suicide prevention efforts that focus on identifying individuals at risk in order to provide referrals to treatment or indicate selective prevention efforts. The first multistage suicide assessment system includes the Columbia Suicide Screen and the DISC (Shaffer & Craft, 1999; Shaffer, Wilcox, et al., 1996). The Columbia Suicide Screen is an 11-item self-report instrument that assesses suicide attempts and suicidal ideation, negative mood, substance abuse, and whether the respondent has a self-perceived need for treatment and is or is not receiving treatment (Shaffer et al., 2004). The algorithm for identifying risk on the Columbia Suicide Screen with the best balance between sensitivity and specificity yielded 75% sensitivity and 83% specificity (Shaffer et al., 2004). However, the 8-day test–retest reliability of this algorithm was only in the “fair” range (Altman, 1991), largely due to symptom attenuation (reduction of symptoms reporting at a second assessment). As noted by Shaffer and colleagues (2004), the significance of the drop-off in responding at a second assessment point is unclear, as is whether the initial or second assessment time points were more “valid.” Because of these questions and the possibility for a large number of false positives when screening large groups of students (as is typically done with the Columbia Suicide Screen), it is recommended that the DISC be used as a second-stage screening to identify appropriate students (Shaffer et al., 2004). On the basis of these results, the clinician can meet individually with at-risk students to determine whether they need referrals for treatment. The Columbia Suicide Screen method is being increasingly disseminated and is capable of identifying many at-risk students in need of services. It is less clear whether refer-

ral to treatment actually reduces their risk for suicidal behavior, and studies are currently underway to examine this possibility. One practical concern that is sometimes voiced about large-scale screenings for suicide risk, such as the Columbia Suicide Screen, is that the number of students identified may potentially overwhelm school counselors’ offices. Hence, it is important to ensure that resources are in place to meet the needs of newly identified at-risk students, and that referrals for treatment are available for students in need.

A second multistage screening assessment includes the Evaluation of Suicide Risk among Adolescents and the Imminent Danger Assessment (Bradley & Rotheram-Borus, 1990; Rotheram, 1987; Rotheram-Borus, 1989). The first-stage screening instrument may be used to help identify adolescents who are suicidal or at risk for suicidal behavior. This instrument includes a number of questions about both suicidality (e.g., lifetime suicide ideation and attempts, recent suicide attempts, exposure to suicidal behavior), and symptoms of depression and conduct disorder. Individuals who screen positive in the first-stage evaluation may then be evaluated with the Imminent Danger Assessment, described earlier in the section on assessing imminent risk of suicide. Interrater reliability for this set of assessment procedures was found to be very high (Rotheram-Borus & Bradley, 1991). These screening procedures have been used in settings with high-risk adolescents, including runaway teenagers, GLB teenagers, and teenagers who present for crisis services (Rotheram-Borus & Bradley, 1991; Rotheram-Borus, Hunter, & Rosario, 1994; Rotheram-Borus, Walker, & Ferns, 1996).

A third multistage screening assessment includes the High School Questionnaire (with the embedded Suicide Risk Screen [SRS]) and the Measure of Adolescent Potential for Suicide (MAPS) (Eggert, Thompson, & Herting, 1994; Eggert, Thompson, Herting, & Nicholas, 1995; Thompson & Eggert, 1999). In the first part of this assessment, adolescents are asked to complete the High School Questionnaire. Embedded within it are items assessing current suicidal thoughts and behavior, depression, and alcohol or substance use. Individuals who are considered at risk on the basis of the initial screen are then administered the MAPS via computer. The MAPS, a 2-hour assessment, covers “direct suicide risk factors” (e.g., sui-

cidal thoughts, suicidal behaviors, exposure to suicide, preparation for suicide), “related risk factors” (e.g., depression, hopelessness, substance abuse, school dropout risk), and protective factors (e.g., self-esteem, support from others, sense of personal control). This screening system has been used to identify students thought to be at high risk for engaging in suicidal behavior in the schools (Eggert et al., 1994, 1995; Thompson & Eggert, 1999; Thompson, Eggert, & Herting, 2000; Thompson, Eggert, Randell, & Pike, 2001). Classifications of risk made with the SRS were found to be differentially and predictably related to both an independent measure of suicidal ideation and clinicians’ judgments of risk (Thompson & Eggert, 1999). Ratings on the MAPS scales had correlations ranging from .52 to .79 with a scale of “suicide potential” (Eggert et al., 1994). Although this screening assessment is advantageous because of its assessment of multiple risk behaviors and its integration with a brief supportive intervention, difficulties may be encountered in its implementation or in sustaining its use in the school systems because of the large number of false positives associated with the first stage of screening (Hallfors et al., 2006).

The final multistage assessment combines the SIQ and the SBI (Reynolds, 1991). This multistage assessment differs from the others insofar as it focuses primarily on suicidal thoughts and suicidal behaviors rather than other risk and protective factors. Both of the instruments used in this multistage assessment have excellent psychometric properties and were described previously. However, Reynolds has suggested that screenings with the SIQ alone can result in an unacceptable number of false positives; for example, approximately 10% of screened adolescents tend to score above the cutoff (Reynolds, 1991). Hence, it is useful to follow up with more detailed assessment of suicidality and risk in individuals identified as suicidal in the initial screen. A potential difficulty with this approach is that the initial screen (the SIQ) assesses suicidal thoughts but not suicidal behavior (Goldston, 2003). Given that suicidal ideation may fluctuate over time, even among individuals with histories of suicidal behaviors, this screening approach may miss adolescents at high risk for subsequent suicidality by virtue of their past suicidal behaviors (Goldston, 2003).

Assessment of the Clinical Characteristics of Self-Harm Behaviors

The clinical characteristics of suicide attempts (e.g., stated intent, medical lethality) are often considered to be good indicators of risk for future suicidal behavior by treatment providers. For example, in a survey of psychologists, Peruzzi and Bongar (1999) found that “medical seriousness of past attempts” was rated the most important or critical factor by psychologists in estimating the degree of risk for suicidal behavior in a hypothetical patient with major depression. As described by Goldston (2003), a number of instruments assess clinical characteristics of suicidal behavior, such as intent or medical lethality. These instruments may be useful for descriptive purposes, in particular, for capturing the “topography” of suicidal behavior, such as methods, degree of planning, and so on—information that may be of use in treatment planning. In some cases, clinical characteristics have been found to be related to later suicidal behaviors in adult populations. However, the relationship between clinical characteristics of suicidal behavior and either the occurrence of future suicidal behavior among adolescents or the clinical characteristics of future suicidal behavior has not yet been demonstrated empirically (Goldston, 2003).

Examples of two instruments that assess clinical characteristics of suicidal behavior are the Beck Suicide Intent Scale (SIS; Beck, Schuyler, & Herman, 1974) and the Lethality of Suicide Attempt Rating Scale (Smith, Conroy, & Ehler, 1984). The SIS is administered as a semistructured interview and is considered by its authors to be appropriate for both adolescents and adults (Steer & Beck, 1988). The SIS comprises two parts—one assessing the objective intent associated with a suicide attempt, and the other assessing subjective intent. The part that assesses objective intent focuses on aspects of the suicidal behavior or context that can be observed, such as precautions taken against discovery, amount of planning, communications to others, and whether a suicide note was left. The section assessing subjective indications of intent includes the perceived seriousness of the suicide attempt and whether the respondent expected to die. The SIS has been used in clinical settings with adolescents who attempt suicide (Groholt, Ekeberg, & Haldorsen, 2000; Hawton, Kingsbury, Steinhardt,

James, & Fagg, 1999; Kingsbury, 1993; Nock & Kazdin, 2002; Spirito et al., 1994, 1996) and has been shown to have good interrater reliability (Brent et al., 1988). The subjective portion of the scale, in particular, was found to be internally consistent (Spirito et al., 1996). In one study, the two sections of the SIS were not strongly associated (Kingsbury, 1993), raising questions about the degree to which they are tapping into the same construct. SIS scores have concurrent validity, as evidenced by correlations with hopelessness, depression severity, and suicidal ideation constructs (DeMaso et al., 1994; Enns, Inayatulla, Cox, & Cheyne, 1997; Nock & Kazdin, 2002; Spirito et al., 1996). Among adults, suicide intent in previous suicide attempts, as assessed with the SIS, has been found to be related to eventual death by suicide (Harriss, Hawton, & Zahl, 2005; Suominen, Isometsa, Ostamo, & Lonnqvist, 2004), although the positive predictive value of intent as a predictor was low (Harriss et al., 2005). In adolescents, intent did not differentiate between single and repeat attempters in a 1-year follow-up (Hawton et al., 1999), nor was it related to repeat suicide attempts in a 3-month follow-up (Spirito et al., 1994).

The Lethality of Suicide Attempt Rating Scale (Smith et al., 1984), a clinician-rated scale of degree of medical lethality resulting from suicide attempts, has been used with adolescents in various settings (Lewinsohn, Rohde, & Seeley, 1993; Lewinsohn et al., 1994, 1996) and has demonstrated both good interrater reliability (Nasser & Overholser, 1999; Smith et al., 1984) and 6-month test-retest reliability (Nasser & Overholser, 1999). Higher ratings of medical lethality have been found to be related to more severe depression (Lewinsohn et al., 1996) and indications of higher suicide intent, such as taking precautions to prevent discovery, not communicating with others about the attempt, and higher expectations of death associated with attempts (Nasser & Overholser, 1999). Nonetheless, the predictive validity of the Lethality of Suicide Attempt Rating Scale with adolescents has yet to be examined.

ASSESSMENT FOR TREATMENT MONITORING

Several instruments may be used in clinical settings to monitor the process of treatment and clinical outcomes. For example, if the purpose

of an intervention is to reduce the severity of an adolescent's suicidal thoughts, detection instruments may be used to monitor the course of suicidality or the effectiveness of the intervention. Additionally, it may be the case that an adolescent who is not suicidal at the beginning of an intervention needs to be monitored for the emergence of suicidality, because he or she is depressed or is receiving medications. Close monitoring is particularly important in conjunction with pharmacotherapy given recent findings of self-harm adverse events associated with antidepressant medications in youth (FDA, 2004; TADS Team, 2004). Finally, risk factors associated with suicidality are sometimes the target of treatment. For example, treatment may focus on the reduction of a factor, or set of factors, such as hopelessness. One of the most important considerations in choosing an instrument for treatment monitoring is sensitivity to changes in clinical status.

The two detection instruments that have been used most commonly for treatment monitoring are the BSS and the SIQ, both of which have been described previously (Beck & Steer, 1991; Reynolds, 1988). The BSS assesses suicidal ideation over the last week, whereas the SIQ assesses suicidal thoughts over the last month. With both the BSS and the SIQ, the clinician should also monitor suicide attempts since the last assessment. The SIQ does not include an item regarding self-harm behavior, and the single item regarding past attempts on the BSS may not be sensitive to recurrent suicidal behaviors.

The BSS was used successfully in a quasi-experimental study of dialectical behavior therapy (DBT) to demonstrate pre- to posttreatment reductions in suicidal ideation (Rathus & Miller, 2002). The SIQ was used to compare the effectiveness of DBT and treatment as usual (TAU) in an inpatient setting; both DBT and TAU resulted in significant reductions in suicidal ideation (Katz, Cox, Gunasekara, & Miller, 2004). No differences were found in SIQ suicidal ideation scores between adolescents randomized to routine care and those in routine care plus home visits and family intervention, although scores decreased in both groups over time (Harrington et al., 1998). However, in subgroup analyses, there were lower suicidal ideation scores in the experimental group condition relative to those in the routine care alone for youth without major depres-

sion; there were no treatment effects for youth with major depression (Harrington et al., 1998). In an open trial of fluoxetine for depression in adolescents, the medication resulted in significant reductions in SIQ-assessed suicidal thoughts for seven of the eight patients (Colle, Belair, DiFeo, Weiss, & LaRoche, 1994). In the TADS, 439 adolescents were randomized to four conditions: fluoxetine (and general support), placebo (and general support), cognitive-behavioral therapy, and combined fluoxetine and cognitive-behavioral therapy (TADS Team, 2004). Twelve weeks after the initiation of treatment, suicidal ideation, as assessed with the SIQ-JR, had been reduced in all four conditions. However, there were differences in the rates of reductions of suicidal ideation, with the combination treatment group evidencing greater rates of change than the placebo group, and the other two groups evidencing rates of change that did not differ significantly from placebo (TADS Team, 2004).

Hopelessness is a risk factor that has been targeted in different interventions, with the goal of reducing suicidality. A suicide prevention intervention in Israel resulted in reductions in hopelessness as assessed with the BHS for targeted students in some, but not all, schools in which the intervention was used (Orbach & Bar-Joseph, 1993). Formerly hospitalized suicidal teenagers receiving individual and family therapy evidenced reductions in BHS scores from initial assessments to 6-month follow-up later; similar changes in hopelessness were not evident for teenagers who declined treatment (Pillay & Wassenaar, 1995). Hopelessness as assessed with the HSC did not differ as an outcome between suicidal adolescents randomized to routine care and those randomized to routine care plus an in-home family intervention (Harrington et al., 1998).

ASSESSMENT FOR TREATMENT PLANNING PURPOSES: THE FUNCTIONAL ANALYSIS

There is much heterogeneity among youths who engage in self-harm behavior, and it is unlikely that a single intervention approach will be effective with every adolescent. Developing a functional analysis for an individual who is suicidal or self-harming is useful for understanding the context of self-harm behavior and may be helpful in developing an individualized, targeted treatment plan. One approach to

the development of a functional analysis is the S-O-R-C (stimulus–organism–response–consequences) model described by Goldfried and Sprafkin (1976). In the S-O-R-C model, the *S* refers to the discriminative stimuli or triggers thought to be associated with the behavior of interest (self-harm behavior). The *O* refers to vulnerability or protective factors that are specific to the organism or individual. These factors may moderate or mediate the relationship between the precipitants in the environment and the likelihood of a response of interest (suicidal or nonsuicidal self-harm behavior) occurring. For example, it may be the case that an adolescent attempts suicide in the aftermath of a breakup with a romantic partner. Clearly, not every adolescent attempts suicide when breaking off a relationship, so there must be factors that increase or decrease the likelihood of suicidal behavior occurring in the presence of those environmental events. The *R* in the S-O-R-C model represents the response of interest, in this case, suicidal or nonsuicidal self-harm behavior, and the topography of the responses (e.g., methods). The *C* in the model represents consequences that occur after an individual engages in the self-harm behavior.

To illustrate how the functional analysis may be used in treatment planning, consider the *S* part of the model. The most common precipitants for suicidal behavior in adolescents are interpersonal loss or conflict and disciplinary or legal action (Adams et al., 1994; Beautrais et al., 1997; Gould et al., 1996). With information about the specific precipitants, the clinician can help the adolescent anticipate such situations and develop strategies for coping with or avoiding problematic situations. Alternatively, the clinician can help the adolescent ascertain whether the initial precipitating crisis has been resolved or is likely to recur, and plan steps to ensure that there is not a recurrence of these difficulties (e.g., family therapy to reduce the likelihood of arguments in the home).

With regard to the *O* part of the model, there are a number of risk and protective factors for suicidal behaviors, as described earlier in this chapter. With knowledge of these risk and protective factors on an individual basis, the clinician may focus on helping the adolescent to decrease risk and enhance protective factors. For example, an adolescent may evidence markedly poor problem-solving skills in the face of high levels of distress, and may fail to perceive that behavioral options other than continued mis-

ery or suicide exist. In such a case, the clinician can focus on problem-solving ability, working with the adolescent specifically to develop facility in generating and adopting alternative solutions to different problems. The clinician may try to reduce dysregulation of mood by focusing on associated cognitions with cognitive-behavioral approaches, or may focus on problematic patterns in relationships and role transitions that contribute to distress with interpersonal approaches. Alternatively, the clinician may help the adolescent to recognize or develop reasons for living, to plan for the future, or to participate in activities that may lead to increased positive social support.

Information about the response (self-harm behavior) itself can provide potentially useful information for treatment planning purposes. For example, with regard to information about the methods used, no research, to our knowledge, has demonstrated that individuals are more likely to choose the suicide method they used previously relative to other methods. However, the fact that the youth has used this method previously does let the clinician know that this method is in the youth's behavioral repertoire; there no longer is any doubt that the youth is capable of using this method to engage in self-harm. Similarly, suicidal thoughts and preparatory behaviors antecedent to actual suicide attempts may provide useful information about what the adolescent is considering, or how he or she goes about planning for suicide. The clinician may incorporate such information into safety planning, for example, restricting access to certain methods. For example, if an adolescent has thought about or tried to wreck a car as a way to attempt suicide, it makes sense to restrict access to the automobile and to driving, until the adolescent is no longer feeling suicidal.

Last, there are always consequences (the C in the functional analysis) following self-harm behavior. To the extent that the self-harm behavior results in a reduction in negative mood (e.g., relief or catharsis), the response will have been negatively reinforced. To the extent that self-harm behavior results in attention or support from peers or family that otherwise was not available, or to the extent that a difficult situation becomes resolved (because everyone realizes how "upset" the individual is), the response will be positively reinforced. In both cases, from a behavioral perspective, the response (self-harm) is more likely to occur when the individual is once again in the presence of

the discriminative stimuli, because of the reinforcing consequences. To this end, the therapist may work to reduce sources of positive attention for self-harm behavior or to help the adolescent develop new behaviors that yield the same consequences of support or relief.

The Functional Analysis and Psychiatric Comorbidities

As described by Goldston (2004), when suicidal or self-harm behavior is comorbid with psychiatric disorders, for treatment planning purposes it often is useful to identify the functional similarities of the co-occurring problems. For example, to varying degrees, suicidal behavior may have antecedents, risk and protective factors, or consequences similar to the other problem behaviors. To the extent that such functional commonalities may be identified, chances of developing an integrated treatment approach increase and interventions may be selected to impact multiple problem areas.

An example of a functional analysis focusing on the similarities between suicidal behaviors and substance abuse is presented in Figure 7.1. The information presented in the boxes is the actual functional analysis (the precipitants, risk and protective factors, consequences, etc.). In the circles are examples of interventions that may be used to target different aspects of the functional analysis to reduce suicidal and substance use behaviors. The arrows from the circles to the boxes illustrate targeted aspects of the context of the problem behaviors.

As an illustration, for a particular teen, the antecedents of both suicidal behaviors and substance use may be chronic arguments with parents. Based on this analysis, the clinician can choose an intervention that focuses on reducing the pattern of conflict between the adolescent and parents. The adolescent may have poor problem-solving skills that make it difficult to choose alternative behaviors in stressful situations. The clinician may provide problem-solving training or help the adolescent to anticipate difficult situations, so that he or she can plan accordingly. To the extent that an adolescent engages in both substance use and self-harm behaviors to reduce negative affect (i.e., "self-medicates"), the clinician can focus on helping him or her to learn new coping strategies (e.g., relaxation techniques, meditation) to reduce or to help the adolescent "let go" of unpleasant feelings or increase positive feelings.

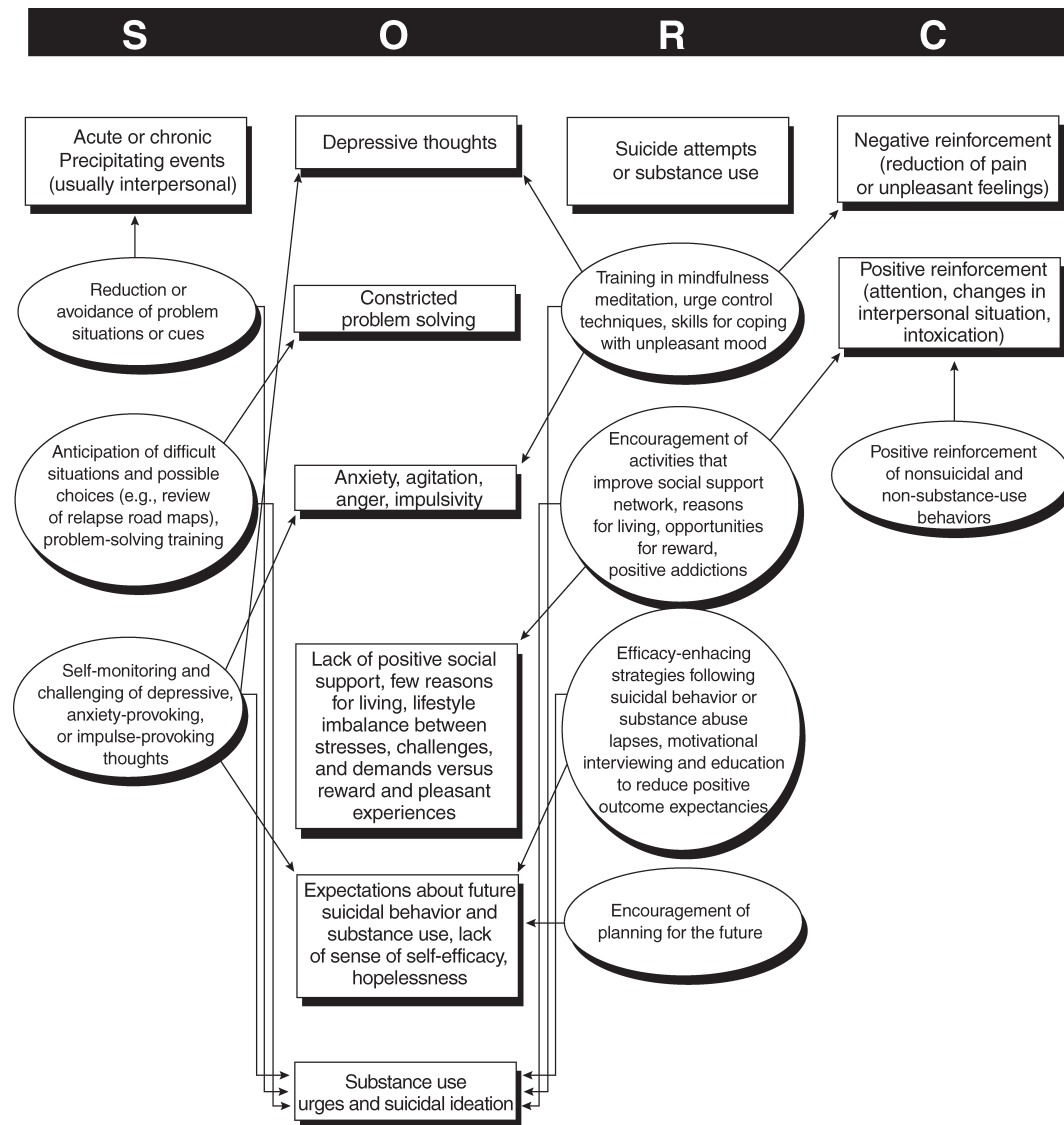

FIGURE 7.1. An example of a functional analysis of factors potentially affecting both suicidal behavior and substance use, and possible targets for intervention. From Goldston (2004). Copyright 2004 by Elsevier. Reprinted by permission.

The Functional Analysis and Cultural Considerations

A number of cultural differences and nuances in the context of suicidal behavior should be considered in assessment. These cultural differences in suicidal behavior and its context may also be described with the functional analytic model (Goldston et al., under review). For example, in terms of triggers, Asian Americans

may experience “loss of face” when they do not meet expectations for their behavior or they “upset group harmony” (Zane & Mak, 2003). Loss of face in turn can be associated with depression and suicidal behavior. In another example, Zayas, Lester, Cabassa, and Fortuna (2005) noted that among Latinas, the precipitants for suicidal behavior often occur in the context of the family and may manifest as conflicts between the culture of origin and ma-

majority culture in areas such as role expectations and socialization (e.g., the centrality of the family, independence, dating).

In terms of vulnerability and protective factors, numerous examples of cultural nuances and differences should be considered in assessment related to suicidal risk. For example, among Native Americans, a sense of loss due to a history of forced relocations, suppression of traditional language and religion, and attempts at forced acculturation (e.g., boarding schools) is believed to be associated with hopelessness or demoralization (Brave Heart, 1998; 1999; Duran & Duran, 1995; O'Neil, 1993). Conversely, enculturation, or the degree to which an individual is involved in his or her traditional native activities or religion, or with tribal elders or extended family (Whitbeck, Adams, Hoyt, & Chen, 2004) may help to protect against mental health problems or suicidality (Goldston et al., under review). Similarly, among African Americans and other ethnic groups, perceived discrimination and racism may be associated with increased stress (Clark, Anderson, Clark, & Williams, 1999), and increased risk factors for suicidal behavior, such as hopelessness and increased substance use (Gibbons, Gerrard, Cleveland, Wills, & Brody, 2004; Nyborg & Curry, 2003; Wong, Eccles, & Sameroff, 2003). Nonetheless, the cultural cohesion of stable African American communities and extended family may help to impart a greater sense of ethnic identity, which in turn protects against various problem behaviors (Wong et al., 2003). Among both Latino and Asian American communities, acculturative stress may result in discrepancies in values, expectations for behaviors, and roles between the country of origin (or the parents' country of origin) and the majority culture. Such conflicts may increase distress and risk for suicidal behavior (e.g., Hovey, 2000a, 2000b).

The reactions to suicide and suicidal behavior in different cultures vary. For example, it has been noted that African American women sometimes "normalize" distress (Brown, Abe-Kin, & Barrio, 2003) and associated problems such as depression, considering such difficulties to be a "normal" part of day-to-day living that may be overcome through hard work and determination (Breland-Noble, 2004). Asian American families may be reluctant to talk about suicide because they fear the shame it will bring to the family (Morrison & Downey, 2000). Latino families may interpret suicidal

behaviors as part of a cultural syndrome associated with distress, *ataques de nervios* (Zayas et al., 2005). In each of these cases, the cultural context tends to mitigate against seeking professional help for suicidal behaviors. Hence, careful assessment of the cultural context and reactions to suicidal behavior is critical to develop culturally relevant treatment plans to engage and retain individuals from diverse backgrounds.

ETHICAL CONSIDERATIONS IN ASSESSMENT AND MONITORING OF SUICIDAL PATIENTS

Careful assessment and monitoring of suicidal behaviors and risk are ethically mandated in clinical care. Berman, Jobes, and Silverman (2006) have pointed out that in general, two major issues are associated with liability in the care of suicidal patients. The first is *foreseeability*; that is, it is incumbent upon the health care provider to evaluate risk for suicidality by obtaining relevant history, current suicidal thoughts and intent, and information about risk factors for suicidal behaviors. This information should come from multiple sources, if possible, but particularly from direct interview and assessments with the adolescent patient and his or her parents or guardians. Foreseeability refers not only to the assessment of suicidal behaviors and risk at an initial assessment, but particularly for patients who are currently suicidal or thought to be at risk, also to an ongoing process of risk assessment.

In the second issue of liability, *reasonable care* (Berman, Jobes, & Silverman, 2006), the clinician should take appropriate and adequate steps to ensure development of a treatment plan to reduce the patient's suicidality and associated problems. This treatment plan should include steps by the clinician to assess safety issues and to develop an adequate safety plan that includes monitoring younger patients and removing means for attempting suicide. If the patient is not responding to treatment, the clinician should evaluate adequacy of the treatment approach. The instruments described in this chapter can help in the assessment of progress or adequacy of treatment over time. Reasonableness of care also refers to the ethical mandate not to abandon patients, particularly high-risk or suicidal patients.

As described earlier, one of the most important tasks for a clinician is the assessment of

imminent risk for suicidal behaviors. In this regard, when an adolescent is imminently dangerous to him- or herself, confidentiality should be broken to ensure that parents or guardians are informed of the situation, and the patient is monitored adequately. The breaking of confidentiality when patients pose a danger to themselves is consistent with the ethical guidelines of the American Psychological Association and the American Psychiatric Association. In terms of reasonableness of care, clinicians should try to resolve crises or decrease distress without higher levels of care, but referral for evaluation of the need for hospitalization is sometimes necessary to ensure that the patient remains safe.

BEST-PRACTICES APPROACH TO EVALUATING SUICIDALITY IN CLINICAL PRACTICE

To summarize, there are multiple purposes and considerations in assessing suicidal and nonsuicidal self-harm behaviors and risk. Far too often, suicidal and nonsuicidal self-harm behaviors are simply not assessed, even in clinical settings, for a variety of reasons. This lack of assessment, particularly with youth known to have psychiatric, behavioral, or substance use difficulties, and especially with youth suspected of having depression or a high level of distress, is negligent and even dangerous. Hence, the first “best practice recommendation” is that self-harm behaviors and ideation about self-harm be routinely assessed in all youth in clinical settings, or known to have behavioral, emotional, or substance abuse problems, regardless of whether the “presenting problem” described by the youth or parents concerns suicidality. For youth with depression, a high degree of problem severity (e.g., as indicated by comorbidities or psychiatric hospitalization), a history of self-harm behavior (no matter how remote), or for youth receiving pharmacological treatment for depression, continued and ongoing monitoring of self-harm behavior and risk is recommended.

Youth often report considerably more self-harm behavior or thoughts of self-harm than adults in their lives report about them. Hence, a second best-practice recommendation is that assessment of suicidal behavior and risk should always include direct reports from youth themselves. Ideally, suicide assessments should include multiple methods (e.g., interview, ob-

servations, questionnaires) and multiple informants, but reports of the youth should always be considered. Granted, there may be occasions in which youth deny suicidal intent or provide “mixed signals” about their risk or suicidal intent; in such cases, the clinicians should always err on the side of safety and of being conservative, because the risks of not acting in such a matter (e.g., someone killing themselves) are simply too high.

In assessing imminent risk of self-harm, particularly in emergency settings, a third best-practice recommendation is that the clinician should consider youth reports not only about suicide intent (because he or she may be denying suicidality out of embarrassment or a desire to avoid hospitalization) but also about available support individuals, and whether the adolescent can articulate credible alternatives to suicidal behavior if crises continue or recur. Other factors that should be considered include youth history of self-harm, and parents’ ability to monitor the youth and maintain a safe environment in the home.

A fourth best-practice recommendation is that when specific interviews, screens, or questionnaires are used to help in the detection of suicidality, clinicians use instruments that are known to be valid and to be reliable. Such detection instruments include diagnostic interviews such as the DISC and the K-SADS, interviews focused specifically on self-harm such as the SBI, and questionnaires such as the BSS and the SIQ. The latter two instruments have also proven to be useful in treatment monitoring.

A fifth best-practice recommendation is that when clinicians use “risk assessment” instruments to evaluate risk or self-harm behavior, the chosen instruments should be reliable and have predictive validity (which far too often is not the case). Available instruments that assess risk variables, such as hopelessness and severity of depression, and protective variables, such as perceived reasons for living, have demonstrated predictive validity with youth. In assessing risk, the clinician also should remember that many “detection instruments” have predictive validity insofar as past suicidal behavior is one the best predictors of future suicidal behavior. Information about clinical characteristics of past suicidal behavior, such as medical lethality or stated intent, should not be considered in risk assessments until such time that those clinical characteristics have actually been shown in prospective studies to portend higher risk among youth.

A sixth and final best-practice recommendation is that rather than a be-all and end-all, assessment of self-harm is part of a process that includes therapeutic action. For example, if a clinician determines that an adolescent is at imminent risk of suicidality, his or her obligation is to help ensure the safety of the adolescent, either by reducing risk or by referring the adolescent to a setting where he or she can be monitored more closely. If the clinician finds that a youth in treatment has thoughts about self-harm, he or she has an obligation to address these thoughts, to discuss safety considerations with both the adolescent and caretaker, and to develop a plan for reducing these thoughts and risk. If a youth continues to be suicidal, despite therapeutic efforts, the clinician has an ethical obligation to examine the adequacy of the treatment approach.

SUMMARY AND DIRECTIONS OF FUTURE ASSESSMENTS

For the reduction and prevention of adolescent self-harm behaviors, clinicians need to recognize and assess risk for self-harm and history of engaging in these behaviors. Careful clinical assessment is often useful in identifying youth at risk and in monitoring treatment progress. In this regard, it is notable that far fewer instruments are available for detecting the presence of nonsuicidal self-harm than for assessing the presence or severity of suicidal self-harm. It also is striking that against the backdrop of the large number of risk assessment instruments for suicidality, no instruments, to our knowledge, have been developed specifically to assess risk for nonsuicidal self-harm behaviors. To the extent that there is overlap between suicidal and nonsuicidal self-harm behaviors and their motivations (with the exception of wanting to die), it would be useful to evaluate whether risk assessment instruments developed for suicidal self-harm behaviors might also have utility in predicting nonsuicidal self-harm.

In addition, better understanding of the relationship between risk factors and suicidal behavior over time is needed. For example, many presumed risk factors may simply be covariates of increased distress, and it should be no surprise that distress is related to increased risk for self-harm behavior. Distress may wax and wane over time, and any predictive relationships between risk factors and

suicidality may similarly vary as a function of when those risk factors are assessed. To reduce long-term risk for self-harm behavior, it makes most sense for preventive and treatment interventions to target attributes associated with increased risk that are both modifiable and relatively stable over time. In this regard, a recent prospective study demonstrated that risk factors for adolescent and young adult suicide attempts include both trait and state variance, and the more stable trait variance in these measures is most strongly linked over time to suicide attempts (Goldston, Reboussin, & Daniel, 2006).

Research has increasingly focused on different facets of impulsivity assessed with laboratory measures and their relationship to different areas of brain functioning and suicidality (e.g., Dougherty, Mathias, et al., 2004; Mathias et al., 2003). Likewise, considerable research has focused on biological correlates and processes, particularly those related to serotonergic functioning, potentially associated with suicidal self-harm behaviors (e.g., Tyano et al., 2006). Nonetheless, despite a need for multimethod assessments, the utility of laboratory and biological measures in identifying individuals who may be at increased risk for subsequent suicidality has not been demonstrated and should be a focus of future research.

There is considerable heterogeneity among self-harming adolescents (e.g., Goldston et al., 1996, 1998; Mandell et al., 2006; Walrath et al., 2001). Different groups of self-harming adolescents are likely to have different characteristics and different developmental trajectories. Nonetheless, more research is needed to identify and characterize these different developmental trajectories and the varied courses of self-harming behaviors over time. Hand in hand with such efforts, we need to tailor assessment instruments more specifically toward identifying not only global risk for self-harm behaviors but also different groups of self-harming individuals with their own identifiable trajectories.

Finally, much research has been devoted to identifying who engages in self-harm, and the risk and protective factors for suicidal behavior. Recent research on adolescent nonsuicidal self-harm has taken this one step further by identifying the different behavioral functions of nonsuicidal self-harm behaviors. These functions, in turn, may be useful in developing individualized intervention plans for such adoles-

cents. The utility of a functional analysis for understanding self-harm behaviors on an individual basis was described earlier in this chapter. As an adjunct to such efforts, the field would greatly benefit from assessment instruments that help to identify the functions associated with suicidal thoughts and behavior, in a way that leads to a clearer understanding of the context of these behaviors and needed directions for treatment efforts.

PART IV

Anxiety Disorders

Anxiety in Children and Adolescents

Michael A. Southam-Gerow
Bruce F. Chorpita

Problems related to fears and anxiety in youth are relatively common, with lifetime prevalence rates of clinical disorders ranging from 6 to 15% in epidemiological studies (e.g., Silverman & Ginsburg, 1998; U.S. Public Health Service, 2000). Youth with anxiety problems experience significant and often lasting psychosocial impairment, such as poor school performance, social problems, and familial conflict (e.g., Langley, Bergman, McCracken, & Piacentini, 2004; Silverman & Ginsburg, 1998). The co-occurrence of these problems with disruptive behavior problems, depression, or additional anxiety disorders is also quite high, with rates of co-occurrence ranging up to 65% in epidemiological samples (Fergusson, Horwood, & Lynskey, 1993; Zoccolillo, 1992) and up to 84% in clinic samples (e.g., Albano, Chorpita, & Barlow, 2003; Kendall et al., 1997). Thus, the problems found in these youth are substantial (e.g., Costello, Angold, & Keeler, 1999; Pine, Cohen, Gurley, Brook, & Ma, 1998).

Accumulating evidence also supports the notion that such problems have an early onset in childhood and adolescence. Among the anxiety disorders, separation anxiety disorder and specific phobia have the earliest average onset (approximately age 7), whereas generalized anxiety disorder and obsessive-compulsive disorder

typically have their onset in middle childhood (age 9–10); onset of social phobia is typically in early adolescence, and onset of panic disorder comes latest, around the age of 15 (e.g., Morris & March, 2004). Anxiety also appears to run a chronic course into adulthood (Albano et al., 2003; Pine et al., 1998). Thus, the impairment associated with anxiety in youth has important long-term implications for adult functioning (Pine et al., 1998), with most research suggesting that anxiety symptoms actually worsen over time (Kendall, 1994) and possibly lead to depression (e.g., Chorpita & Barlow, 1998) or substance use disorders (e.g., Compton, Burns, Egger, & Robertson, 2002; Grant et al., 2004). Survey data from public schools using a conjunction of various measures of impaired functioning indicate that 45.8% of children diagnosed with anxiety disorders are also classified as seriously emotionally disturbed (Costello, Angold, & Burns, 1996).

Given the heightened prevalence of problematic fears and anxiety among children and adolescents, the long-term and broad implications of not addressing these problems (Albano et al., 2003; Ollendick, King, & Chorpita, 2005; Pine et al., 1998), and the significant degree of distress and impairment experienced by anxious and fearful youth across a range of activities and situations, research on which treat-

ments are most effective and useful has grown substantially (Chorpita & Southam-Gerow, 2006). Most treatments, however, depend heavily on the clinician's ability to assess a child's anxiety and evaluate his or her need for treatment. Fortunately, developments in the area of assessment have made similar strides in helping professionals to identify youth with anxiety-related problems, so that treatment may be provided when necessary (Chorpita & Southam-Gerow, 2006; see also Compton et al., 2004; Ollendick et al., 2005).

This chapter examines the research literature on assessment of anxiety in children and adolescents. We begin with a discussion of the various anxiety disorders common among children and adolescents. Next, we discuss conceptual issues relevant to assessment, including the importance of multimethod assessment approaches and the distinction between content and process in assessment. Next, we describe the purposes of assessment and provide a brief overview of common assessment methods. We then present a comprehensive review of instruments used in the assessment of anxiety in children; in this review, we offer specific assessment approach recommendations. Finally, we offer some suggestions for future research. Our focus throughout the chapter is on the real-world applicability of assessment. As clinical researchers move toward understanding factors essential to dissemination of research-based interventions, many have encouraged the need for a similar direction for clinical assessment (e.g., Mash & Hunsley, 2005; Silverman & Ollendick, 2005). We hope that this chapter serves as a basis for clinicians and administrators in selecting assessment tools for use in applied settings.

CHILDHOOD ANXIETY DISORDERS

In the fourth, text revised version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; American Psychiatric Association [APA], 2000), children may be diagnosed with any of nine anxiety disorders: separation anxiety disorder (SAD), panic disorder (PD), agoraphobia, generalized anxiety disorder (GAD, formerly overanxious disorder), social phobia/social anxiety disorder, specific (simple) phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and acute stress disorder. These disor-

ders share the emotion of anxiety as the predominant feature, expressed through specific and discrete cognitive, physiological, and behavioral reactions. What distinguishes one anxiety disorder from the next is often the focus of the child's anxiety. In this section we define the core and associated features of specific anxiety disorders affecting children and adolescents. A listing of DSM-IV-TR criteria is provided in Table 8.1 for each disorder. The reader interested in the assessment of PTSD and acute stress disorder is referred to Fletcher (Chapter 9, this volume) for a comprehensive review (see also Chorpita & Southam-Gerow, 2006, for discussion of the treatment of PTSD). This review of childhood anxiety disorders and their features is designed to be brief and illustrative. Interested readers are referred to more in-depth discussion of these topics elsewhere (e.g., Albano et al., 2003; Beidel & Turner, 2005; Morris & March, 2004).

Separation Anxiety Disorder

SAD is the only true *childhood* anxiety disorder that remained when DSM-IV (APA, 1994) was published. The essential feature of SAD is excessive anxiety and fear concerning separation from home or from those to whom the child is attached (e.g., parents or caretakers). Such anxiety must be inappropriate for the child's age and expected developmental level given that separation anxiety is a normal developmental phenomenon from approximately age 7 months to 6 years (Beidel & Turner, 2005; Silverman & Dick-Niederhauser, 2004). Children must evidence at least three of the eight symptoms for at least 4 weeks to qualify for a diagnosis of SAD. Moreover, the disturbance must be accompanied by clinically significant distress or impairment in social, academic, or other important areas of functioning. Table 8.1 highlights the DSM-IV criteria for SAD.

Children diagnosed with SAD are more likely to report somatic complaints than children diagnosed with phobic disorders (e.g., Beidel & Turner, 2005; Last, 1991). Children with SAD may also drop out of activities such as clubs or sports, if their parents are not actively involved, but not for lack of interest in the activity. Friendships may wane due to the child's repeated refusal to attend activities away from home, although children with SAD in general are socially skilled and well liked by

TABLE 8.1. Brief Diagnostic Criteria for anxiety Disorders from DSM-IV-TR

Separation anxiety disorder (SAD)	<ul style="list-style-type: none"> • Developmentally inappropriate and excessive anxiety concerning separation from home or from those to whom the individual is attached • Duration: at least 4 weeks
Generalized anxiety disorder (GAD)	<ul style="list-style-type: none"> • Excessive worry about multiple situations • Perception that worry is uncontrollable • At least three physiological/cognitive symptoms • Duration: at least 6 months
Social phobia	<ul style="list-style-type: none"> • Excessive and disabling fear of social or evaluative situations. • Avoidance of situations or endurance with extreme distress • Duration: at least 6 months
Obsessive–compulsive disorder (OCD)	<ul style="list-style-type: none"> • Obsessions (recurrent intrusive unwanted thoughts) and/or compulsions (repetitive behavior or mental act that person is driven to do, usually to reduce distress caused by obsession)
Specific phobia	<ul style="list-style-type: none"> • Excessive and disabling fear of specific stimuli • Avoidance of situations or endurance with extreme distress • Duration: at least 6 months
Panic disorder	<ul style="list-style-type: none"> • 1+ panic attacks for no discernible reason • Persistent concern about having additional attacks or worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, “going crazy”) or a significant change in behavior related to the attacks • Duration: at least 1 month.

Note. All disorders have as one criterion that the symptoms must cause significant distress and/or functional impairment. From American Psychiatric Association (2000). Copyright 2000 by the American Psychiatric Association. Adapted by permission.

peers (Last, 1989). Academic performance may be compromised by the child's repeated requests to leave class, and distress and preoccupation with separation concerns. In extreme form, children with SAD who refuse to attend school miss important social and academic experiences available only in the school setting (Kearney, 2001). At times, efforts are made to provide these children with tutoring and assignments to complete at home; however, repeated absences place a child at risk for failure to meet the standards for attendance set forth in state regulations. Consequently, some children are then required to repeat the academic year and, in extreme cases, are remanded to the legal system for compliance with school attendance.

Epidemiological studies have suggested the prevalence of SAD ranges from 2.0 to 12.9%, with higher prevalence rates for studies involving younger children (e.g., Silverman & Dick-Niederhauser, 2004). However, more recent studies have reported somewhat lower prevalence rates, under 5% (e.g., Bolton et al., 2005;

Ford, Goodman, & Meltzer, 2003; Shaffer, Fisher, Dulcan, & Davies, 1996). Gender discrepancies have been reported, with more females than males having the disorder, but the finding is not consistent across all studies (e.g., Beidel & Turner, 2005; Silverman & Dick-Niederhauser, 2004). SAD is the least stable of the anxiety disorders, with some studies suggesting up to 80% natural remission (e.g., Foley, Pickles, Maes, Silberg, & Eaves, 2004). However, in studies of youth with SAD who later do not meet SAD criteria often meet criteria for another anxiety disorder diagnosis (Beidel & Turner, 2005).

Generalized Anxiety Disorder

The core symptoms of GAD in DSM-IV-TR are listed in Table 8.1. The disorder is characterized by excessive and uncontrollable worry about multiple topics that lasts at least 6 months. Because there is a high rate of comorbidity among anxiety disorders (see below), an important diagnostic consideration relates to

the focus of the youth's worries. If restricted solely to (1) separation from an attachment figure (SAD), (2) social situations (social phobia), or (3) a specific event, stimulus, or situation (specific phobia), GAD is not the appropriate diagnosis. It is worth noting that until the release of DSM-IV (APA, 1994, 2000), overanxious disorder (OAD; DSM-III, APA [1980] and DSM-III-R, APA [1987]), was considered the diagnosis for youth who worried excessively. As a result, research on GAD in youth has only been amassed in the past 12 years.

Vasey's (1993) developmental theory of worry contends (1) that GAD should be more prevalent in older compared to younger children; (2) that older youth worry about a greater diversity of topics; and that (3) with age, a youth's ability to elaborate cognitively on worries increases. Evidence has generally supported these propositions. For example, although worry is common across childhood, it is more prevalent in older children (e.g., Vasey, 1993). Worry topics shift across development, too. Younger children worry more about their *physical* well-being, whereas older children worry more about their behavioral competence, social evaluation, and *psychological* well-being. Evidence also suggested that as age increases, children's ability to elaborate the potential negative consequences of worries increases. Different comorbidity patterns are also present in youth with GAD, depending on age, with younger children (ages 5–11) more likely presenting with separation concerns and attention-deficit/hyperactivity disorder (ADHD), and older children showing more comorbid major depression and specific phobias (Masi, Favilla, Mucci, & Millipiedi, 2000; Strauss, Lease, Last, & Francis, 1988). In addition to the aforementioned symptoms, disturbing dreams have been associated with GAD in adolescents, especially girls (Nielsen et al., 2000). Finally, because headaches, stomachaches, muscle tension, sweating, and trembling are commonly reported physical complaints of children with GAD, many children are referred for treatment by their pediatricians or by gastrointestinal specialists (e.g., Bell-Dolan & Brazeal, 1993).

As a result of the shift from OAD to GAD, epidemiological studies of GAD in youth are relatively few. We also examined studies of OAD because, in general, research has suggested that youth diagnosed with OAD have tended to be diagnosed with GAD when DSM-IV criteria were applied (Kendall & Warman,

1996; Tracey, Chorpita, Douban, & Barlow, 1997). Community studies have reported prevalence rates for OAD ranging from less than 2 to 19%. Rates of GAD appear lower, ranging from 0.4 to 4.2%. Childhood anxiety disorder clinic studies have reported the prevalence of disorders in their samples, with prevalence of OAD and GAD being quite high, from about 20% to over 70% depending on the clinic (see Chorpita & Southam-Gerow, 2006, for review). In clinics serving a general clinical population, rates of OAD and GAD are considerably lower, in the 5–10% range (e.g., Southam-Gerow, Weisz, & Kendall, 2003).

Social Phobia

In DSM-IV, the essential feature of social phobia is a marked and persistent fear of one or more social or performance situations in which the person fears that embarrassment may occur. Upon exposure to the social or performance situation, the person almost invariably experiences an immediate anxiety response that may take the form of a panic attack. Individuals with social phobia may either avoid these situations or endure them with extreme distress. DSM-IV-TR criteria for social phobia are highlighted in Table 8.1. If the fear includes most social situations, a specifier of "generalized" is added.

Children with social phobia present with significantly higher levels of depressed mood than do normal children (Beidel, Turner, & Morris, 1999; La Greca & Lopez, 1998). Moreover, compared to their nonanxious peers, these children generally endorse significantly lower perceptions of cognitive competence and higher trait anxiety (Beidel & Turner, 2005; Beidel et al., 1999), with higher self-reported state anxiety during an evaluative task (Beidel, 1991). Furthermore, many youth with social phobia appear to have impaired social skills, as assessed in observational studies (Beidel et al., 1999; Spence, Donovan, & Brechman-Toussaint, 1999). Youth with social phobia may also become oppositional about going to school (Kearney, 2001).

Community epidemiological studies suggest that between 0.5 and 2.8% of youth meet criteria for social phobia (Beidel & Turner, 2005; Beidel, Turner, & Morris, 1995; Canino et al., 2004; Ford et al., 2003; Shaffer et al., 1996). Rates are generally higher for older youth and females; also, rates in studies in the United States and Puerto Rico were higher than those

in studies in Britain. The vast majority of youth with social phobia, up to 92% in some studies, meet criteria for the “generalized” type (e.g., Beidel, Morris, & Turner, 2004; Hofmann et al., 1999). In addition, adolescents with generalized social phobia are distinguished from those with the nongeneralized form by (1) earlier age of onset, (2) greater impairment in functioning, (3) higher risk for the development of comorbid conditions, and (4) greater likelihood of earlier inhibited temperament or familial adversities (see Velting & Albano, 2001, for a review). Onset for social phobia is typically in early adolescence (age 11–12 years; Beidel et al., 2004; Beidel & Turner, 2005). In specialty anxiety clinic samples, rates of social phobia are in the 15–25% range (e.g., Kendall, Brady, & Verduin, 2001; Silverman et al., 1999).

Obsessive–Compulsive Disorder

OCD is characterized by recurrent and intrusive obsessions and compulsions that are time-consuming (greater than 1 hour per day) and cause marked distress for the child or significant functional impairment (APA, 2000). Table 8.1 provides a summary of the DSM-IV-TR criteria for OCD. In contrast to the adult criteria, the DSM does not require the child to realize that his or her obsessions or compulsions are excessive or unreasonable. Typical obsessions in youth include contamination fears, sexual or religious themes, or aggressive/violent images, and typical compulsions include washing, checking, ordering, and arranging (March, Franklin, Leonard, & Foa, 2004; Piacentini & Langley, 2004).

Comorbid anxiety and depression are among the most common associated features of OCD (March et al., 2004; Piacentini & Langley, 2004; Wewetzer et al., 2001), though concurrent mood disorders are typically more prevalent in older children (Geller et al., 2001). Earlier age of onset has been associated with an increased risk of ADHD and other anxiety disorders, including specific phobia, GAD, and separation anxiety (Geller et al., 2001; March et al., 2004). There is a higher incidence of OCD in children and adults with Tourette’s disorder (35 to 50%); the incidence of Tourette’s disorder in children and adults with OCD is lower, with estimates ranging between 5 and 7% (e.g., Geller et al., 2001).

Epidemiological studies suggest that between 1 and 2% of children meet DSM criteria

for OCD (Geller et al., 1998; Piacentini & Langley, 2004), with studies that obtained higher rates relying on self-report checklists rather than clinical interviews. In childhood and early adolescence, there are slightly more males than females with OCD; with age, this gender discrepancy disappears (Beidel & Turner, 2005; March et al., 2004). Age of onset has ranged from 7 to 10 years according to the literature (e.g., Geller et al., 1998).

Specific Phobias

Specific phobia is diagnosed in youth who have a marked and persistent fear of certain objects or situations; the feared stimuli cannot include social situations, fear of having a panic attack, or separation concerns. As with social phobia, exposure to the stimulus is met with a severe fear response and is either avoided or endured with distress. Unlike adults, children may not recognize that the fear is excessive or unreasonable. Table 8.1 outlines the DSM-IV-TR symptoms for specific phobia. Common subtypes of specific phobia include fear of animals, blood, injection/injury, and natural environment.

Oppositional behavior is common in youth with a specific phobia insofar as they oppose adult efforts to expose them to the feared stimulus. As discussed below, specific phobia often co-occurs with other anxiety disorders, particularly GAD. A key to diagnosing specific phobia lies in differentiating between normal fears that are common throughout childhood, and the severe and impairing fears associated with specific phobia.

Reported rates of specific phobia are typically between 3 and 10%, with lower rates in studies relying on clinical interviews and rigorously adhering to the DSM impairment criteria (Essau, Conradt, & Petermann, 2000; Ollendick, King, & Muris, 2002; Verhulst, van der Ende, Ferdinand, & Kasius, 1997). Animal and natural environment phobias were the most common subtypes, with high levels of psychosocial impairment reported during the worst episode of the disorder. Despite such impairment, few adolescents receive any help for their phobia. Not surprisingly, phobias are especially common in childhood anxiety clinics. Ollendick and colleagues (2002) report that 15% of youth in such clinics meet criteria for a phobia diagnosis, though rates as high as 48% have been reported in the literature (Kendall et al., 1997). The disorder is more common among girls and younger children than among

boys and older children (e.g., King, Muris, & Ollendick, 2004; Muris, Schmidt, & Merckelbach, 1999).

Panic Disorder

Until recently, many in the clinical and research communities debated whether children and adolescents can have panic disorder, believing that youth were not capable of having the catastrophic cognitions that typify panic disorder (see Kearney & Silverman, 1992; Moreau & Weissman, 1992; Nelles & Barlow, 1988). However, it is now generally accepted that panic attacks and panic disorder can occur in youth (e.g., Hayward, Killen, Kraemer, & Taylor, 2000; Kearney, Albano, Eisen, Allan, & Barlow, 1997; Ollendick, Mattis, & King, 1994). Panic disorder is defined by the occurrence of at least one *unexpected* panic attack, followed by at least 1 month of any one (or more) of the following: persistent fear of experiencing future attacks, worry about the implications of the attack or its consequences, or a significant change in behavior related to the attacks (APA, 2000). Table 8.1 outlines the diagnostic criteria for panic disorder.

In addition to panic symptoms, children and adolescents with panic disorder may display concomitant “agoraphobia,” defined as the fear of being in situations from which escape may be difficult or embarrassing, or in which help is not readily available in the event of a panic attack (Kearney et al., 1997; Masi et al., 2000). A child with panic disorder may also avoid school situations, such as riding the bus and going to gym class, or refuse to attend school. Youth with panic disorder may also present with comorbid GAD, specific phobias, SAD, and depression (Kearney et al., 1997; Masi et al., 2000).

Rates of panic disorder in children and adolescents are not very well known given how recently the diagnosis in this age range has been given serious attention. Nevertheless, available estimates range from 0.5 to 5.3% for panic disorder, with rates of panic attacks being much higher—as high as 63% in some reports (Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993; Masi et al., 2000; Ollendick, Birmaher, & Mattis, 2004; Verhulst et al., 1997). Panic disorder rates as high as 10% have been reported in mental health service settings (e.g., Kearney et al., 1997). Evidence suggests that rates are higher for females and increase with age across childhood and adoles-

cence (Ollendick et al., 2004). Peak age of onset occurs in late adolescence, though 10–20% of youth with panic disorder report that their first panic attack occurred before age 10 (Ollendick et al., 2004).

Other Descriptive Issues

In the following three sections, we discuss a few additional issues related to childhood anxiety disorders. First, we briefly describe common psychiatric comorbidities associated with anxiety disorders. Then we provide a concise review of the sparse research on childhood anxiety in diverse samples. We conclude with a short *précis* of research and theory concerning the etiology of anxiety.

Common Comorbidities

The issue of comorbidity in the childhood anxiety disorders plays a critical role in the understanding of childhood anxiety more generally (e.g., Caron & Rutter, 1991; Doss & Weisz, 2006). The focus of our chapter precludes a more than cursory review of the important data on common comorbidities. For more, the reader is referred to recent texts that focus more on childhood psychopathology (e.g., Albano et al., 2003). Evidence is clear that youth with anxiety disorders are likely to have at least one comorbid disorder (Brady & Kendall, 1992; Russo & Beidel, 1994), with rates in excess of 65% in epidemiological (Angold, Costello, & Erkanli, 1999; Bird, Gould, & Staghezza, 1993) and clinically referred samples (Kendall et al., 1997; Silverman & Ginsburg, 1998) commonly reported. In particular, comorbidity among the anxiety disorders is common, with GAD, SAD, and social phobia frequently co-occurring. Among the anxiety disorder diagnoses, OCD is the least likely to be associated with a comorbid anxiety disorder diagnosis, though comorbidity is still relatively common (e.g., Beidel & Turner, 2005). Aside from other anxiety disorders, depressive disorders are another common comorbidity (Brady & Kendall, 1992). As we discuss later, there are some theoretical reasons that this overlap makes sense (see “Conceptual Issues in Assessment”). Finally, there is also frequent comorbidity with disruptive behavior disorders, such as oppositional defiant disorder (ODD) and ADHD (e.g., Russo & Beidel, 1994).

A primary implication of comorbidity in the assessment of anxiety is that an assessor needs

expertise in more than anxiety assessment tools. Conducting a differential diagnosis becomes an essential task. As an example, endorsement of the symptom “difficulty concentrating” might reflect at least three different diagnostic considerations within the mental health domain: an anxiety disorder diagnosis (e.g., GAD), a depressive disorder diagnosis, or ADHD. Thus, although we believe this chapter provides a comprehensive overview of the tools needed for anxiety assessment, we strongly advise mental health professionals to read the remaining chapters of this book and apply the lessons from them, before assessing a child suspected of having an anxiety disorder.

Anxiety in Diverse Samples

Despite calls for work with diverse samples, research with such samples has been lacking. In this brief section, we provide an overview of the literature focused on anxiety in youth, with regard to gender, ethnicity, and family income; our discussion is illustrative. The presence of gender differences in anxiety disorders among adults has been a robust finding (Yonkers & Gurguis, 1995). In youth, gender differences are also present, though they appear to emerge for many anxiety disorders in late childhood or early adolescence, in a manner similar to that found in the depression literature (e.g., Albano & Krain, 2005; Muris, Mayer, et al., 1998). As noted earlier, male cases predominate in samples of children with OCD until adolescence, at which point the male:female ratio becomes equivalent (e.g., March et al., 2004; Piacentini & Langley, 2004).

In general, very little research has focused on childhood anxiety in low-income samples. Some evidence does suggest that lower socioeconomic status and lower parental education level are associated with a greater prevalence and risk of anxiety disorders (Bird, Gould, Yager, Staghezza, & Canino, 1989; Last, Hersen, Kazdin, Finkelstein, & Strauss, 1987; Valez, Johnson, & Cohen, 1989). Recent work by Southam-Gerow and colleagues (Southam-Gerow, Chorpita, Miller, & Taylor, 2007; Southam-Gerow, Weisz, et al., 2003) has suggested that youth with anxiety disorders who present in clinics serving low-income families are more likely to have multiple disorders and increased family difficulty. The lack of research on childhood anxiety in low-income families is particularly problematic given the link between income and child psychopathology, par-

ticularly externalizing disorders (e.g., Atkins, Graczyk, & Frazier, 2003; Attar, Guerra, & Tolan, 1994; Costello, Compton, Keeler, & Angold, 2003; Kim-Cohen, Moffitt, & Caspi, 2004). Thus, future research should include more low-income families.

There are relatively more studies that include participants from diverse ethnic backgrounds, although, overall, this literature, too, is greatly lacking (e.g., Austin & Chorpita, 2004; Safren et al., 2000). Some studies have found differing levels of anxiety symptoms in African American versus European American youth, though the direction of the difference has not been consistent across studies (e.g., Compton, Nelson, & March, 2000; Last & Perrin, 1993). Issues of culture and ethnicity are important to consider in the assessment of childhood anxiety, because they play an important role in determining how child behaviors are perceived within a cultural group. For example, one behavior may generate a clinical referral in one cultural group, whereas in another, it may not. Relatedly, cultural and ethnic variables impact emotional development, and not all cultures share the same views on emotion expression and regulation (e.g., Fredrickson, 1998; Friedlmeier & Trommsdorff, 1999; Matsumoto, 1990).

In summary, although a growing body of research has focused directly on the demographic composition of anxiety disorders in children and adolescents, the available data are still too limited to allow for broad inferences. Studies vary on selection and recruitment procedures, geographical boundaries, incentives for participation, and opportunities for treatment. Cultural or racial biases may influence whether children from specific minority groups are referred for treatment of internalizing disorders such as anxiety. Moreover, the majority of studies in the literature with clinic-referred youth stem from specialty clinics for anxiety disorders in youth, whose samples have the potential for recruitment bias. Families who seek mental health services may be in a better position to be referred or to afford such services, and the clinical assessment literature is best interpreted with these caveats in mind.

Major Etiological Perspectives

A complete review of the major etiological perspectives of anxiety disorders is beyond the scope of this chapter, and the interested reader is referred elsewhere (e.g., Albano et al., 2003;

Beidel & Turner, 2005; Morris & March, 2004). Albano and colleagues (2003) summarized the “triple vulnerability” model of anxiety development (Barlow, 2000, 2002) as involving the interaction of a heritable biological diathesis, a psychological vulnerability related to “feeling” an uncontrollable/unpredictable threat or danger, and early learning experiences.

In terms of the first vulnerability, considerable evidence supports the notion that anxiety has a heritable component (Eaves et al., 1997; Eley et al., 2003). Many have suggested that this vulnerability for the development of anxiety manifests as an “inhibited” temperamental style, defined as the tendency to withdraw from novel or social experiences (e.g., Biederman et al., 1993; Kagan, Reznick, & Snidman, 1988). Other models of temperament and anxiety have focused more directly on the organization of biological systems that underlie motivation and emotion (e.g., Gray & McNaughton, 1996). For example, Gray’s (1982) model of inhibition, independent of Kagan’s work, has inspired rich theorizing regarding the relation of biological and temperamental factors to anxiety and anxiety disorders (e.g., Barlow, Chorpita, & Turovsky, 1996; Lonigan & Philips, 2001). Yet another area of temperament research has focused on the relation of anxiety disorders and depression to broader personality and affective variables, such as those represented in the Big Five model (i.e., Surgency/Extraversion, Agreeableness, Conscientiousness, Emotional Stability/Neuroticism, and Openness).

One of the most well researched of these models is Clark and Watson’s (1991) tripartite model of emotion and its relation to anxiety and depression in children, a perspective suggesting that factors of positive affectivity (PA), negative affectivity (NA), and physiological hyperarousal (PH) account for the relation of anxiety and depression (Mineka, Watson, & Clark, 1998). This model has found empirical support in childhood anxiety research (e.g., Chorpita, Albano, & Barlow, 1998; Lonigan, Hooe, David, & Kistner, 1999) and has led to new assessment developments, as we discuss in some detail below.

Complementing these genetic and temperament models, several psychosocial factors associated with the development of anxiety disorders include coping strategies (Kendall, 1994), social–familial transmission (Chorpita, Al-

bano, & Barlow, 1996), information processing (Vasey, Daleiden, Williams, & Brown, 1995), and complex forms of conditioning (Bouton, Mineka, & Barlow, 2001). One organizing theme involves the role of perceptions of control in both the expression and the development of negative emotions (Barlow, 2000, 2002; Chorpita, 2001). Many treatment approaches have focused on information-processing and learning histories as the key correlates, as evidenced by the prominence of cognitive-behavioral treatments in the child anxiety area (e.g., Chorpita & Southam-Gerow, 2006). Still, relational factors represent another important risk factor. For example, insecure early attachment is related to the development of anxiety disorders (Manassis, 2001; Warren, Huston, & Egeland, 1997), and problem-solving styles appear to be consistent within families of youth with anxiety disorders, such that avoidant strategies are emphasized (Chorpita et al., 1996).

The third area of vulnerability, as articulated by Barlow (2001), involves specific learning experiences that may precipitate specific disorders. For example, youth with existing inhibited temperament in conjunction with psychosocial risk factors of uncontrollability or poor problem solving are thought to be at increased risk to develop an anxiety disorder upon experiencing a specific fearful conditioning event. In general, early theories of how such conditioning occurs are quite diverse, including notions of associative and instrumental learning (Delprato & McGlynn, 1984; Mowrer, 1960), observational learning (Bandura, 1977), and verbal instruction (e.g., Rachman, 1977). Such concepts have now been incorporated in more contemporary, integrative developmental models (Albano et al., 2003; Chorpita, 2001; Vasey & Dadds, 2001) that emphasize core developmental psychopathology concepts such as temperament–environment fit, multifinality, equifinality, and multiple and reciprocal determinism (cf. Kazdin & Kagan, 1994; Sroufe, 1990).

CONCEPTUAL ISSUES IN ASSESSMENT

Proper assessment rests upon assumptions about a clearly articulated theory, and the child anxiety literature has faced some historical challenges in this area. Cronbach and Meehl (1955) offered the term *nomological network*

to describe “the interlocking system of laws which constitute a theory” (p. 290) and argued that to understand the meaning of any chosen construct (e.g., childhood fear or anxiety), we must have certain ideas about how it will relate to other constructs.

Presumably, “anxiety” is a central construct in the relevant theoretical network, but to what degree is “anxiety” related to constructs such as “fear,” “panic,” “dread,” “sadness,” “inhibition,” and so forth? Because many of the most widely used measures of childhood anxiety were originally developed prior to the contemporary theoretical positions regarding negative emotions (e.g., Barlow, 1988; Clark & Watson, 1991, Gray & McNaughton, 1996), a number of measures represent constructs in a network that has since been refined or strongly challenged by the accumulation of new evidence.

For example, the behavioral and emotional outputs of brain systems underlying fear and anxiety are consistent with a number of constructs related to vulnerability for anxiety disorders and depressive disorders from other literatures (Brown, Chorpita, & Barlow, 1998; Clark & Watson, 1991; Gray & McNaughton, 1996). Clark, Watson, and Mineka (1994) described NA as a “stable, highly heritable gen-

eral trait dimension with a multiplicity of aspects ranging from mood to behavior” (p. 104). Thus, NA may be of considerable value in predicting the future emergence of anxious pathology. Furthermore, the model allows for improved understanding of the comorbidity among disorders of emotion. Perhaps most importantly, tests of the model in the context of dimensions of anxiety and depression have revealed the benefit of a hierarchical assessment framework (e.g., Chorpita, 2002; Zinbarg & Barlow, 1996); that is, it appears important to assess not only the symptoms of particular disorders or syndromes but also the higher-order affective and arousal dimensions related to those syndromes.

Research has provided at least an initial outline of the relation between the constructs of NA and PH, and has resolved the issues of terminology to some degree as well (Brown et al., 1998; Chorpita, 2001; Chorpita et al., 1996; Chorpita, Plummer, & Moffitt, 2000; Joiner, Catanzaro, & Laurent, 1996; Lonigan et al., 1999). Figure 8.1 shows the basic relations identified in children among dimensions outlined in the DSM-IV and the broader constructs of NA and PH. This general model has been confirmed in four studies in children and adolescents in both clinical and nonclinical

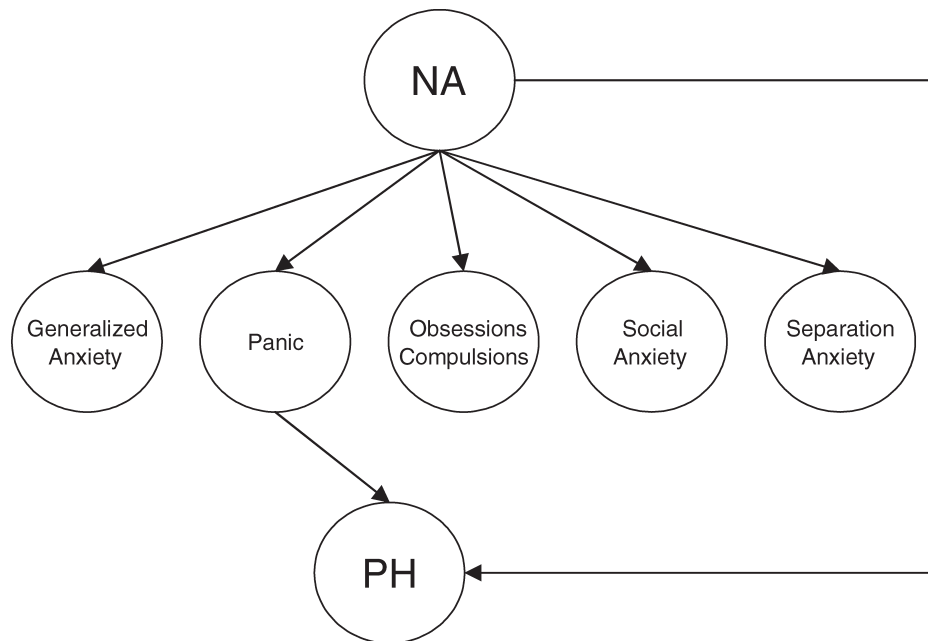

FIGURE 8.1. Model of relations among affective dimensions.

samples, and suggests that NA serves as a risk factor for all of the anxiety syndromes, whereas PH is related only to particular dimensions (Brown et al., 1998). Similar results from an adult clinical sample warranted the reformulation of the tripartite model (Mineka et al., 1998): Rather than being uniformly associated with anxiety, PH is associated with only particular anxiety syndromes (e.g., panic; Brown et al., 1998).

This integration of the literature on PH and NA with diagnostic syndromes also serves to explain the historical divergence of the child assessment literature and the diagnostic classification system. It seems likely that most of the traditional measures of anxiety in children were designed to assess broad trait dimensions; hence, they converged with broader constructs such as NA. More recent strategies keyed to diagnostic symptoms yielded confirmation of those respective syndromes. Taken together, these results illustrate two conceptual levels by which to consider clinical manifestations of fear and anxiety in youth. Given the current state of the literature, it appears that an understanding of both general factors (i.e., negative affect and arousal) and specific syndromes (e.g., clinical disorders) are important in terms of informing the treatment of anxious psychopathology.

Because accumulating evidence suggests that the broad term “anxiety” may be multifactorial, traditional measures of “anxiety” may be conceptually overinclusive. Not surprisingly, early measures of childhood anxiety had demonstrated problems with discriminant validity. For example, Perrin and Last (1992) found that the Revised Children’s Manifest Anxiety Scale [RCMAS], the Fear Survey Schedule for Children—Revised [FSSC-R], and a modified version of the State–Trait Anxiety Inventory for Children—Trait [STAIC-T] (Fox & Houston, 1983) failed to discriminate between boys with anxiety disorders and those with ADHD, and that the FSSC-R failed to discriminate between boys with anxiety disorders and those with no history of psychiatric illness. The laws of the nomological network, however preliminary, suggest that children with anxiety disorders should score higher on anxiety measures than children with other disorders or no disorders. Similar results have been found with the related construct of anxiety sensitivity, a measure of which failed to discriminate between children with ADHD and those with

anxiety disorders (e.g., Rabian, Peterson, Richters, & Jensen, 1993). Given these issues, Stark and Laurent (2001) have considered whether “it is time to move to [the] next generation of measures” in assessing childhood anxiety (and depression). Fortunately, some new measures (reviewed later in the chapter) are consistent with the multidimensional and hierarchical nature of the nomological network.

QUESTIONS RELEVANT TO ASSESSMENT

In this section, we cover two topics: the purposes of assessment, as we see it, and assessment methods typically employed.

Purposes of Assessment

Essentially, assessment is an activity performed to inform a plan. That plan may include educational placement, a psychosocial treatment plan, the decision to start day care, the use of medication, and so forth. Assessment approaches for childhood fears and anxieties (see below) are extremely diverse. However, given issues related to stigmatization and test error, assessors should generally employ incremental approaches, and use increasingly more tests only as dictated by a lack of clarity for impending clinical or caregiver decisions.

Assessment generally informs three major decisions: (1) identification–screening, (2) triage–treatment planning, and (3) outcome assessment. The first decision involves determining whether the child has a fear or anxiety disorder that warrants treatment; that is, one must identify (1) whether the condition is developmentally inappropriate in the observed context, and (2) whether the condition causes sufficient distress or interference to merit being addressed formally in some way. We refer to this as the identification and screening phase. The first part of this decision is often guided by measures of anxiety or related constructs, to determine whether intensity or severity is outside of the developmentally normative range. The second part of that decision, however, must typically be informed by a measure related not to fear or anxiety per se, but to its functional consequences. For example, failure to attend school, lack of friends, feelings of extreme distress, and academic impairment—all indicators of possible need for treatment—are not always assessed solely by anxiety measures.

A related screening purpose that is becoming more common, universal screening for identification of at-risk youth (e.g., for prevention programs), may also be called prescreening, because the goal is not so much to determine need for treatment as to determine need for further screening. We differentiate this *prescreening* from the screening that might happen at the time of a mental health referral, because the latter also represents the beginning of the second purpose of assessment, treatment planning.

Once sufficient information is available to suggest the need for treatment, the second decision involves determining the nature of the fear or anxiety, so that appropriate treatments can be tailored to the condition. We refer to this phase as triage and treatment planning. Traditions for informing this decision vary widely, from diagnosis to functional analysis, to various case conceptualization approaches; these methods are reviewed in some detail below.

Finally, the third assessment decision typically involves measuring the ongoing effects of a plan or intervention (i.e., outcome measurement). Such measurement strategies typically involve brief, focused measures that provide regular feedback about the effects of treatment and its components. For example, weekly observation of the frequency of speaking in class might indicate whether particular aspects of a social anxiety intervention are working as intended. These repeated assessments are typically briefer and more focused than the earlier comprehensive assessments, although they often share common measurement tools.

Sometimes, all three assessment goals—identification—screening, triage—treatment planning, and outcome measurement—may be served by the same assessment tool; however, this is not often the case. A measurement tool designed to differentiate between normal and abnormal levels of anxiety may not inform treatment planning well, except to indicate that treatment is indicated. For example, a high score on the Screen for Child Anxiety Related Emotional Disorders (SCARED; Birmaher et al., 1997) informs the assessor about broad diagnostic areas of concern (e.g., separation anxiety) but does not identify the proximal influences on those concerns (i.e., the related antecedents, behaviors, and consequences that need to be addressed to remedy the problem). As another example, relevant outcomes may shift throughout treatment as the client im-

proves, or as new treatment goals emerge. As such, outcome measurement needs to shift and may often be different than the initial assessment tools used to screen or identify treatment foci. Throughout our review of the available assessment tools, we clarify the use(s) of each tool for these three purposes.

Assessment Methods

In this section, we briefly describe the primary methods used to assess child anxiety. The primary assessment methods in the child anxiety literature are similar to those in other areas and consistent with the multifaceted nature of anxiety in youth. These methods include questionnaires, structured diagnostic interviews, direct observation, and physiological assessment. Our discussion of questionnaires and interviews here is brief and restricted to providing an overview of the method; the subsequent measures review provides specific examples of measures, along with psychometric data. Our discussion of observational and physiological methods is more extended, because we do not provide a review of specific methods in the review section later. We conclude the section with a description of case conceptualization, a method frequently used in practice, but one for which it is difficult to gather traditional psychometric data.

Questionnaires

Questionnaires possess tremendous efficiency, especially in clinical practice. Most questionnaires do not require expertise for administration; thus, they are easily implemented in a busy clinical practice by an assistant. In some instances, computer-aided administration is possible, allowing the client to complete the questionnaire at home in between sessions. Questionnaires also permit a high degree of respondent confidentiality/privacy, in the sense that the respondent is permitted to reveal personal feelings without having to speak them to another person. Questionnaires also have the advantage of being the most thoroughly researched assessment methods. As such, there is a relative plethora of data on the performance of many of questionnaires. Furthermore, questionnaires have the advantage of multiple versions to include multiple reporters, a key issue in assessing children. Disadvantages to the use of questionnaires include the lack of a system-

atic way to follow up on responses to clarify meaning or to ensure validity. As an example, a respondent who may not fully understand the meaning of a question might respond in a less than valid manner. Another problem with questionnaires is that the information gleaned is limited to what is asked. Finally, questionnaires require literacy. This issue complicates their use with younger children, youth (and parents) with limited literacy, and youth for whom a questionnaire is not available in his or her primary language.

Structured Diagnostic Interviews

The current state of the art for clinical diagnosis involves the structured diagnostic interview (Shaffer, Lucas, & Richters, 1999). Compared with unstructured clinical interviews, structured diagnostic interviews (1) yield more objective and quantifiable data, (2) facilitate comprehensive assessment of a range of disorders, and (3) increase the specificity of the information gathered (Costello, Egger, & Angold, 2005; Shaffer et al., 1999). One of the main limitations of these interviews is the lengthy administration time. Assessment of a child and parent with a typical interview may take up to 4–5 hours, not including scoring and interpretation. Although the data obtained are often quite rich, such procedures are likely not feasible in many service settings. As a compromise, it may be preferable to administer the portions of a structured interview that seem relevant based on some screening work (via phone, etc.). In an investigation of such an approach, Chorpita, Yim, and Tracey (2002) report that preliminary evidence suggests similar accuracy can be obtained in less time, when screens are performed with carefully selected instruments.

In general, two types of structured interviews are available: (1) respondent-based and (2) interviewer-based (e.g., Shaffer et al., 1999). The former interview has as its prime advantage the ability to use lay interviewers. With respondent-based approaches, the format of the interview is tightly controlled, requiring mostly yes–no responses. The questions are also worded such that no special knowledge of the DSM is needed to administer the interview. Interviewer reliability, then, is rarely an issue so long as the interviewers are well trained to follow the protocol. However, such interviews have the possible disadvantage of respondent unreliability given that an interviewer is allowed to clarify only conceptual issues (e.g.,

the meaning of “obsessions”) within certain limits. Furthermore, an interviewer is not permitted to probe yes–no answers, even when he or she suspects that the respondent misunderstood a question. Interviewer-based approaches, on the other hand, require a clinically trained interviewer who is familiar with the DSM. Such interviews allow the interviewer to ask multiple questions to gather a thorough understanding of responses.

Observational Methods

Because relying on child and parent report alone limits what one can learn, it is often advisable to use assessment procedures other than questionnaires and interviews. The most common observational procedure for anxiety assessment, the behavioral avoidance test (BAT), can be administered in either laboratory or naturalistic settings. These procedures have been used to assess fears of heights (Van Hasselt, Hersen, Bellack, Rosenblum, & Lamparski, 1979), social interaction (Eisen & Silverman, 1991), blood (Van Hasselt et al., 1979), animals (Evans & Harmon, 1981), and darkness (Kelly, 1976). For the most part, these measures were designed for specific, idiographic purposes, and not for nomothetic standardization. In other words, these measures were created and adapted to specific uses within a particular study, or for the treatment of a specific child. As a result, they do not possess the same evidence base as the interviews and questionnaires we describe shortly. However, because of the utility of BATs in clinical practice, we recommend their use as a means of assessing treatment progress and outcome. The BAT has numerous advantages, including (1) a straightforward procedure, (2) a direct relevance to desired outcomes, and (3) concurrent monitoring of different types of responses (e.g., physiological responses and motor behavior).

That said, there are also several limitations of the BAT. First, as we noted, the absence of a standardized BAT procedure makes cross-study comparisons difficult. This can also complicate interpretation of BAT results. For example, criteria used to determine clinical severity (e.g., the need for formal intervention) of a particular response may be rather subjective, with some judges, but not others, interpreting a given response as abnormal. Second, as typically used, a BAT affords the subject a high level of control, a factor that is not likely to occur in natural settings. Although the BAT may

track a specific outcome of interest, it is not clear how well BAT results generalize to new situations and contexts. Thus, clinicians may choose to design BATs that include less control for clients, and that are implemented in natural or varied settings.

As an illustration, we routinely use questionnaire data both to conduct initial assessment and to track progress and outcome. Questionnaires are generally designed to capture broad patterns of symptoms or functioning. Often, however, treatment for a youth with an anxiety disorder may have a few specific outcomes in mind, such as a return to school or an increase in social interaction. The use of a BAT to track these specific outcomes is often more sensitive and outcome-relevant than questionnaire or interview data. In the case of Frank, an 11-year-old youth with school refusal behavior stemming from social and separation anxiety, we used multiple questionnaires throughout treatment. However, a key index was observing and tracking his approach and avoidance behaviors regarding school. We implemented a naturalistic, “moving-target” BAT with school attendance as the goal, so that as Frank was successful in lower level approach behaviors, we continually updated the goal criterion. At first, this meant that time he spent in the parking lot of the school was tracked. However, as treatment progressed, we tracked the time spent in the classroom. In parallel fashion, we also measured Frank’s specific avoidance behaviors, such as covering his head with his coat. In the end, although other, more general outcome indices showed improvement as well, these specific areas tapped by a customized BAT very likely assessed the most important outcome from the perspective of the consumers.

There are some measurement issues that all observational methods have in common (Barrios & Hartmann, 1997). One such issue is accuracy, which is the ability to obtain data that reflect without distortion the domain under investigation (Foster, Bell-Dolan, & Burge, 1988). To ensure accuracy, observational methods must be compared with an objective criterion; however, oftentimes such a criterion does not exist, so the accuracy of observational methods cannot be ensured (Foster & Cone, 1980). Another issue is reactivity, which means that the mere presence of observers can influence the behavior being observed (Tyron, 1998), leading subjects to act differently than they would otherwise act. There is some evidence, however, that children are not as prone as adults to reactivity

(Foster & Cone, 1980). Some methods for minimizing reactivity include using participant observers, and video cameras or tape recorders; minimizing subject–observer interaction; and allowing enough time for reactivity to lessen (Haynes & Horn, 1982). Yet another issue is factors that may bias the reports of observers, such as expectancies and observer drift. For example, knowing the experimenter’s expectations might influence observers. “Observer drift” describes tendency of trained observers to rate the same events differently over time (Tyron, 1998). Regular agreement checks and effective observer training are important to minimize observer bias (Harris & Lahey, 1982). A final problem is that direct observation methods often lack feasibility in applied settings. They are not only more challenging to administer but also the chances that such methods in clinical settings have the same scope of dissemination and penetration as standardized questionnaires and checklists—now often available on the Internet—seem relatively low.

In summary, observation methods clearly have a place in assessment of anxiety. However, given the lack of standardization and norms, they likely work best when supplemented with other methods, such as structured interviews, self-report measures, and psychophysiological measurement to obtain a full picture of the phenomenon of anxiety. Furthermore, observational methods are most useful as measures of treatment planning and outcome rather than for screening purposes. Indeed, repeated BATs in some ways are difficult to distinguish from treatment itself. Finally, although observational measures have been used for many years, their psychometric standing is relatively unknown in clinical populations of children. As our review indicates, only a handful of studies have examined the properties of these assessment methods. In the end, though observational measures are important tools in the assessment armamentarium, they no longer play the central role they played in the past (Mash & Foster, 2001).

Physiological Assessment

Another assessment method that eliminates the reliance on potentially subjective reporting is using physiological indices, such as heart rate, blood pressure, cortisol levels, or galvanic skin response (Beidel, 1988, 1991). Although measurement of anxiety with physiological methods makes theoretical sense, because anxiety (and stress) have clear physiological mani-

festations and underpinnings (Barlow, 2002), anxiety-focused research on such measures with children is rare (e.g., Beidel & Turner, 2005; see also Wilhelm & Roth, 2001, for discussion of the rarity of such measures in adult anxiety research). Thinking broadly, physiological measurement of reactivity to stress typically focuses on two systems: the hypothalamic–pituitary–adrenal (HPA) and the sympathetic–adrenal–medullary (SAM) systems (e.g., Bauer, Quas, & Boyce, 2002). In the child anxiety literature, most measures have focused on the SAM system, relying on indices such as heart rate (HR) or blood pressure (BP). Some studies have also used galvanic skin response (GSR). To date, the number of such studies that has examined psychometric properties of these methods is quite small; hence, we do not review them in the section below.

As noted, HR and BP (and, to a lesser extent, GSR) are used as indices of SAM activity. Recent psychophysiological research has suggested that better measures for SAM activity may exist, so that it is possible to disentangle sympathetic and parasympathetic arousal (e.g., Brenner, Beauchaine, & Sylvers, 2005; deGeus & van Doornen, 1996). Both HR and BP gauge the combined activity of the two systems (Bauer et al., 2002). Two indices, heart rate variability (HRV; essentially, variance in observed HR) and respiratory sinus arrhythmia (RSA; HR fluctuation as it relates to respiration), are thought to tap parasympathetic arousal. There is some controversy as to the optimal way to gauge RSA and HRV, discussion of which is beyond the scope of this chapter (de Geus & van Doornen, 1996). A third index, the preejection period (PEP; time between two cardiac events—the depolarization of left ventricle and ejection of blood into the aorta), is thought to index sympathetic arousal. Together, RSA or HRV and PEP afford a good way to gauge the complexity of SAM activity (de Geus & van Doornen, 1996). However, the utility of these indices for anxiety assessment is less clear for at least two reasons. First, we could not identify any studies that specifically link any of these measures to anxiety in a child population. Thus, there is too little research in the area to judge the value of these measures. Second, because all three measures are likely to gauge constructs broader than anxiety alone (e.g., Beauchaine, 2001; Thayer & Lane, 2000), their use in assessment of anxiety (e.g., vs. negative temperament, depression) is not

clear. Still, there has been increasing interest in these measures to gauge several anxiety-related constructs, including children's stress reactivity, child temperament, and child emotion regulation (e.g., Alkon et al., 2003; Boyce et al., 2001; Calkins & Dedmon, 2001; Granger, Weisz, & Kauneckis, 1994; Kagan et al., 1988). Thus, future researchers should consider including measures such as RSA, HRV, or PEP in their child anxiety studies to inform the field as to their helpfulness.

Studies concerning markers of the HPA system in the child anxiety literature are even rarer than those that focus on the SAM system, perhaps because such measurement entails collection of blood, urine, or saliva, adding both complexity to the study design and implementation, and a potentially unpleasant demand on participants. HPA activity is usually assessed through measurement of cortisol levels (in blood, urine, or saliva) or, less often, measurement of adrenocorticotrophic hormone (Bauer et al., 2002). Some have advocated measuring HPA activity via other means (e.g., dehydroepiandrosterone [DHEA] and its sulfated ester [DHEAS]; Granger & Kivlighan, 2003). Research on HPA activity has been somewhat more common in youth with depressive or conduct disorders (e.g., Goodyer, Park, & Herbert, 2001; Pajer, Gardner, Rubin, Perel, & Neal, 2001; van Goozen, Matthys, Cohen-Kettenis, Thijssen, & van Engeland, 1998). Similar to our conclusions about the newer indices of the SAM system, research is needed to determine the utility of biochemical markers of the HPA system for assessing anxiety.

In summary, physiological measures represent an exciting yet understudied area in the assessment of anxiety in children. Because of scant available data about the performance of these measures in assessing anxiety in children, we cannot yet recommend them for any of the three primary purposes of clinical assessment: (1) screening, (2) treatment planning, or (3) outcome measurement. However, we do see a potential for growth in the role of these measures in the coming years, especially as they are better studied and their methods become less intrusive. Indeed, there may be a time when physiological measurement becomes a key part of screening for anxiety or anxiety risk, as well as an important outcome measure. It is even conceivable that should methods become more accessible, treatment planning might be aided by physiological measurement.

Case Conceptualization

We conclude our review of assessment methods with a brief description of a method that is an important component of any assessment, yet is not itself subject to scientific study: *case conceptualization*. Although case conceptualization takes many forms, we focus here on functional assessment (FA). The basic premise behind case conceptualization is that in addition to nomothetically oriented assessment tools, an idiographic formulation is needed for each client/patient to individualize treatment (e.g., Freeman & Miller, 2002). A case conceptualization is essentially a “story” that describes the client’s problems and strengths, posits hypotheses for why they have come to be, and offers possible remedies for the problems (e.g., Freeman & Miller, 2002). In this way, case conceptualizations must be rooted in theoretical assumptions about the variables that cause and influence behavior. Two recent treatment programs, multisystemic therapy (MST; Henggeler, Schoenwald, Rowland, & Cunningham, 2002) and primary and secondary control enhancement training (PASCET; Weisz, Southam-Gerow, Gordis, & Connor-Smith, 2003), include aspects of case conceptualization. In the case of MST, there is explicit and ongoing use of the specific case conceptualization method FA throughout treatment.

In FA, a number of steps are followed. The problem(s) is defined as behaviorally as possible. Then, a number of factors relevant to the problem are identified, including (1) background/historical variables assessed, (2) antecedent events, (3) established operations (i.e., events or conditions that alter the effect of other events or conditions), and (4) consequences. Once the relevant factors are identified, hypotheses are developed that connect the factors to the problem, then tested in the treatment process, and the new data that emerge are used to modify the case conceptualization. In this way, case conceptualization that uses FA is an ongoing and iterative process: The case formulation is fluid and not static.

INSTRUMENT REVIEW

Review Parameters and Procedures

Our intention in this chapter is to identify the most commonly used instruments for child anxiety and to review their psychometric prop-

erties to help guide assessors in selecting the best instruments for the assessment task. To do that, we have used several strategies. First, we conducted a PsycINFO search using the following parameters: [anxiety or fear or worry or panic or avoidance or phobia or obsession or compulsion or stress] and [measure or instrument or scale or questionnaire or assessment] and [child or children or youth or adolescent]. We included only articles from 1970 to the present. The PsychINFO search netted 6,052 articles. In addition, we searched through the reference lists of anxiety measurement review articles (e.g., Barrios & Hartmann, 1997; Myers & Winters, 2002), related chapters on treatment (e.g., Chorpita & Southam-Gerow, 2006), and the reference lists of articles we retrieved from the initial search. With additional articles added from reference list searches, we identified a pool of 7,218 articles. We then screened this pool using the criteria listed in Table 8.2.

From our initial sample of over 7,200 articles, 188 met the criteria in Table 8.2. A team of coders examined these studies using a detailed coding manual (available upon request). The coding process involved extracting data from the articles in the categories listed in Table 8.3, consistent with criteria proposed by Stallings and March (1995; see also Greco & Morris, 2004). Coding meetings were held at least biweekly during the coding, and all coders were in regular contact. Of the 188 articles, 15% (30) were double-coded to ensure consistency. Interrater kappa coefficients were over .90 for all codes.

Results and Discussion of Review

As noted earlier, there are different procedures and methods that can be used to assess anxiety, including questionnaires, interviews, observations, and physiological measures. The two former methods have received the most research attention by far, at least according to the criteria we used to establish our sample. With regard to questionnaires, we found 150 articles that met our criteria, whereas for interviews, we found 33 articles meeting those same criteria.

The number of articles meeting our criteria that focused on physiological or observational measures was considerably smaller. This outcome was not surprising for physiological measures given their expense and concerns raised

TABLE 8.2. Screening Criteria for Article Coding

-
1. The article evaluated a measure that purports to assess an *anxiety-related* construct, including *but not limited to*:
 - Anxiety
 - Fear
 - Worry
 - Panic
 - Avoidance
 - Any DSM anxiety disorder (e.g., phobia, OCD, GAD)
 - But *not* including the following
 - Traumatic stress or PTSD
 - Anxiety-relevant temperamental characteristics
 - Test anxiety
 - Medical- or dental-related anxiety

To meet this criterion, the evaluated measure must have at least one anxiety-specific scale. Measures that included broad anxiety/depression scales only (e.g., Child Behavior Checklist) were not included.
 2. The study had a minimum sample size of 25 child/adolescent (i.e., ages 5–18) cases. Studies of infants, toddlers, and preschoolers were not included.
 3. The primary or secondary focus of the article was an examination of a measure's psychometric properties (reliability and/or validity and/or factor analysis). In other words, the study must have as one of its purposes the examination of the psychometric properties of a measure of an anxiety-related construct.
-

about their reliable use with children (e.g., Beidel, 1991). Because we were able to identify only a handful of studies that examined physiological measures and met our inclusion criteria, we chose not to discuss specific physiological measures in this chapter.

It was surprising that our search identified so few psychometric studies of observational measures, in contrast to earlier chapters on fears and anxieties (e.g., Barrios & Hartmann, 1997). Our review suggests that questionnaires and interviews are now the prominent methods of assessment. Furthermore, inspection of the studies on observational measures in earlier chapters reveals that most of the cited studies had very small samples, many with an *n* of 1. Our criterion requiring a minimum sample size

of 25 excluded many of these studies. Even studies with sample sizes above 25 were primarily treatment studies, whose focus was evaluation of a treatment and not the psychometric properties of any particular measure. As a result, available psychometric data of the observational measure were inadequate. Furthermore, as described earlier, the measures were typically designed for a specific study and were often idiographic (i.e., designed for a specific child's clinical presentation). Thus, we do not discuss observational measures further.

Questionnaires

We identified 151 articles examining the psychometric properties of 48 different questionnaires. Among the 48 questionnaires were multiple variants of certain questionnaires; for example, the FSSC has multiple revisions and has been translated into several languages. Almost one-third of the articles we identified were published in 2000 or later, indicating an accelerating trend in anxiety assessment research. Questionnaires studied ranged in size from 10 items to over 400. Overall, the large majority of questionnaires had child report versions (38 of the 48 questionnaires). We identified 13 different measures in our review that had parent report versions, 6 that had a teacher

report version, and 2 that had a clinician report version. From a purely quantitative view, the RCMAS (Reynolds & Richmond, 1978), the STAIC (Spielberger, 1973), and the FSSC-R (Ollendick, 1983) were the most studied measures, with more than 15 articles on each of the measures. However, since 2000, the most frequently studied measures were the SCARED (Birmaher et al., 1997), the STAIC, and the Childhood Anxiety Sensitivity Inventory (CASI; Silverman, Fleisig, Rabian, & Peterson, 1991). Descriptive data on the 14 most studied questionnaires are listed in Table 8.4.

The discussion of our findings is divided into two sections. First, we provide a brief description of the 14 instruments that received the most empirical attention (see Table 8.4). After a brief description of each measure, we discuss the psychometric characteristics of each. Because of the great number of questionnaires studied, we focus our discussion here on the 14 most frequently studied measures.

OVERVIEW OF QUESTIONNAIRES

We identified three basic types of questionnaires in our review. First, there were two “trait” measures referred to by Muris, Merckelbach, and colleagues (2002) as “traditional” anxiety measures: the RCMAS (Reynolds & Richmond, 1978) and the STAIC (Spielberger, 1973). Second, there were several “multidimensional” anxiety questionnaires, most of which focus on DSM-IV categories, including the Revised Child Anxiety and Depression Scale (RCADS; Chorpita, Yim, Moffitt, Umemoto, & Francis, 2000), the SCARED (Birmaher et al., 1997), and the Spence Child Anxiety Scale (SCAS; Spence, 1998). The Multidimensional Anxiety Scale for Children (MASC; March, Conners, et al., 1999), another multidimensional instrument, does not follow DSM criteria as closely in its construction. Finally, several questionnaires assessed more specific problem areas or *syndromes* within the anxiety spectrum, including social anxiety, OCD, worry, phobias/fears, and school refusal. In this section, we briefly describe each of these 14 measures to provide an overview before presenting the psychometric characteristics of each.

We begin with the two trait measures of anxiety, the STAIC and the RCMAS. Explicitly based on the state–trait distinction (Gaudry, Vagg, & Spielberger, 1975), the STAIC includes

two separate 20-item scales (i.e., state and trait anxiety) that may be administered separately or together.¹ The measure consists of statements (e.g., “I worry too much,” “I get jittery”) for which a respondent is rated on a 3-point scale (*Hardly ever, Sometimes, Often*). The STAIC has been translated in to multiple languages, including Chinese (e.g., Li, Cheung, & Lopez, 2004a, 2004b), Dutch (Muris, Gadet, Moulart, & Merckelbach, 1998), and Thai (Chaiyawat & Brown, 2000). Another traditional trait measure, the RCMAS, is a 37-item instrument that possesses a “total” scale, three anxiety-related subscales (i.e., worry/oversensitivity, concentration, and physiological anxiety), and a “lie” scale. The RCMAS comprises a series of yes–no questions (e.g., “Often I have trouble getting my breath,” “I often worry about something bad happening to me”).

Alternatively, the multidimensional measures of anxiety include three DSM-IV–based scales and one additional multidimensional scale (see Table 8.5). The RCADS, a 47-item DSM-IV–based instrument, includes a total anxiety and depression scale and a total anxiety scale. In addition, there are five anxiety disorder–related scales and a major depressive disorder scale (see Table 8.5). RCADS items are designed to index DSM-IV syndromes; a respondent uses a 4-point scale (*Never, Sometimes, Often, Always*). Another DSM-IV–based instrument, the SCARED, has two different versions: the original SCARED and a revised version (SCARED-R). The former has 41 items (e.g., “I am nervous,” “When I get frightened, my heart beats fast”) and possesses a “total” scale and five DSM-IV subscales (see Table 8.5). The SCARED-R has 66 items, with a “total” scale and nine DSM subscales (see Table 8.5). The SCARED and SCARED-R both employ a 3-point scale (i.e., *Almost Never, Sometimes, Often*). The SCAS, the final DSM-IV–based scale, has 44 items (e.g., “I worry about being away from my parents,” “I feel afraid if I have to talk in front of my class”) and includes a “total” scale and six DSM-IV subscales (see Table 8.5). The SCAS uses a 4-point scale (i.e., *Never, Sometimes, Often, Always*). Although all three of these instruments are DSM-IV–

¹Although data exist with regard to the State version, our discussion here is focused on the Trait version of the measure.

TABLE 8.4. Descriptive Information for Selected Questionnaires

Measure name	Abbrev.	Type	Construct	No. of subscales	No. of items	Time to complete (min)	Cost (company)?
Revised Children's Manifest Anxiety Scale	RCMAS	Trait	Anxiety	3	37	9	Yes (Pro-Ed)

based, they do not cover the same disorders (see Table 8.5 for details).

The final multidimensional measure of anxiety, the MASC, does not draw solely on a DSM conceptualization of anxiety. The MASC is a 39-item (e.g., “I feel tense or uptight,” “I get scared when my parents go away”) measure that indexes a single personality dimension, as well as physiological arousal and two clinical syndromes. The MASC possesses a “total” scale and four subscales: (1) Harm Avoidance, (2) Physical Symptoms, (3) Separation Anxiety, and (4) Social Anxiety. In addition, two other subscales have been developed for the MASC, an Anxiety Disorder Index and a 10-item “Short” version of the total instrument. The MASC uses a 4-point scale (i.e., *Never true, Rarely true, Sometimes true, Often true*).

In addition to the trait and multidimensional measures, we also identified several measures that trade off bandwidth for fidelity (e.g., Cronbach, 1970) by focusing exclusively on narrow, anxiety-related syndromes (e.g., social anxiety, phobias/fears). For example, two measures of social anxiety received a lot of empirical attention: the Social Anxiety Scale and variants (SAS; e.g., La Greca, Dandes, Wick, & Shaw, 1988) and the Social Phobia and Anxiety Inventory and variants (SPAI; Beidel et al., 1995). The SAS, a 22-item (e.g., “I worry about what others think of me,” “I get nervous when I talk to peers I don’t know very well”) measure, has been studied in its child (SASC), revised child (SASC-R), and adolescent (SAS-A) versions. Across all versions, there has been a “total” scale and three subscales: (1) Fear of Negative Evaluation, (2) Social Avoidance and

Distress–New Situations, and (3) Social Avoidance and Distress–General Situations. The SAS uses a 5-point scale (i.e., from *Definitely not true* to *Definitely true*). The child version of the SPAI, the SPAI-C, is a 26-item (e.g., “I avoid social situations,” “I feel afraid if have to ask questions in class”) measure with a “total” scale and three subscales: (1) Fear of Adults, (2) Fear of Familiar Peers, and (3) Fear of Unfamiliar Peers. However, these scales have not been consistently confirmed across all studies; some researchers have posited other scales based on factor analysis (e.g., Storch, Masia-Warner, Dent, Roberti, & Fisher, 2004). The SPAI-C uses a 3-point scale (i.e., *Never, Sometimes, Most of the time/Always*).

Of the several measures of OCD receiving empirical attention, only the Child Yale–Brown Obsessive–Compulsive Scale (CY-BOCS; e.g., Scahill, Riddle, & McSwiggin-Hardin, 1997) and the Leyton Obsessional Inventory—Child version (LOI-C; e.g., Berg, Rapoport, & Flament, 1986) have been studied psychometrically. The CY-BOCS, based on an OCD measure for adults, was originally developed as a clinical interview, later adapted into a clinician-administered questionnaire, and has recently been adapted into a checklist. There is a 10-item clinician-administered version of the measure comprises a “total” scale and three (or four) subscales (depending on the study): (1) Obsessions, (2) Compulsions, (3) Severity, and (4) Disturbance. There is also a 79-item checklist of the measure that can be self-administered; this version possesses a “total” scale and the four subscales listed earlier. The CY-BOCS uses a 5-point scale (i.e., higher rat-

ings indicate greater severity). The LOI-C has 20- and 44-item versions (e.g., “Do you hate dirt and dirty things?”; “Do thoughts or words ever keep going over and over in your mind?”). Across several studies, different factor structures have been reported, from a total score plus two-factor (i.e., Total Obsessive and Total Interference scales) version to a total score plus four-factor (i.e., General Obsessive, Numbers/Luck, Dirt/Contamination, School) version. The LOI-C employs a yes–no response format.

Although several measures that were studied tapped worries, only one measure was the focus of more than one study: the Penn State Worry Questionnaire for Children (PSWQ-C; Chorpita, Tracey, Brown, Collica, & Barlow, 1997). This 14-item (e.g., “My worries really bother me,” “I am always worrying about something”) measure has a single total scale. The PSWQ-C employs a 4-point scale (i.e., *Never true, Sometimes true, Most times true, Always true*).

Another “syndrome” measure, the School Refusal Assessment Scale (SRAS; Kearney & Silverman, 1993), is a 24-item (e.g., “How often do you have bad feelings about going to school because you are afraid?”; “How often do you feel you would rather be with your parents than go to school?”) instrument designed to assess the function of the school refusal. The measure has four “scales,” essentially the four “functions” of school refusal: (1) Attention Getting, (2) Avoidance/Negative, (3) Escape/Negative Affect, and (4) Tangible Rewards. The SRAS employs a 0- to 6-point scale (*Never to Always*).

The FSSC measure and its variants are designed to tap the severity of fears in childhood and as such represent a gauge of the DSM category specific phobia. For our review, we included studies of the FSSC-R and the second version of the FSSC. The FSSC-R has 80 items (e.g., “Being killed or murdered,” “My parents criticizing me”) and the FSSC-II, 78 items. The FSSC-R uses a 3-point scale (*None, Some, A lot*). It has a “total” scale and five subscales reflecting specific domains of fear: (1) Fear of Animals/Minor Injuries, (2) Fear of Death/Danger, (3) Fear of Failure and Criticism, (4) Fear of the Unknown, and (5) Medical Fears. However, not all studies have identified the same factor structure. Finally, we note that there are psychometric data for Chinese (e.g., Dong, Xia, Lin, Yang, & Ollendick, 1995), Greek (e.g., Mellon, Koliadis, & Paraskevo-

poulos, 2004), and Hawaiian (e.g., Shore & Rapport, 1998) versions of the FSSC and variants.

Both the CASI (Silverman et al., 1991) and its revised version (CASI-R; Muris, 2002) are 18-item (e.g., “It scares me when I feel shaky,” “When my stomach hurts, I worry I might be really sick”) measures, although a 44-item version has also been studied. As described earlier, the CASI “fits” into either the syndrome or response domain category and is often used in studies of panic as an outcome measure and as a marker of sensitivity to the physiological component of anxiety. The CASI employs a 1- to 3-point scale (i.e., *None to A lot*). The measure is generally thought to possess a single “total” scale, though factor-analytic work, described later, has suggested up to five scales.

RELIABILITY

Overall, the literature has no lack of studies examining the reliability of the measures; internal consistency (tapped by Cronbach’s alpha) is by far the most frequently examined psychometric characteristic. Many studies also examined retest reliability using the Pearson r or, more recently, the intraclass correlation coefficient (ICC). Interpretation of the reliability of tests measuring psychological constructs is not a straightforward endeavor; hence, a few prefatory remarks are in order. First, our discussion focuses on measures that tap “trait” (vs. state) experiences (Gaudry et al., 1975). As a result, retest reliability in particular becomes an important indicator. Furthermore, recent emphasis on the multidimensionality of anxiety, discussed throughout this chapter, implies that both total scales and subscales should possess strong reliability. Finally, although the literature has relied almost exclusively on Cronbach’s alpha as an estimate of internal reliability, we do note the current controversy concerning the use of that estimate; the interested reader is referred to this literature (e.g., Becker, 2000; Schmidt, Le, & Ilies, 2003; Zinbarg, Revelle, Yovel, & Li, 2005).

INTERNAL CONSISTENCY

Classic test theory suggests that internal consistency statistics above .80 represent high reliability; estimates between .70 and .80, moderate to low reliability; and scores below .70 represent low reliability (e.g., Murphy &

Davidshofer, 1998). Internal consistency coefficients below .70 raise obvious concern about the reliability of a measure; less obvious are the concerns raised by coefficients that are “too” high. For example, Streiner and Norman (2003) have noted that internal consistency scores exceeding .90 suggest significant item redundancy, a problem that impacts the efficiency of the measure, especially for use in busy clinical settings. Thus, we examined our data for measures scoring “too high” or “too low.” We follow our framework of discussing measures in the following order: (1) trait measures, (2) multidimensional measures, and (3) syndrome measures.

Most studies, and most scales, were found to have strong internal consistency. Table 8.6 summarizes data for the 14 instruments. In particular, the “total” scores for all measures had at least moderate reliability, with the exception of one estimate for the STAIC, which scored .69 (Papay & Hedl, 1978). This is not surprising, because “total” scores represent a reliability estimate with the greatest number of items for each scale; Cronbach’s alpha increases as the number of items increases (Anastasi, 1988). Examining the performance of the subscales of the various measures, we found that most also met the criterion of .80 or higher.

Examining the extreme ends of the spectrum, however, we did find “problems” at both the high and low ends of reliability. Several instruments were found to have reliability estimates exceeding .90. Of the instruments with “high” internal consistency coefficients, the two scales measuring social anxiety (SPAI-C, and SASC and SAS-A) demonstrated potential item redundancy. Concern about the performance of the FSSC-R is also warranted because of the high cost of that measure with regard to item number. Although the SCARED and the SCAS exhibited “excessive” internal consistency coefficients, both screening measures are designed to cover a lot of conceptual ground. As such, the high number of items seems justified. Still, the SCAS appears to be the more efficient measure, if judged solely by internal consistency standards.

Examining the low end of the internal consistency spectrum, none of the “total” scales for any instrument had an internal consistency coefficient below .70. However, several of the instruments’ subscales did yield “low” internal consistency estimates, including scales from the

RCMAS, SCARED, SCAS, MASC, SASC-R, and FSSC-R.

Taken together, these various internal consistency findings yield a few conclusions. First, as would be expected, the “total” scale for each measure performs better than the various subscales. Thus, in general, confidence in the reliability of a measure is greatest for the “total” score. A few instruments were notable for their strong reliability results, including the CASI, RCADS, PSWQ-C, SRAS, and STAIC. Furthermore, many of the subscales from the MASC, SCAS, and SCARED also merit mention. However, as noted, some of the scales were “poor performers”—and some were consistently so. For example, the Concentration and Physiological Anxiety subscales of the RCMAS performed consistently poorly, whereas the Worry subscale of that measure showed more mixed findings.

RETEST RELIABILITY

Given their long history, it was surprising to see a relatively small number of studies examining the retest reliability of the RCMAS and STAIC. Comparably more studies were identified for newer measures such as the SCARED, SCAS, and MASC. In general, most of the statistics were positive: More than 80% of the findings reported a retest correlation above .50. Table 8.6 summarizes the findings from our review. As would be expected, most of the highest coefficients were for relatively brief time periods, 1 to 3 weeks. However, several measures had retest correlations above .70 for time periods of 3 months or longer, including the RCMAS (parent and child report), the CASI, and the SCARED. There was a clear pattern, with longer retest intervals associated with lower reliability estimates.

In short, retest reliability estimates of these various child anxiety measures were strong. However, retest reliability was relatively infrequently assessed. Thus, the strength of our conclusions is limited by the relative paucity of studies, especially in comparison to the much larger number of studies examining internal consistency. Given that the test-retest paradigm measures a different test property than does internal consistency, and is arguably a more robust index of reliability, more research on the reliability of common measures seems warranted.

RELIABILITY: SUMMARY

Overall, there is a reasonable level of confidence in the reliability of many of the questionnaires developed to gauge child anxiety. In particular, the “total” scale of all of the measures performed well. Although this same point also holds for many of the subscales of the measures, there were notable exceptions, especially with respect to scales tapping fears and phobias. We also noted that despite this relatively high level of reliability, the efficiency of some measures must be considered. Measures with potential redundancy generally provide more detailed item-level information; thus, they may be best suited for screening/identification and treatment planning, but not outcome measurement. Finally, data on retest reliability, though somewhat sparse, suggest good support for the measures studied.

VALIDITY

We coded articles for four validity-related measurements: convergent validity (concurrent and predictive), divergent validity, and discriminant validity. In general, the validity evidence amassed for anxiety questionnaires was less impressive than the reliability evidence. Table 8.7 summarizes validity data for the 14 instruments.

The most common pattern in the studies we reviewed was to examine concurrent convergent validity and to do so within informant (e.g., positive correlations of two self-report measures of the same or similar constructs). In these cases, most studies had modestly supportive results. Such a procedure may inflate validity estimates, because some of the shared variance between scores represents informant and method variance (Campbell & Fiske, 1959; Cronbach & Meehl, 1955). When validity was assessed across reporters, correlations were typically not as impressive—an unsurprising finding. Cross-informant discrepancies in reporting on psychopathology are the rule in the literature (Meyer et al., 2001). Thus, it is not clear that poor cross-informant correlations suggest poor validity (Achenbach, McConaughy, & Howell, 1987). Nevertheless, our review suggests that evidence for the validity of many measures of childhood anxiety is still relatively tenuous.

Throughout our discussion of the validity findings for the 14 measures, we focus on the

validity of the “total” scales. We only examine validity evidence of the subclass for the multidimensional measures and the SRAS (by design, the SRAS does not have a “total” scale).

A variety of studies speak to the validity of the “Total Anxiety” subscales of two trait anxiety measures: RCMAS and STAIC. In a particularly informative study evaluating the RCMAS and STAIC, Muris, Merckelbach, and colleagues (2002) reported correlations among these two and four other anxiety measures: FSSC-R, MASC, SCAS, and SCARED. Intercorrelations among these six scales were quite high, exceeding .50 in all cases for the “total” scales of each.

Evidence for the RCMAS is also moderately strong with regard to convergent validity, with correlations with other anxiety measures in appropriate ranges (i.e., above .50). However, correlations with the Children’s Depression Inventory (CDI) were quite high (above .65) across several studies, suggesting the measure may lack divergent validity. Discriminative validity evidence was mixed with some, but not other, studies reporting positive results (e.g., Perrin & Last, 1992). The RCMAS did consistently distinguish between anxious and non-clinical youth groups, but evidence for distinctions among multiple clinical groups was less positive. For example, Chorpita, Moffitt, and Gray (2005) showed that the RCMAS did not significantly discriminate between children with anxiety disorders and children with other disorders ($\alpha = .01$), and that the effect size for this discrimination was approximately one-third that for the RCADS in making the same discrimination.

Finally, regarding the STAIC, there were many more studies examining the validity of the Trait than the State scale. Correlations with contemporary anxiety scales suggested good validity for the STAIC–Trait, with some coefficients exceeding .80 (e.g., RCMAS, SCARED). Evidence was also relatively supportive of the distinction between the Trait and State scales, with correlations falling below .45 across multiple studies. The only study that measured divergent validity for STAIC examined the parent report version (Southam-Gerow, Flannery-Schroeder, & Kendall, 2003); findings suggest moderate divergent validity support, with the STAIC–Trait correlating below .35 with measures of child aggression and externalizing behavior problems. Evidence of discriminative validity was similar to that found for the

Note. Measures for which convergent validity coefficients could not be coded are not included in the table.

* Negative association was predicted (i.e., criterion should be negatively correlated with scale).

RCMAS and the FSSC-R; the STAIC-Trait distinguishes between anxious and nonclinical youth groups, but does not distinguish between anxious and other clinical groups (Perrin & Last, 1992).

Among the multidimensional measures, validity evidence was relatively strong for the "total" scales. For example, the SCARED total scale correlated very highly with the SCAS, RCMAS, MASC, and STAIC total scales ($r > .80$) and nearly at that level with the Youth Self-Report Internalizing Scale (.77), a broad self-report measure of anxiety, depression, withdrawal, and other internalizing dimensions (Achenbach & Rescorla, 2001). Another

notable fact about the SCARED is that compared to any other questionnaire, more studies examined its validity. In comparison, the validity coefficients for the SCAS were also high but not consistently above .80 as were those of the SCARED. Still, most correlations reported for the "total" scale were above .70, suggesting rather strong relationships among these measures of anxiety. Another DSM-based scale, the RCADS, showed similarly high correlations with the RCMAS. However, there were relatively fewer data on the RCADS compared to the SCARED.

The MASC is another measure designed to index multiple dimensions of anxiety, but it

does not rely solely on a DSM conceptualization. Validity evidence for this measure is comparable to that of the SCAS and RCADS, in that correlations were above .60 and often exceeded .70 for relevant child report anxiety measures (e.g., RCMAS, STAIC, SCAS, SCARED).

Overall, the “total” scales for the MASC, RCADS, SCAS, and SCARED all performed quite well with regard to within-reporter correlations. Evidence for cross-reporter correlations is sparse for these measures, and existing data are not highly positive. As an example, the MASC “total” scale correlated .14 with parent report STAIC, despite correlating .60 with the child report STAIC.

Validity data concerning the subscales of the multidimensional scales are best for the SCARED, SCAS, and RCADS. Much of the relevant data concerning the SCARED and SCAS come from a Muris, Merckelbach, and colleagues (2002) study comparing the two instruments (along with four others). On the positive side, the SCARED GAD subscale correlated highly with the PSWQ-C, the RCMAS Worry subscale, and the SCAS GAD subscale. Furthermore, two articles indicated good discriminative validity for the SCARED (Birmaher et al., 1997; Muris & Steerneman, 2001). The SCARED OCD subscale has not been examined in a study including another OCD subscale (e.g., LOI-C, CY-BOCS) except the SCAS OCD subscale; correlations between the two scales were above .65 across two articles. No relevant discriminative validity evidence exists. Similarly, the SCARED Panic Disorder subscale correlates well with the SCAS Panic Disorder subscale (above .73 across two articles). However, the scale correlation is also nearly as high with more general scales, such as the RCMAS (.73) and the STAIC-Trait (.71).

The SCARED SAD scale correlated highly with the SCAS SAD subscale (above .78) across two articles; correlation with the MASC Separation Anxiety subscale was also consistent with expectation (above .60). However, the correlations with the STAIC-Trait and RCMAS total scale were quite high (above .65), reducing the strength of confidence in the distinctness of the scale. The discriminative validity evidence for the scale is positive, however, showing good discrimination even in youth with anxiety disorder diagnoses. The SCARED Social Anxiety subscale did not perform as well. Although correlations with

broader measures were lower than the other subscales reviewed, correlations with the SCAS Social Phobia subscale was lower than expected, around .40, and lower at times than other correlations with other, less relevant scales (e.g., the SCAS OCD subscale). Furthermore, discriminative validity was modest: The scale discriminated between anxious and non-anxious and youth with disruptive behavior disorders, but no within-anxiety specificity was demonstrated. Finally, the evidence for the Phobia subscales of the SCARED was less impressive, mirroring the reliability evidence reported earlier. As an example, the Animal Phobia subscale did not correlate particularly highly with the Animal Fears subscale of the FSSC-R. Because the majority of evidence for the SCARED scales was from studies also examining the SCAS, similar conclusions may be drawn about the subscales of that measure. The SCAS GAD subscale was correlated with the SCARED GAD subscale, though it was as highly correlated with the STAIC-Trait and RCMAS, as well as the SCARED Panic Disorder subscale. Discriminative validity evidence was not strong for the measure. A somewhat better result was found for the SCAS OCD subscale, which correlated highly with the SCARED OCD subscale but less so with more general scales (e.g., RCMAS, STAIC-total), though these correlations were still above .55. The SCAS Panic Disorder subscale was highly (.80) correlated with its corresponding SCARED scale, with other scales correlating moderately to highly (r 's $\leq .71$). A similar pattern was found for the SCAS SAD subscale, though correlations were in general lower across the various measures. Finally, as noted earlier, the SCAS Social Phobia subscale did not correlate as highly as would be expected with the SCARED Social Phobia subscale (below .60).

Recent tests of the validity of the RCADS in a clinical sample lend relatively strong support to its validity. For example, the subscales all correlated positively with the RCMAS (r 's = .59 to .72), with interview-derived ratings of corresponding clinical syndromes (r 's = .34 to .54), and with similar clinician ratings derived from parent interviews (r 's = .22 to .31). As a point of comparison, the RCMAS validity coefficients with these same parent interview-derived ratings ranged from $-.01$ to .16 (all nonsignificant). In a stringent test of divergent validity, four of the five RCADS anxiety scales

(all but panic) failed to correlate significantly with depression scores controlled for variance, as measured by the RCMAS. Thus, although there are few studies on this measure, its psychometric support is so far quite strong.

Next we turn to the validity evidence for the syndrome measures, starting with the social anxiety questionnaires: the SPAI-C and the SASC and SAS-A. Relative to the SPAI-C, a much greater number of studies have focused on the SAS and its variants. Correlations between the two “total” scales have been greater than .60. A positive finding is that both measures correlate more highly with each other than with anxiety measures with more bandwidth, though correlations with these broadband measures are generally above .40. The “total” scale of the SAS and its variants also had modest relationships with a variety of measures of social competence (e.g., number of friends), with Pearson r 's in the range of .15 to .30. Correlations were typically higher for girls than for boys, although examinations of difference were not always reported. Similarly, the SPAI-C “total” scale was modestly related to observed social behavior, again in the .15 to .30 range, though some relationships approached .40 (e.g., speech latency).

Although the SPAI-C has several subscales, we deemed the evidence too preliminary to evaluate their validity, particularly given the notion that the measure itself may possess greater validity for subdimensions than the criteria to which it might be compared (Cronbach & Meehl, 1955). The subscales of the SAS and variants have received somewhat more empirical attention. The SAS has three subscales: (a) Fear of Negative Evaluation (FNE), (2) Social Avoidance/Distress–General (SA/D-Gen), and (3) Social Avoidance/Distress–New Situations (SA/D-New). In general, these scores had intercorrelations in the .50–.60 range, suggesting that though they do have considerable overlap, there is also support for their distinctness. For convergent validity, studies compared the subscales with the RCMAS or measures of social and relational functioning. The FNE subscale correlated above .50 with the RCMAS across three articles, whereas the magnitude of the correlations for the other two subscales (SA/D-Gen and SA/D-New) was somewhat lower across these studies, with correlations around .40. All three scales also correlated with the Social Acceptance subscale of the Harter Social Competence Measure; these correlations were

higher for girls than boys. For the FNE and SA/D-New subscales, correlations with other measures of social competence (e.g., number of friends, social skills) were modest (.20 and below); somewhat stronger ($r = .30$) relationships emerged between these same indices and the SA/D-Gen. In general, the subscales did not perform as well as the “total” scale. In general, both the SAS and the SPAI subscales face the challenge of validation in an area in which suitable validity criteria are difficult to identify. Although evidence does not appear to favor either instrument, data to date are more plentiful for the SAS (and variants).

As noted earlier, the FSSC and variants (e.g., revised version, non-English versions, FSSC-II) tap fears and phobia. The measure has demonstrated moderately strong convergent validity evidence, with correlations above .50 with the RCMAS, STAIC, MASC, SCAS, and SCARED. However, some studies have reported correlations as low as .31. The two articles reporting discriminative validity evidence were mixed: One (Ollendick, 1983) found that the measure distinguished between phobic and normal youth, whereas the other (Perrin & Last, 1992) found that the measure did not distinguish between anxious and normal youth or those with ADHD.

Turning now to measures of OCD, we note preliminarily that the CY-BOCS was sometimes administered as a questionnaire and sometimes as an interview. For this discussion, we include data on both versions. Between the LOI-C and CY-BOCS, the latter has the best validity profile, with relevant validity correlations exceeding .60 for the total scale. Furthermore, correlations with general anxiety measures (e.g., RCMAS, MASC total) were appropriately lower (below .40), suggesting that the CY-BOCS is not simply a measure of general anxiety. We discuss the factor-analytic results of the measure shortly. However, there is little discriminant validity evidence for the measure. Evidence for the LOI-C is much weaker. In fact, of the two articles we identified that examined the validity of the measure, neither was particularly supportive. None of its scales correlated significantly with relevant measures in one article (Berg et al., 1986). Although some discriminant validity evidence was reported insofar as the measure distinguished between youth with OCD and nonclinical controls, the measure did not consistently distinguish between youth with OCD and

those with other psychiatric diagnoses (Berg et al., 1986). It is notable, too, that the validity of the measure has not been examined in almost two decades.

As noted earlier, only one measure of worry in children has been examined by more than one study—the PSWQ-C. Extant data are promising for the measure; correlations were above .60 for other measures of worry or GAD, such as the RCMAS Worry subscale and the SCARED GAD subscale. Furthermore, although correlations with other anxiety measures were also high, the correlation for the most relevant scale was always highest (e.g., correlation with SCARED GAD was higher than any other SCARED subscale). In the Chorpita et al. (1997) study, other indices of validity were positive: the PSWQ-C correlated highly with the number and intensity of worries, as well as symptom reports on the Anxiety Disorders Interview Schedule—Child version (ADIS-C) of uncontrollable worry. Correlations with excessive worry were more modest, suggesting the measure may not capture either the “excessive worry” or the “uncontrollable” aspects of GAD.

Validity of the SRAS was examined across three articles, with one focusing primarily on factor analysis (discussed below). In general, results are supportive of the four subscales. In the original development paper, Kearney and Silverman (1993) confirmed their hypotheses that the Escape, Avoidance, and Attention Getting subscales correlated above .30 with anxiety measures, whereas the Tangible Rewards subscale correlated below .10. Similarly, the Tangible Rewards and Attention Getting subscales were correlated more highly with the Child Behavior Checklist (CBCL) Externalizing subscale. A similar pattern emerged in the Higa, Daleiden, and Chorpita (2002) study of the measure; for example, the patterns of youth meeting criteria for internalizing versus externalizing disorders mapped as expected onto the four SRAS subscales. In short, the validity evidence for the SRAS is promising, though limited by a small number of studies.

Finally, overall validity evidence for the CASI is rather modest. The measure correlates rather highly with a variety of other anxiety measures, such as FSSC-R, RCMAS, STAIC, and MASC, with validity coefficients ranging from .50 to .74. Arguably, the measure should have as its highest correlates measures related to the physiology of anxiety. Although the mea-

sure did correlate highest with the SCAS Panic Disorder subscale (among the various SCAS subscales), correlations with other physiology-related measures were less consistent. Furthermore, one discriminative validity study (Rabian et al., 1993) suggested that although the measure did discriminate between anxious and nonanxious youth, it was not able to discriminate between anxious youth and those with externalizing behavior problems. Furthermore, the effect size for the CASI in discriminating children with panic disorder from those with other anxiety disorders was found to be lower than that of the STAIC (Chorpita & Lilienfeld, 1999), casting some doubts about the relevance of the CASI to panic disorder in youth.

Interviews

Our review identified 33 articles examining the psychometric properties of structured diagnostic interviews, representing 11 instruments. As noted earlier, there are two basic types of structured interview: (1) respondent-based and (2) interviewer-based (Shaffer et al., 1999). Respondent-based interviews attempt to maximize reliability through standardization of the interview, such that most responses to questions can be “yes” or “no” and do not require the interviewer to know much about DSM criteria. As such, with adequate training, these interviews may be employed by lay interviewers. They are typically viewed as ideal for epidemiological settings, but not in clinical settings. On the other hand, interviewer-based interviews require a high level of professional knowledge given that the interview is only semistructured, such that probe and follow-up questions are at the discretion of the interviewer. Therefore, a clinician is required to conduct the interview. Furthermore, their reliability, particularly interrater reliability, requires close scrutiny. We summarize the reliability findings for the interviews in Table 8.8.

In the study of anxiety disorders in youth, only one respondent-based interview has been examined in a study reporting psychometric data, the Diagnostic Interview Schedule for Children (DISC; Shaffer, Fisher, Dulcan, & Davies, 1996). Several interviewer-based interviews have reported psychometric data, including the Anxiety Disorders Interview Schedule, Child and Parent versions (ADIS-C/P; Silverman & Albano, 1996; Silverman &

TABLE 8.8. Aggregated Ranges of Reliability Estimates for Interviews

Terry	Bidaut-Russell, Valla, Thomas, Begeron, & Lawson (1998); Valla et al. (2000)	.65 to .90	.72 (ICC) .70 to .76 (κ)	—

Note. α , Cronbach's alpha; ICC, intraclass correlation coefficient; κ , Cohen's kappa; r , Pearson correlation.

Nells, 1988), the Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 2000), the Children's Assessment Schedule (Hodges, McKnew, Cytryn, Stern, & Kline, 1982), the Diagnostic Interview for Children and Adolescents (DICA; Welner, Reich, Herjanic, Jung, & Amado, 1987), and the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Kaufman, Birmaher, Brent, & Rao, 1997). A unique aspect of the ADIS-C/P compared to the other interviews is its use of dimensional ratings concerning severity, intensity, interference, avoidance, and uncontrollability at the symptom and syndrome levels. In addition, three separate picture-based interviews identified in our review are discussed separately. Our review and discussion are by instrument, starting with the respondent-based interview. Although we identified 11 separate instruments in our review, our discussion is limited to those with the most data.

As noted, the DISC is a respondent-based interview that, among other advantages, is designed for lay interviewers. We identified six articles on the psychometrics of the DISC that specifically included at least one childhood anxiety disorder diagnosis. Studies of retest and interrater reliability have been reported (see Table 8.8). Retest reliability coefficients, with retest periods of 1–3 weeks, varied by diagnosis. With such small time frames, these coefficients represent a reasonable gauge of the measure's reliability. Coefficients (kappa or ICC were typically reported) for specific/simple phobia, SAD, GAD/OAD, and social phobia were highest, with mean coefficient values above .50. Panic disorder and agoraphobia mean coefficients were both below .50, and those for panic disorder, .22.

Interrater reliability has also been reported for the DISC. An interesting artifact of the development of the DISC is the use of lay and professional (i.e., MD or PhD) interviewers. As a result, interrater reliability has been studied within and across these categories of interviewer, something that occurs rarely in studies of the other interviews. These data have been reported for agoraphobia, GAD/OAD, SAD, simple/specific phobia, and social phobia. Across the two articles examining interrater reliability, coefficients were highest when parent and combined reports were considered, with mean kappas for all diagnoses around .50 for each, whereas the kappa for interrater reliabil-

ity for child reports was .25. For the combined and parent report kappas, social and simple/specific phobia had the best overall coefficients (.55–.60), with GAD/OAD in the middle (about .50), and SAD the lowest (below .45). Comparing lay versus lay and lay versus psychiatrist interrater reliability did not suggest notable differences in the magnitude of kappa, suggesting that lay interviewers agreed with each other about as well as lay interviewers agreed with psychiatrists using the DISC. In general, these interrater reliability coefficients are not promising, especially given the design of the DISC as a highly standardized instrument, a point to which we return in our conclusion to this section on interviews.

Turning to the interviewer-based interviews, we start with the ADIS-C/P, which, not surprisingly, was the most commonly studied interview for childhood anxiety disorders. Retest reliability data, reported in the 1- to 3-week range, are largely positive, with coefficients above .70 for most diagnoses. A few general findings emerge. First, concerning age differences, older group tended to have *lower* retest reliability. A good example of this phenomenon is found for GAD, reported in a study by Silverman, Saavedra, and Pina (2001). Child, parent, and combined report diagnoses were examined across a 10-day period. The retest coefficient for the younger (ages 7–11) children was above .70 for GAD in all three reports (i.e., child report, parent report, and combined report) whereas for older (ages 12–16) children, only one of the three was at .70 (combined), with the other two below .60. A second general finding is that the “combined” report yielded the best retest coefficients, followed by parent report.

Although fewer interrater than retest reliability data are reported for the ADIS-C/P, there is still a reasonable database on this property of the interview. Again, the data are largely positive. As noted earlier, kappa coefficients above .74 (e.g., Landis & Koch, 1977) are typically considered adequate for diagnostic interviews. Studies have demonstrated the ADIS-C/P meets this standard often, though not always. For example, the kappa for OAD was below criterion for parent and combined reports in the Silverman and Eisen (1992) article. Similarly low coefficients for social phobia were reported in the same study by combined and child reports. However, the general trend was for acceptable kappas for the ADIS-C/P. But-

treaching this conclusion is the finding by Lyneham and Rapee (2005) that kappas were acceptable for in-person compared to phone interviews across multiple diagnoses (i.e., specific phobia, social phobia, SAD, and GAD). Despite these rather positive data, there is a notable lack of data for the OCD diagnosis, though, most likely a result of its rarity.

Four other interviewer-based interviews have psychometric data available concerning anxiety disorders: CAPA, CAS, DICA, and K-SADS. For all four, however, data are rather limited. Taking the CAS as an example, data for the instrument are only available for two diagnoses (OAD and SAD). Retest data are modestly supportive for SAD (.56) and less so for OAD (.38). Interrater reliability data are even sparser, with a pre-DSM-III-R study by Hodges, McKnew, and colleagues (1982) noting that such reliability was above .70. Data on the K-SADS, though more recent, are equally meager. Retest data are available for the DICA in one study across 17 days for two diagnoses (OAD and SAD), and coefficients are moderate to weak (.57 and .32, respectively). Kaufman and colleagues (1997) reported better results for the K-SADS, with kappa at or above .70, but only for GAD and “any anxiety diagnosis.” No interrater reliability data were available for either DICA or K-SADS. Unlike the other interviews, however, CAS, DICA, and K-SADS have some reported validity evidence. For example, in a rare study comparing two structured diagnostic interviews, Hodges, McKnew, Burbach, and Roebuck (1987) found moderate to low agreement between CAS and K-SADS for “any anxiety disorder” diagnosis, with kappas ranging from .37 to .54. Boyle and colleagues (1997) compared the diagnoses achieved using the DICA compared to the Ontario Child Health Study (OCHS), a behavior problem checklist; kappas were poor for SAD and OAD (below .40). Overall, data for these three interviews is sparse. Although data for the K-SADS and CAPA are relatively stronger than those for the other two interviews, there is overall very little known about these four interviews concerning childhood anxiety disorders.

The most important point to make about interviews is that despite the promise for improved reliability afforded by the DSM, surprisingly little evidence supports the use of DSM-based interviews for anxiety disorders, with one important exception, the ADIS-C/P. Given that the ADIS-C/P was developed specif-

ically for anxiety disorders in children, it is not surprising that this interview stood out in our review. Still, it is worth noting that the ADIS-C/P is the only structured interview with reliability data for all of the anxiety disorder diagnoses. Although the DISC is a well-studied instrument, reliability estimates for the anxiety disorders are not particularly strong, especially in comparison to the ADIS-C/P. The other structured interviews have fewer studies, making any conclusions about their use premature.

We conclude our discussion of interviews by noting the emergence of a small number of *picture-based* diagnostic interviews that decrease reliance on verbal report as a means of interviewing children about symptoms related to DSM diagnoses. Two interviews, the Dominic and the Terry, have received attention across multiple studies. In both interviews, a child is shown a series of pictures in which a child exhibits DSM symptoms, and is asked, “Have you ever felt sad (for example), like Terry/Dominic?” Terry and Dominic are the same except that the Terry contains drawings of a black youth and the Dominic depicts a white youth. Psychometric data for the three anxiety disorder diagnoses (OAD, SAD, phobia) covered by the instrument are positive. Retest reliability coefficients exceeded .70 over 10 days. Interrater reliability estimates also exceeded .70. Limited validity evidence has been reported, however. These interviews represent a promising effort to expand the reach of diagnostic interviews.

Before we move to the more general conclusion of our review, we reiterate a point we made earlier concerning the types of interviews. In clinical circumstances, interviewer-based interviews appear to be the preferred choice when design alone is considered. Also, we were somewhat surprised to discover that respondent-based interviews, despite their high degree of structure, did not yield better reliability estimates. As a result, use of an interviewer-based interview such as the ADIS-C/P makes both clinical and empirical sense.

General Summary and Conclusions

Our review revealed a rich literature on the assessment of child anxiety. Since 1970, more than 180 articles have been published, representing more than 700 studies conducted on over 75 measures. Using our search param-

ters, the literatures on questionnaires and interviews are the best developed. Research on observational measures, once considered to have the best psychometric evidence (e.g., Barrios & Hartmann, 1997), has shown a decline over time in psychometric studies. On the other hand, physiological measures, once considered too unreliable with children (e.g., Beidel, 1991), are beginning to receive more attention, though, thus far, mainly in literatures beyond the scope of our review.

We conclude our review with a set of general recommendations. Before doing so, we offer a brief discussion of the clinical feasibility of measurement. Thus far, our focus has been on the traditional psychometric topics of reliability and validity. Although both are necessary properties of a useful instrument, neither dimension speaks directly to *clinical feasibility and utility*. Recently, increasing emphasis on real-world applicability has increased the importance of the feasibility of measures in clinical practice (Mash & Hunsley, 2005; Silverman & Ollendick, 2005). From our perspective, feasibility involves calculation of the *relative economy* of a given measure (compared to its psychometrically equivalent alternatives). A first property to consider here is *time required*, gauged by the number of items or the time needed to complete a given assessment (e.g., interview, observation). Table 8.4 provides the total number of items for each of the questionnaires we have described in detail, along with an estimate of the time required to administer the instrument. Time estimates for interviews are harder to gauge; although some articles indicated the estimated time to conduct the interviews, the estimates varied considerably. Thus, we do not provide any specific estimates except to say that diagnostic interviews typically take at least 60 minutes per reporter (i.e., 120 minutes for a child and a parent); the duration is also typically longer if the child is more symptomatic. Hence, interview times in epidemiological studies are briefer than those in clinical studies. Time required represents one component of the instrument's "cost." As time increases, child and/or parent fatigue has the potential to degrade the *yield* (i.e., decrease validity) and to impact the satisfaction of the client (thus, increasing chance that he or she will stop treatment or seek it elsewhere). Furthermore, in most clinical settings, financial considerations limit the time dedicated to assessment (Sanchez & Turner, 2003). Thus, a clinician

must carefully consider how much time to spend using assessment tools.

Another cost associated with some measures is an actual financial cost. Some of the measures are copyrighted and have a cost associated with their use (see Table 8.4). The ADIS-C/P and the DISC are also copyrighted instruments with cost associated with their use. Obviously, financial cost has implications for feasibility. As an example, within the health care system, consumers are increasingly seeing coinsurance fees for medical tests (e.g., strep test, cholesterol test). It is conceivable that such issues will arise in mental health practice, particularly if the number of "free" measures decreases.

Economizing on *time required* and reducing actual *financial cost* are components of feasibility. However, another important consideration concerns the ultimate *yield* of the measure. In other words, how much information does a measure generate considering its cost (e.g., in time, financial cost)? Although our field has not elaborated a method for determining this ratio, we offer the following preliminary framework to guide our discussion.

Considering the purposes of assessment we discussed earlier (identification/screening, triage/treatment planning, and treatment evaluation), a yield for a measure varies depending on which purpose it is meant to serve. We posit that the overall *yield* curve is likely to have a bell shape. Specifically, at the identification phase, keeping *time required* low is likely to be critical, because relatively few youth who complete the screen will need any follow-up. Thus, engaging in extensive measurement does not appear necessary or feasible. However, in the triage/treatment planning phase, greater tolerance for cost is likely. During this phase, an assessor seeks to identify *caseness*, to triage the client into the appropriate treatment(s), and to identify key treatment goals. Thus, a wider net is preferred. Furthermore, at the outset of treatment, extended time for assessment may be expected and "billable" within mental health systems. Overall, the need for sensitivity may make the relative cost of the time spent lower during screening and treatment planning.

Note, however, that the yield of a measure for triage/treatment planning purposes is likely maximized as the ratio between the number of relevant constructs measured (e.g., DSM disorders) and the time spent increases; lower ratios

are associated with higher “cost” insofar as the measure does not provide much information despite the time spent. Thus, despite greater tolerance for higher cost, economic concerns remain in the triage/treatment planning stage.

As one moves to outcome measurement, efficiency remains a prime concern, because of the limited time available during and after treatment for lengthy assessments. Furthermore, the focus of treatment is likely to be narrow; thus, measurement of those specific goals may be most critical in gauging the effects of treatment.

We pause briefly to point out that this focused measurement stands in contrast to a typical, randomized, controlled trial posttreatment battery, which often contains multiple measures of similar constructs. Although such measurement represents a state-of-the-art approach to clinical assessment in a research trial, the context of that assessment must be considered. In the absence of real-world financial and time pressures, such an extensive battery of measurements may indeed be the best choice. As valuable as such assessments are to the science of outcome assessment, however, the practice of outcome assessment must by necessity be more parsimonious.

In addition to the notion of feasibility, another dimension relevant to applied use of these instruments involves optimal conditions of use. A close read of our discussion thus far suggests that some measures are better suited for a certain purpose, whereas others are better suited for other purposes. Table 8.9 summarizes our recommendations.

For the purpose of identification, questionnaires represent the best choice. Because parsimony is of the essence, a measure such as the STAIC–Trait is a strong choice, with only 20 items. We also recommend the Positive and Negative Affect Scale for Children (PANAS-C), because it has stronger conceptual ties to notions of temperament, although is not an anxiety measure per se. Although the DSM-based scales are lengthier, several offer norms that allow for the determination of percentile or *T*-scores, which can help in determining whether or not treatment is warranted. Of these, RCADS is the briefest and covers several anxiety diagnoses, as well as depression.

For triage and treatment planning, working with one of the DSM-based scales makes best sense in terms of locating the type of anxiety and degree of comorbid elevations. Despite their length, such measures may be worthwhile because of their superior precision in identifying areas for treatment focus. Indeed, as we and others have discussed elsewhere (e.g., Chorpita & Nakamura, 2004), use of DSM-based questionnaires may also represent a way to plan for the efficient use of an accompanying structured diagnostic interview. The choice among the three anxiety-related DSM questionnaires is not simple, because of the lack of uniform coverage of the DSM disorders (see Table 8.5). The SCARED-R has the broadest scope, screening for all seven of the DSM-IV anxiety disorders; the first version of the SCARED only included four diagnoses (plus school phobia). The RCADS affords the advantage of screening for depression and anxiety

TABLE 8.9. Recommendations by Assessment Purpose

Purpose	Identification	Triage/treatment planning	Outcome during treatment	Outcome posttreatment
Questionnaire	STAIC ^a	RCADS	Syndrome questionnaire	Syndrome questionnaire
Questionnaire	PANAS-C	SCARED		RCADS
Questionnaire	RCADS	SCAS		SCARED
Interview		ADIS-C/P		ADIS-C/P
Interview		K-SADS		K-SADS
Other		Process measures (e.g., SRAS, functional assessment)	Idiographic measures (e.g., number of panic attacks)	Idiographic measures (e.g., number of panic attacks)
Other		Idiographic measures (e.g., number of panic attacks)		

^a Although there are data on the State version, our focus here is the Trait version of the STAIC.

but does not screen for PTSD and specific phobia. The SCAS screens for the same anxiety disorders as the RCADS (with the addition of physical injury fears) but does not screen for depression. Considering coverage, the RCADS would appear to be a reasonable choice. However, psychometric evidence for the measure, although uniformly positive, is not as extensively documented as that for the SCARED and SCAS. Furthermore, if full coverage of the anxiety disorders is desired, especially PTSD (though see Fletcher, Chapter 9, this volume), the SCARED-R may be preferable. Use of the trait measures is not recommended at the treatment planning stage.

The use of a structured diagnostic interview is clearly an important tool for treatment planning. The data clearly identify the ADIS-C/P as the superior interview for anxiety disorders. If cost is an issue, the K-SADS may be a viable option, though data are sparse. However, because all structured interviews are costly with regard to time and training required, we recommend using one of the DSM-based multidimensional questionnaires in clinical practice as a way to identify components of diagnostic interviews most worth administering (cf. Chorpita & Nakamura, in press).

A notable gap in the assessment literature is the paucity of process- or function-oriented measures that offer data on the mechanisms causing or maintaining the problem behaviors. This is a critical gap, because an important goal of treatment planning involves hypothesizing the causal or maintaining factors of the anxiety. However, almost all of the measures we identified gauge only symptom severity, frequency, or interference, not their presumed causes. In most clinical situations, data on functions of the problem behaviors are obtained with loosely structured, clinical interviewing techniques. As discussed earlier, we prefer the use of functional assessment (FA) as a guide to identifying the “process” of the problem(s) identified. Our recommendation comes from the accumulation of related data reported by those using FA and similar approaches (e.g., Francis & Chorpita, 2004; Henggeler et al., 2002; Persons, 1989). Although some of the gap in measuring causal variables may be due to the relatively poor understanding of etiology and mechanisms of treatment action in general (Kazdin, 2001), this understanding cannot be advanced without strategies to measure potential mediators and moderators of treatment.

A small number of questionnaires appear potentially useful in the regard, specifically, the SRAS and CASI. In cases of school refusal, the SRAS is a tool to gauge the reasons for the school refusal and to plan treatment. Least clear is the role of the CASI in developing a treatment plan. Although anxiety sensitivity is related to several anxiety disorders, no studies have demonstrated any added benefit of using the CASI along with other questionnaires in treatment planning.

Regarding outcome measurement, there are two types of outcome one may be interested in assessing: (1) ongoing, during-treatment assessment and (2) posttreatment assessment. One way to address the first of these is to use the instruments recommended for triage/treatment planning questionnaires: RCADS, SCARED, or SCAS. However their use may not be warranted in many cases, because the focus of treatment is generally more limited. Thus, there may be more parsimonious ways to assess outcome, and more focused assessment methods are typically recommended. Specifically, ongoing assessment of outcome can be measured efficiently by an instrument specific to the syndrome in question. For example, one could choose between SPAI-C or the SAS and variants to measure social anxiety. Our review recommends the latter, because there are relatively more data on the measure, and it has four fewer items.

A problem with this plan emerges for problem areas without a specific measure. For example, panic disorder and SAD do not have stand-alone questionnaires specifically designed for them. Furthermore, although the FSSC-R taps fear severity, it is not likely to serve as a particularly useful outcome tool for treatment of specific phobia, because treatment will likely focus on a finite number of specific fears; thus, their declining severity and reduced avoidance is of more of interest than an inventory of a child's fear of a wide array of stimuli. In short, then, use of syndrome-specific questionnaires for outcome measurement is limited to GAD, OCD, and social phobia.

An alternative may be to extract individual scales from the DSM-based multidimensional questionnaires. A problem with this procedure concerns the lack of psychometric data for the scales as stand-alone measures. Furthermore, as noted earlier, available psychometric data on some of the scales are not particularly strong. For example, doubts concerning the reliability

of the OCD and phobia scales make their use questionable. Still, use of these scales individually merits consideration and may prove to be a fruitful future research direction. Furthermore, the CY-BOCS represents a strong choice for OCD, so the only diagnoses that are not well covered may be phobias. And, as we discuss shortly, idiographic measurement may represent the best choice in this instance anyway.

Observational measures may also serve as good, idiographic ways to track ongoing treatment progress. Homework assignments, though not usually conceptualized as such, are often assessments of treatment progress. In exposure-based treatments, administration of a BAT may be used to determine treatment progress. This may be the optimal method for tracking progress in treating phobias. Less formal observational measures, such as client self-monitoring, also may provide insight into treatment effects. However, as noted, psychometric study of these methods is challenging, and little research has documented the reliability or validity of these methods.

To this point, we have suggested tracking treatment progress for discrete syndromes or problems. However, in cases with multiple diagnoses identified at the initial assessment, for which treatment has been multiply focused, such an approach may be less helpful. Furthermore, because estimates of comorbidity are high across epidemiological and clinical studies, this situation is likely to be quite common. In these instances, the broader DSM screening instruments may be needed to track ongoing treatment progress.

At posttreatment, if there is interest in identifying response generalization effects of treatment (i.e., reductions in other problems areas), broader instruments or a structured diagnostic interview may be the best route. Such methods allow the clinician to confirm that no (additional) problems remain (or have emerged). Considering economy, on the other hand, a clinician may again choose to use a specific questionnaire, perhaps paired with areas selected from a follow-up structured diagnostic interview. In addition, in some cases, the use of a BAT may also be a useful way to conclude treatment, allowing the client to demonstrate gains made in treatment in a more obvious way than might be achieved with a questionnaire or interview.

As summarized in Table 8.9, our recommendations with regard to assessment tools depend

on the purpose of assessment. Furthermore, some of our recommendations are more tentative than others, because important gaps that remain in the literature preclude stronger recommendations. Finally, we remind the reader of our overall caveat for the chapter. Our focus has been on measures of child anxiety. As such, we have not discussed measures of other problem areas (e.g., disruptive behavior disorders, general child functioning measures). Thus, our recommendations are limited to anxiety-related measures. If we were recommending measures for broad clinical assessment, we would change our list. Overall, our review and the related recommendations are meant as a guide for clinicians to make evidence-based decisions for the assessment of child anxiety.

FUTURE DIRECTIONS

A review of nearly 40 years of research on assessment of anxiety in children points to several issues in the literature that call for additional research. First, there appears to be a need for additional evidence on parent report questionnaires. It is well documented that parents and youth often disagree about the psychological symptoms the youth is experiencing (e.g., DiBartolo, Albano, Barlow, & Heimberg, 1998; Frick, Silverthorn, & Evans, 1994). As a result, considerable debate exists regarding the preferred reporter of children's anxious symptomatology—parent or child. Some researchers have suggested that children may be better reporters of their own distress (e.g., Edelbrock, Costello, Dulcan, Conover, & Kala, 1985; Jensen, Traylor, Xenakis, & Davis, 1988), whereas others have found that parents may more reliably report their children's anxious distress (e.g., DiBartolo, Albano, Barlow, & Heimberg, 1998; Rapee, Barrett, Dadds, & Evans, 1994; Schniering, Hudson, & Rapee, 2000).

The controversy over whose report is preferable notwithstanding, few disagree that the use of parent reports in conjunction with child reports confers significant advantages over an exclusive reliance on youth self-report. It is unclear how reliable the reports of younger children (before age 10) are in discriminating subtle emotional states such as worry, anxiety, and depression (e.g., Edelbrock, Costello, Dulcan, Conover, & Kala, 1985; Harris, 1993; Silverman & Eisen, 1992; but see Silverman &

Rabian, 1995). Schniering and colleagues (2000) reported a trend in which children have more difficulty reporting on complex details, such as the duration and onset of symptoms. Similarly, Perez, Ascaso, Massons, and de la Osa Chaparro (1998) found that children demonstrate difficulties in thinking retrospectively and in answering questions that require the most metacognition (e.g., questions about internal thoughts or feeling states). Because children almost never refer themselves for clinical treatment, ignoring the parent's view seems clinically contraindicated. Finally, with only one reporter, assessment or diagnostic inferences cannot be corroborated as easily. Thus, we urge measure designers to continue to develop and investigate parent report versions of questionnaires.

Second, it appears more generally that the field would benefit simply from more measurement research. The child anxiety measurement literature is replete with "single-study" instruments (i.e., measures developed and tested in one [or a few] studies, only to be replaced or eclipsed by another, similar "single-study" instrument). Given that establishing the validity of an instrument and articulating its boundaries conditions (e.g., clinical, school samples) are highly complex endeavors (Cronbach & Meehl, 1955), it seems advisable that there be at a minimum some additional research on the field's most commonly used measures.

Loevinger (1957) outlined three components of construct validity that are worth considering here: substantive validity, structural validity, and external validity (for more recent explications of construct validity, see Embretson, 1983; Hogan & Nicholson, 1988; Messick, 1995). In short, these components respectively imply that (1) the content of the items on a test should be consistent with the investigator's theory regarding the trait being assessed, (2) the structural relations among the items of a measure should correspond to theoretical expectations (e.g., internal consistency or factor structure), and (3) the measure's relations with extratest correlates should accord with theoretical prediction. Few of the instruments reviewed here have demonstrated strong findings in all of these areas.

Most lacking across the board is the evidence for substantive validity (cf. content validity; Haynes, Richard, & Kubany, 1995); that is, many measures appear to have been designed with an initially underdeveloped item pool,

such that factor-analytic findings often yield two- or three-item factors, or scales are otherwise underrepresented or unclearly related to theoretical domains (e.g., Chorpita & Daleiden, 2000). This observation suggests that future test development and revision should seek to be quite clear about the theory of the constructs in question, and should be explicitly overinclusive with initial item pools (Loevinger, 1957) to clearly demarcate an instrument's construct boundaries.

With respect to screening/identification, we agree with the now not-so-recent sentiment of Stark and Laurent (2001) regarding the need for a new generation of measures. On the one hand, multidimensional scales, particularly those that index DSM syndromes, appear to have high utility for identifying areas of concern. For the purpose of measuring treatment progress and outcome, on the other hand, it would be helpful to continue to develop and refine the more focused measures, obviating the need for the use of extended measures at repeated intervals (unless, of course, comorbidity is an issue, in which case multidimensional approach remains a strong choice). That said, the vast majority of research on the assessment of child anxiety involves single-instrument evaluation. Although important, single-instrument approaches to assessment are rarely appropriate in clinical circumstances. More studies on how various measures may be used in conjunctive accord and on empirical tests of combinatorial algorithms would be highly useful for the field. There has been little or no research on the use of data combination strategies other than rule-based interviews and linear sums of questionnaire items. More sophisticated approaches such as item-response theory (Reise, Ainsworth, & Haviland, 2005), associative network theory (Peng & Reggia, 1996), and Bayesian logic models (e.g., Chorpita et al., 2000) may ultimately point the way to the optimal inference strategies that draw from an efficient yet comprehensive battery of instruments. The promise of these new approaches is not well known in this context; we hope, therefore, that they will be frequent subjects of study as assessment approaches continue to be developed and improved for youth with anxiety.

Finally, that despite increasing calls for research with diverse sample, our review indicates that most of the evidence to date involves samples of mostly white youth. Given socio-demographic trends in the United States and

other countries, the evidence base needs major work in this area if we are to maintain confidence in its external validity. In the area of child anxiety assessment, the work needed is both practical and conceptual. On the practical end, we simply need more studies with diverse samples. Although diversity of ethnic groups is one important direction (Austin & Chorpita, 2004; Safren et al., 2000), we also need work that examines measurement with poor and rural youth (e.g., Atkins et al., 2003; Costello et al., 2003). On the conceptual end, we also may need to rethink assumptions about anxiety measurement, because cross-cultural research has identified different manifestations of anxiety symptomatology in different cultural groups. For nations with increasing multicultural populations, sensitivity to such differences becomes a critical public health issue.

ACKNOWLEDGMENTS

Preparation of this chapter was supported in part through a grant from the Hawaii Department of Health, through the Research Network on Youth Mental Health, sponsored by the John D. and Catherine T. MacArthur Foundation, and by National Institute of Mental Health Grant No. K23 MH69421. We would like to thank Lauren Akselrod, Lauren Brown, Joella Newgen, Kathryn Taylor, and Katie Burns for their assistance with materials for this chapter.

Posttraumatic Stress Disorder

Kenneth E. Fletcher

The evaluation of posttraumatic stress reactions in children, adolescents, and young adults is not as straightforward a process as it might first appear. Whereas the assessment process shares similar challenges with any assessment of behavioral and emotional problems in children, it faces additional challenges of its own, some of which may not be readily apparent to clinicians who are less familiar with the research on childhood posttraumatic stress disorder (PTSD). PTSD, for example, is one of the few mental disorders that requires exposure to a high-magnitude stressor that has the potential for producing traumatic reactions. Some of the challenges clinicians face in this regard are to establish whether the child under consideration was exposed to a stressor, whether that stressor qualifies as a potentially traumatic stressor, whether the child experienced it as such, and finally whether the child's behaviors that appear to be symptomatic of PTSD actually began as a consequence of exposure to the stressor under consideration. The first section of this chapter describes these and other factors that need to be taken into account in the process of evaluating traumatic responses. The second section suggests which of the currently available assessment tools might allow the clinician to evaluate children for PTSD most effectively.

The need to assess the possible presence of traumatic reactions in an infant, child, adoles-

cent, or young adult may arise in a variety of circumstances. An informed caregiver or other adult in the child's life may be concerned for the child after a particularly difficult crisis disrupts the child's life. This is most likely to happen after a major disaster that affects entire communities, such as hurricanes or tsunamis often do, or the disaster may have more personal repercussions for the child, such as the loss of a home to fire. Increasingly, children are being referred for assessment after they are discovered in homes embroiled in domestic violence. Victims of physical or sexual abuse (see Crooks & Wolfe, Chapter 14, and Wolfe, Chapter 15, this volume), and sometimes of emotional abuse or neglect, are likely to be referred for evaluation as well.

At other times, children may be referred for reasons seemingly unrelated to posttraumatic stress, but someone, perhaps even the clinician, recognizes the need to examine them for possible posttraumatic reactions, if only for purposes of differential diagnosis. Children's traumatic reactions are frequently not recognized as such, in part, due to adults in their lives minimizing the possibility of traumatic reactions in their children. It may also be due to lack of recognition of the potential stress an event might pose for the child. In other instances, adults in the child's life may simply be unaware of the kinds of stressful experiences to which a child is exposed. Some children, for example, live

with daily bullying on the way to school and again on the way home, but never reveal these experiences to an adult. On the other hand, a conspiracy of silence may surround a child who is the victim of maltreatment.

In this sense, posttraumatic stress can be a silent referral. Therefore, clinicians need to be particularly alert to the possibility that a good many symptomatic behaviors that at first suggest other problems may actually be symptoms of reactions to traumatic experiences. Referrals for problems related to apparent hyperactivity, aggressiveness, social withdrawal, depression, anxiety, separation anxiety, dissociative experiences, substance abuse, runaway behavior, excessive risk-taking behavior, and sexual acting out all may provide clues to the possible presence of traumatic reactions in infants, children, adolescents, and young adults. In addition, many difficult or inexplicable physical complaints, such as gastrointestinal problems, chronic pain of any kind, or fibromyalgia, among others, also may point to traumatic experiences.

The likelihood that children referred for reasons other than trauma reactions have been exposed to one or more potentially traumatic events is surprisingly high. In one large, longitudinal study (Costello, Erkanli, Fairbank, & Angold, 2002), one in every four children reported experiencing at least one event of high-magnitude stress by the time he or she reached the age of 16. High-magnitude stressor events in this study encompassed the extreme stressors referred to in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; American Psychiatric Association [APA], 1994), including serious accidents, serious illnesses, natural disasters, fires, war, terrorism, violence within or outside the family, sexual abuse, rape, coercion, death of a loved one, witnessing such an event, or learning about such an event, among others. Of the children who had been exposed to high-magnitude stressors in this study, 18% reported exposure to two such events, and 10% reported experiencing three or more. Moreover, 6% of all of the children in the study reported exposure to a high-magnitude stressor within the past 3 months.

With these results in mind, clinicians might do well to consider first taking a history of any possible high-magnitude stressors children have experienced over their lifetime, then inquiring about current stressors in children's

lives on a regular basis thereafter, regardless of the reasons for the child's referral. This is not to say that clinicians should screen all children for PTSD. However, taking a history of lifetime and current stressors in each child's life might prove informative in several ways. Most obviously, it would assist in identifying circumstances in the child's life that might warrant further assessment for possible traumatic reactions to those circumstances. Cohen and colleagues (1998) pointed out that "routine screening for exposure to domestic or community violence, child abuse, and other common stressors is essential in making [the] determination" (p. 9S) that symptoms of avoidance, numbing, and overarousal were not present prior to exposure to the high-magnitude stressor for which a child is being assessed. Less obviously perhaps, routine screening for exposure to high-magnitude stressors may provide information about life experiences that might be relevant for other problems in the child's life. In fact, given the association between chronic traumatization and major somatic complaints (as described later in this chapter in the discussion of complex PTSD), family physicians and pediatricians would be well advised to screen for such occurrences among their infant, child, adolescent, and young adult patients on a regular basis as well.

THE FULL SPECTRUM OF POSTTRAUMATIC STRESS RESPONSES

Anyone, from infant to older adult, regardless of age, can react adversely when high-magnitude stressors intrude on his or her life (Fletcher, 2003). Reactions to extreme adversity need not necessarily develop into PTSD, however. Other possible reactions include grief, depression, anxiety, fear, and dissociative states, among others. This chapter is concerned with those reactions to high-magnitude stressors that form the cluster of symptoms associated with PTSD.

High-magnitude stressors play an important role in the diagnosis of PTSD. Prior to DSM-IV, PTSD was the only DSM disorder that for diagnosis required exposure to a high-magnitude stressor. A second disorder that depends on such exposure, acute stress disorder (ASD), was added in DSM-IV. The etiology and symptomatology of PTSD and ASD are closely related, to the point that they may represent

different points on a spectrum of posttraumatic stress reactions. If, as its name suggests, ASD can be considered to represent *acute* reactions to high-magnitude stressors, it has been proposed that many of the symptoms listed in DSM-IV as “associated or descriptive features” of PTSD might represent the other end of the spectrum of *chronic* reactions. In fact, these so-called “associated” symptoms were derived from a proposed syndrome for DSM-IV that has been referred to by various names, such as disorders of extreme stress not otherwise specified (DES NOS) or, more recently, complex PTSD (Kilpatrick et al., 1998). Evidence is accumulating that the proposed syndrome complex PTSD provides a reliable and valid clustering of symptoms that should be considered in particular circumstances (van der Kolk, Roth, Pelcovitz, Sunday, & Spinazzola, 2005), which I describe briefly later in the chapter. Moreover, there is evidence that treating the distinctive symptoms of complex PTSD as “associated” or comorbid conditions rather than as an integral part of the posttraumatic response leads to markedly reduced response to treatment (van der Kolk & Courtois, 2005; van der Kolk et al., 2005). All three of these “syndromes”—ASD, PTSD, and complex PTSD—share several characteristics, as I describe later in the chapter. All three syndromes can be distinguished from adjustment disorder based on the criterion that they all represent traumatic reactions to high-magnitude stressors. In fact, DSM-IV specifies that a diagnosis of adjustment disorder should be made when nonextreme stressors are involved, such as moving to a new neighborhood, starting a new school, or the birth of a sibling. This chapter is concerned only with those disorders that develop as a reaction to high-magnitude stressors, including the two DSM-IV disorders, ASD and PTSD, as well as the proposed disorder currently not recognized by DSM-IV, complex PTSD. For the sake of simplicity, complex PTSD is referred to as a syndrome or disorder in the rest of this chapter, despite its lack of recognition in DSM-IV.

The view I take in this chapter is that these three syndromes represent a continuum of posttraumatic stress responses. Someone who has experienced a catastrophic event can only be classified as reacting with symptoms of ASD within 1 month of the event. A victim of traumatic events cannot be classified as having PTSD, until more than 1 month has passed

since the traumatic event. Symptoms that typify complex PTSD tend to appear after exposure to the most extreme kinds of interpersonal trauma, such as sexual, physical, or emotional maltreatment, or after being held captive and tortured. Moreover, these traumatic events tend to be of extended duration and/or to be repetitive in nature, and the responses tend to be of longer duration and more likely to effect substantial changes in the victim’s personality.

Etiology of Posttraumatic Stress Responses

The majority (approximately two-thirds according to one meta-analysis; Fletcher, 2003) of children exposed to high-magnitude stressors do *not* develop enough posttraumatic stress symptoms to qualify for a diagnosis of PTSD. The etiology of posttraumatic stress response syndromes such as ASD, PTSD, and complex PTSD appears to depend on a complex interaction of characteristics of the event itself (e.g., its nature, cause, severity, duration, and the child’s exposure to or dosage of particularly distressing aspects of the event); the child’s cognitive, emotional, psychobiological, and behavioral responses to the event; personal characteristics of the child (including biological vulnerabilities, previous exposure to and reaction to other stressors, developmental stage, age, gender, ethnicity, coping skills, etc.); and characteristics of the social environment (e.g., socioeconomic status, support received from the family and community, the caregivers’ own responses to the child’s experiences, etc.). Several models have been suggested to depict the possible interactions of all of these influences on the child’s ultimate reaction to potentially traumatic events (Fletcher, 2003; Green, Wilson, & Lindy, 1985; La Greca, Silverman, Vernberg, & Prinstein, 1996; Ursano, Fullerton, & McCaughey, 1994). Detailed consideration is given later in the chapter to many of these issues, such as the importance of the characteristics of the stressor, age and developmental stage, gender and ethnic differences, and important beliefs affected by traumatic experience. There is not space to give full coverage to the other factors mentioned here. However, clinicians should always keep in mind the multiple possible pathways to dysfunctional responses to high-magnitude stressors, so the potential influence of the remaining factors is touched upon here. For a more detailed discus-

sion of all of these factors, the reader is referred to Fletcher (2003).

Emotional Reactions

DSM-IV criterion A2 (see Table 9.1) requires an emotional reaction of horror, fear, or helplessness to the high-magnitude stressor, which may also be expressed as disorganized or agitated behavior in young children. Research gives substance to this requirement. Children who lived through Hurricane Hugo and reported feelings of sadness, worry, fear, loneliness, or anger during the hurricane were more likely to respond with symptoms of PTSD afterwards (Shannon, Lonigan, Finch, & Taylor, 1994). Their emotional responses were more strongly associated with symptomatology than with the amount of hurricane damage to their households. Other studies have also indicated that the more fear children experience during a high-magnitude stressor (their emotional peritraumatic response), the more likely they are to develop symptoms of PTSD in the aftermath, whether they are very young children (e.g., ages 4–9) (Rossman, Bingham, & Emde, 1997), adolescents (Udwin, Boyle, Yule, Bolton, & O’Ryan, 2000), or young adults in college (Bernat, Ronfeldt, Calhoun, & Arias, 1998). Clearly, assessing the child’s emotional reactions during the course of the stressor can provide important information about the likely course of his or her reactions once the experience concludes.

Appraisals and Attributions

APPRAISALS

Cognitive appraisals are evaluations that people make concerning the importance and meaning of events in terms of their own personal health and safety (Lazarus & Folkman, 1984). Peterson and Seligman (1983) attempted to apply their theory of learned helplessness to traumatic experience, suggesting that an aversive situation must be appraised as inescapable and unpredictable, if a sense of helplessness is to be felt. Foa, Steketee, and Rothbaum (1989) proposed that exposure to high-magnitude stressors can cause “fear structures” to develop. These “programs for escape or avoidance behavior” (p. 166) include at least three kinds of information: characteristics of the stressful

situation, personal interpretations of the meaning of the situation, and procedures for responding to the threat of the situation.

ATTRIBUTIONS

When people attempt to make sense of their unpredictable, uncontrollable, aversive experiences, they tend to attribute them to either internal or external causes, to stable or unstable conditions over time, and to specific or more global conditions (Abramson, Seligman, & Teasdale, 1978). Self-blame or guilt has been found to be associated with children’s posttraumatic stress symptomatology (Realmuto et al., 1992; Udwin et al., 2000). A “foreshortened” or pessimistic view of the future, in which survivors of high-magnitude stressors do not believe they will live a long and productive life, is an example of an attribution of stable (prolonged) insecurity and lack of safety into the future. Global attributions of causality (“all adults are untrustworthy” vs. “just the adult who abused is untrustworthy”) have been found to be associated with abuse among children (Wolfe, Gentile, Michienzi, Sas, & Wolfe, 1991).

Neurobiological Changes Due to Stressful Experiences

Physiological arousal among individuals with PTSD can manifest as increased heart rate, respiration rate, and skin conductivity (Jones & Barlow, 1990). Evidence is accumulating that exposure to high-magnitude stressors can lead to changes in brain structure and functioning, particularly in the hypothalamic–pituitary–adrenal (HPA) axis, a part of the neuroendocrine system that controls reactions to stress (Bremner, Southwick, & Charney, 1999; Golier & Yehuda, 1998). When exposed to a stressor, neurons in the hypothalamus release a chemical called CRF (corticotrophin-releasing factor), which in turn causes the pituitary gland to release another chemical, ACTH (adrenocorticotrophic hormone), which then stimulates the adrenal cortex to release cortisol, a chemical that influences the body’s response to stress (e.g., it causes the heart to beat faster) (Graham, Heim, Goodman, Miller, & Nemeroff, 1999). Early exposure to chronic abuse and neglect activates the HPA axis, which, because the infant’s neural circuitries are still developing, may lead to permanent changes in the HPA axis and re-

TABLE 9.1. DSM-IV-TR Diagnostic Criteria for Posttraumatic Stress Disorder

-
- A. The person has been exposed to a traumatic event in which both of the following were present:
- (1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
 - (2) the person's response involved intense fear, helplessness, or horror. Note: In children, this may be expressed instead by disorganized or agitated behavior.
- B. The traumatic event is persistently reexperienced in one (or more) of the following ways:
- (1) recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. Note: In young children, repetitive play may occur in which themes or aspects of the trauma are expressed.
 - (2) recurrent distressing dreams of the event. Note: In children, there may be frightening dreams without recognizable content.
 - (3) acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated). Note: In young children, trauma-specific reenactment may occur.
 - (4) intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
 - (5) physiological reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
- C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:
- (1) efforts to avoid thoughts, feelings, or conversations associated with the trauma
 - (2) efforts to avoid activities, places, or people that arouse recollections of the trauma
 - (3) inability to recall an important aspect of the trauma
 - (4) markedly diminished interest or participation in significant activities
 - (5) feeling of detachment or estrangement from others
 - (6) restricted range of affect (e.g., unable to have loving feelings)
 - (7) sense of a foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span).
- D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:
- (1) difficulty falling or staying asleep
 - (2) irritability or outbursts of anger
 - (3) difficulty concentrating
 - (4) hypervigilance
 - (5) exaggerated startle response
- E. Duration of the disturbance (symptoms in Criteria B, C, and D) is more than 1 month.
- F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- Specify if:*
- Acute: if duration of symptoms is less than 3 months
 - Chronic: if duration of symptoms is 3 months or more
- Specify if:*
- With Delayed Onset: if onset of symptoms is at least 6 months after the stressor.

(continued)

TABLE 9.1. (continued)

Associated descriptive features and mental disorders. Individuals with Posttraumatic Stress Disorder may describe painful guilt feelings about surviving when others did not survive or about the things they had to do to survive. Avoidance patterns may interfere with interpersonal relationships. . . . The following associated constellation of symptoms may occur and are more commonly seen in association with an interpersonal stressor (e.g., childhood sexual or physical abuse, domestic battering): impaired affect modulation; self-destructive and impulsive behavior; dissociative symptoms; somatic complaints; feelings of ineffectiveness, shame, despair, or hopelessness; feeling permanently damaged; a loss of previously sustained beliefs; hostility; social withdrawal; feeling constantly threatened; impaired relationships with others; or a change from the individual's previous personality characteristics.

Posttraumatic Stress Disorder is associated with increased rates of Major Depressive Disorder, Substance-Related Disorders, Panic Disorder, Agoraphobia, Obsessive-Compulsive Disorder, Generalized Anxiety Disorder, Social Phobia, Specific Phobia, and Bipolar Disorder. These disorders can either precede, follow, or emerge concurrently with the onset of Posttraumatic Stress Disorder.

sponse to stress. High levels of cortisol can also accelerate death of neurons, predisposing the child to cognitive and memory impairments, and perhaps affective disorders in adulthood (Graham et al., 1999).

Individual Characteristics

BIOLOGICAL VULNERABILITY

Some researchers are investigating the possibility of familial predispositions to posttraumatic responses, although little conclusive evidence has yet been found (Koenen, 2003). It appears that

there is likely no "PTSD gene" that is necessary and sufficient for the development of the disorder. Instead, there are probably many different genes, each of which contributes interchangeably and additively, in a probabilistic fashion, to the inherited liability for PTSD. (Koenen, 2003, p. 1)

Temperament, however, may play a role in posttraumatic response. Research on resilience suggests that resilient children tend to be more outgoing, positive in mood, and adaptable to change as infants (Werner & Smith, 1982). Higher intelligence also may mitigate some of the effects of traumatic experiences (Silva et al., 2000; Werner & Smith, 1982).

PSYCHOLOGICAL STRENGTHS AND VULNERABILITIES

Because traumatic experiences tend to be experienced as uncontrollable, it has been suggested that a sense of self-efficacy or control in stressful situations can attenuate the traumatic ef-

fects of such experiences (Bandura, Taylor, Williams, Mefford, & Barchas, 1985; Foa, Zinbarg, & Rothbaum, 1992). Maltreated adolescent girls with low self-esteem, who consider themselves at the mercy of the environment (demonstrating an external locus of control), have reported higher levels of depression than maltreated girls with high self-esteem, who believe they are in control over their environment (an internal locus of control; Moran & Eckenrode, 1992).

There is good evidence that past experience with high stressors can incline a child to react with symptoms of posttraumatic stress to the current stressful circumstances (Fletcher, 2003). This is particularly true if the child has reacted with posttraumatic symptomatology to past high-magnitude stressors (Daviss, Mooney, et al., 2000; Fremont, 2004; Kassam-Adams & Winston, 2004; Stoddard & Saxe, 2001). A history of stressful life events prior to the high-magnitude stressor has repeatedly been associated with higher levels of PTSD in children after exposure to high-magnitude stressors (Mannarino, Cohen, & Berman, 1994; Seifer, Sameroff, Baldwin, & Baldwin, 1992).

Early stressful experience may not always sensitize a child to later stress, however. The impact of earlier stressful experience may depend more on how the child reacted to that experience than on the fact of exposure itself (Rutter, 1983). Past experience of mastering threatening experiences may help the child deal with later stressful experiences (Rutter, 1983). This suggests that choice of coping strategies can affect posttraumatic stress response. In

one study (Stallard, Velleman, Langsford, & Baldwin, 2001), children and adolescents diagnosed with PTSD after motor vehicle accidents did not differ from those not diagnosed with PTSD in their use of active coping strategies of seeking social support, problem solving, and cognitive restructuring. However, children with PTSD were more likely to report the use of avoidant, emotional coping strategies of social withdrawal, distraction, emotional regulation, and blaming others.

Social Characteristics

Children's reactions to high-magnitude stressors are often closely related to the reactions of their caregivers, especially the mother (Ajdukovic, 1998; Milgram & Toubiana, 1996; Winje & Ulvik, 1998), especially for younger children (Pynoos & Eth, 1985). Social support of any kind is associated with lower levels of PTSD symptomatology (Ajdukovic, 1998; Kendall-Tackett, Williams, & Finkelhor, 1993; La Greca et al., 1996; Udwin et al., 2000). Caregiver parenting style can affect children's ability to cope with extremely stressful experience. A flexible (Baumrind, 1971), warm, caring, and attentive parenting style (Maccoby & Martin, 1983) appears to encourage the development of a sense of competence and self-reliance in children. On the other hand, rigid, coercive parenting appears to reduce children's sense of self-esteem and self-competence (Slater & Power, 1987). The quality of the parental relationship may also have an important impact on children's ability to deal with traumatic experiences. Family conflict prior to, during, and after the traumatic experience has been found to be associated with more severe PTSD symptomatology in children (Green et al., 1991; Pelcovitz et al., 1998; Wasserstein & La Greca, 1998).

Shared Characteristics of the Three Posttraumatic Stress Syndromes

By definition, all three posttraumatic stress syndromes consist of physiological and psychological responses to events "that the person experienced, witnessed, or was confronted with . . . that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others" and "the person's response involved intense fear, helplessness, or horror," which is the description of criterion A

for both PTSD and ASD in the fourth, text-revised edition of DSM-IV-TR (APA, 2000; see Tables 9.1 and 9.2). As noted earlier, ASD is diagnosable if symptoms occur within the first month after exposure to a traumatic event and have endured for at least 2 days. Symptoms of PTSD can be diagnosed only after 1 month has passed since the traumatic experience. Complex PTSD is considered to be a consequence of exposure to "early onset, multiple, extended, and sometimes highly invasive traumatic events, frequently of an interpersonal nature, often involving a significant amount of stigma or shame" (Briere & Spinazzola, 2005, p. 401).

Posttraumatic Stress Disorder

PTSD, ASD, and complex PTSD have many symptoms in common, as well. Someone who appears to manifest the complex PTSD symptom constellation nearly always also meets criteria for PTSD (van der Kolk et al., 2005). The "core symptoms" of PTSD, according to DSM-IV, are symptoms of reexperiencing, avoidance of reminders, and overarousal due to reminders of the stressful event(s). These symptoms are common to all three of the posttraumatic stress syndromes: ASD, complex PTSD, and PTSD. Survivors of traumatic experiences who develop any or all of these disorders tend to be subjected to unbidden thoughts, feelings, or memories (frequently of physical sensations, as well as visual images or sounds) that they associate with the traumatic experience. These memories make survivors feel as though they are reexperiencing or reliving the traumatic event or events (criterion B). Because recall of the memories is involuntary, survivors' sense of helplessness is intensified. In an attempt to regain control over an environment that survivors feel is increasingly out of control, they begin to anticipate danger, and become overaroused and easily startled (criterion D). In an attempt to moderate their overwhelming feelings of fear and anxiety, survivors often try to avoid anything that might remind them of their traumatic experience; in some cases this can lead to social withdrawal, flat affect, and an emotional "shutting down" or numbing (criterion C).

In school-age and younger children, upsetting dreams about the stressful experience can change over time into nightmares of monsters or other fearful and threatening experiences. Reliving of the event(s) may also take the form

of “traumatic play,” wherein aspects of the experience are recreated in play. British children, for instance, played airplane games during the bombing of London in World War II (Freud & Burlingham, 1943), and children held hostage on a school bus played school bus games (Terr, 1981). There have been some reports of a sense of “foreshortened future” among traumatized children, wherein they report feeling as though they will not live to be very old. Anxiety also may be expressed in traumatized children as physical symptoms, such as stomachaches and headaches.

For a diagnosis of PTSD to be made, the child must have been exposed to an event or events wherein death or serious injury was involved or threatened, and the child or adolescent must have reacted with feelings of intense fear, horror, or helplessness (criterion A; see Table 9.1). *The child or adolescent need not have been directly involved in the event or even in direct danger. He or she may have witnessed the event happening to others, or he or she may only have heard about such an event from others, as when told by others* (Saigh, 1985, 1991) *or they may have only viewed such events on television* (Pfefferbaum et al., 2000). The division of traumatic events into two broad types has proved to have heuristic utility (Fletcher, 2003). Type I traumatic events may be considered acute high-magnitude stressors, because they tend to occur once and are of relatively short duration. Natural disasters, such as hurricanes, and man-made calamities, such as fires, are examples of Type I high-magnitude stressors. Type II traumatic events tend to be of prolonged duration, with multiple repetitions. They also tend to be interpersonal and violent. Sexual abuse and physical abuse are examples of Type II high-magnitude stressors, as are violent political kidnappings, witnessing parental torture, and possibly domestic violence between caretakers and their partners. ASD tends to result from Type I traumatic events, and complex PTSD symptoms typically arise from exposure to extremely traumatizing Type II events. PTSD can result from both types of traumatic events, although symptomatic reactions may differ depending on the type of event (Fletcher, 2003).

DSM-IV requires one symptom of reexperiencing of the event after exposure occurs (criterion B). Also required are three symptoms of denial, avoidance, withdrawal, or numbing (criterion C). Requiring three symptoms of de-

nial or avoidance may be too restrictive (Green, 1993), because it is difficult to identify such symptoms, whether the identification is made by the survivor, an observer, or the person making the assessment. This may be difficult when assessing the reactions of children (Scheeringa & Zeanah, 2003; Schwarz & Kowalski, 1991) and particularly when assessing reactions of infants (Scheeringa & Zeanah, 1995).

Criterion D of DSM-IV requires two reactions symptomatic of overarousal to make a diagnosis of PTSD. Criterion E requires that symptoms have endured for at least 1 month. Criterion F requires that these symptoms cause clinically significant distress or disrupt important activities in the child’s or adolescent’s life. Criterion F needs serious consideration by the clinician. It is likely that disruption in more than one sphere of the child’s or adolescent’s life is associated with greater severity of the disorder. Restoring a sense of safety and meaningfulness to these important activities should be an essential and concrete goal in therapy.

Some clinicians and therapists have argued that symptom lists for PTSD included in DSM-IV and in the 10th revision of the *International Classification of Diseases* (ICD-10; World Health Organization, 1992) may not be inclusive enough (Keane, 1993), especially when the reactions of children or infants (Scheeringa, Zeanah, Drell, & Larrieu, 1995) are involved (Armstrong & Holaday, 1993). Still others question the reliance on diagnostic criteria, arguing that a dimensional approach to the assessment of posttraumatic stress responses, rather than the dichotomous diagnostic method of DSM-IV and ICD-10, might prove more fruitful in the long run for both the researcher and the clinician (Keane, 1993; Putnam, 1998).

These points may be illustrated with the results of a study of the aftereffects on first- and third-grade children exposed to a hostage-taking incident in Paris (Vila, Porsche, & Mouren-Simeoni, 1999). The researchers reported the number of children who not only met DSM-IV diagnostic criteria for PTSD, but also those who did not meet full PTSD criteria but did meet all criteria except one of criterion C (avoidance) and one of criterion D (overarousal). Children who met this reduced set of criteria were said to have subclinical posttraumatic stress. They found that 7 (26.9%) of 26 children met the full DSM criteria for PTSD at

some time during the 18-month follow-up period, whereas 13 (50%) met criteria for subclinical posttraumatic stress, while never meeting the full DSM-IV criteria for PTSD diagnosis. Moreover, of the seven children who met the full criteria at some point during the follow-up period, three children originally only met criteria for subclinical posttraumatic stress when they were first assessed.

Prevalence and Incidence

The prevalence of PTSD among children in the community has been estimated to be between 1 and 14% (APA, 1994). However, these figures apply to children and adolescents regardless of whether they have ever been exposed to a high-magnitude stressor. Incidence rates among those who have actually experienced trauma provide more meaningful information for clinical and research purposes. Even then the picture is complicated by the need to take into account the kinds of stressful events involved, the ages and developmental stages of the children or adolescents exposed to the events, their gender and ethnicity, how their reactions were assessed, how soon after their exposure their reactions were assessed, and other potential mediators and moderators of the impact of the stressful events on the survivors (Fletcher, 2003).

After Hurricane Hugo, 5,687 youths between the ages of 9 and 19 were surveyed for their reactions (Lonigan, Shannon, Finch, Daugherty, & Taylor, 1991; Shannon et al., 1994). The overall incidence of those who met criteria A–D of DSM-III-R (APA, 1987) was 5.4%. Girls were more likely (6.9%) than boys (3.8%) to meet all of these criteria. There were no significant differences observed among the ethnic groups, with an incidence of 6.3% among African Americans (who represented 25.8% of the sample), whereas it was 5.1% among all of the other ethnic groups. The incidence was 9.2% among school-age children (ages 9–12), which was higher than the 4.2% rate for those ages 13–15, and the 3.1% rate for those ages 16–19.

The estimated incidence rates of this study are likely to be conservative and perhaps not as accurate as they might have been if a different assessment tool had been employed. The researchers in this particular instance used one of the first assessment tools developed to measure childhood PTSD, the Child Posttraumatic Stress Re-

action Index (CPTS-RI; Frederick, 1985b; Frederick, Pynoos, & Nader, 1992; Pynoos et al., 1987; see Appendix 9.5). The CPTS-RI was not designed to be used to determine PTSD diagnosis using DSM-IV criteria. To do so, researchers are forced to modify the way the measure is scored (Nader, 1993, 1999). Estimates of incidence rates depend on the manner in which researchers choose to dichotomize the 5-point scale response categories for each item. Two choices are possible: (1) to consider a symptom as present if the relevant item is rated with one of the two highest responses, or (2) to use the three highest responses as indicative of the presence of a symptom. The first approach obviously produces lower estimates (as demonstrated by Schwarz & Kowalski, 1991). Shannon and colleagues (1994) and Lonigan and colleagues (1991) used the first, more conservative approach, which may have underestimated incidence rates of PTSD among the children of Hurricane Hugo.

Other studies have found higher incidence rates. Of 1,019 fourth- to eighth-grade students in North Carolina surveyed after a major fire in a chicken-processing plant in the community, 11.9% met DSM-III-R criteria for PTSD (March, Amaya-Jackson, Terry, & Costanzo, 1997). In another study of urban youth exposed to community violence, 24% met PTSD criteria (Breslau, Davis, Andeski, & Peterson, 1991), whereas in a similar study, 34.5% of youth met full PTSD criteria (Berman, Kurtines, Silverman, & Serafini, 1996). A meta-analysis of the empirical literature (Fletcher, 2003) found incidence rates similar to those in the two preceding studies, with estimated rates of 39% for preschool children (≤ 7 years old), 33% for school-age children (6–12 years old), and 27% for adolescents (12 years and older).

Gender Differences

Whether or not gender differences are found among children and adolescent survivors of extremely stressful events depends on several factors. Boys and girls tend to be exposed to different kinds of interpersonal violence. Girls, for instance, are more likely than boys to report having experienced sexual abuse or rape, whereas boys are more likely to report having been a victim of community violence (Bergen, Martin, Richardson, Allison, & Roeger, 2004; Garland et al., 2001; Helzer, Robins, & McEvoy, 1987).

Girls and boys may also react differently to the same traumatic events. Girls may be more likely to react with internalizing behavior problems, such as clinging, worrying, sullenness; whereas, boys may be more likely to react with both internalizing and externalizing behavior problems, such as argument, hot temper, impulsivity, or hyperactivity (Bolton, O’Ryan, Udwin, Boyle, & Yule, 2000; Jaffe, Wolfe, Wilson, & Zak, 1986; Winje & Ulvik, 1998). Sexually abused girls between the ages of 2 and 6 years in one study (Kiser et al., 1988) tended to feel sad and depressed, whereas boys the same age who had been sexually abused tended to act with rage and aggression. Girls reported significantly more feelings of fear, horror, and helplessness in response to a hurricane than did boys (Goenjian et al., 2001). Moreover, although significant bivariate associations indicated that girls reported more symptoms of PTSD than did boys, gender differences disappeared in multivariate analyses when subjective reactions were considered as well. This suggests the possibility that girls may report higher levels of PTSD symptomatology than boys, because girls are liable to experience more fear, horror, and helplessness in the face of traumatic events. Some support for this possibility was found in assessments of reactions of children and adolescents to Hurricane Hugo (Lonigan et al., 1991; Shannon et al., 1994). There, too, girls reported more PTSD symptoms than did boys; in addition, they were more likely to report being distressed by the hurricane, feeling upset by thoughts of it, fearing its recurrence, avoiding reminders of the hurricane, avoiding feelings about it, and experiencing affective numbing, somatic complaints, guilt feelings, and increased startle response.

On the other hand, the coping strategies of girls may be more adaptive than those of boys. Girls may be more likely to seek social support, whether from a caregiver or from peers, after experiencing a severe trauma, and they may be more likely to receive social support from important others once they seek it (Milgram & Toubiana, 1996; Rossman, 1992). Moreover, girls’ use of anger seems to decline with age; although its use by boys appears to decline between ages 8 and 9 years, it seems to increase again between ages 10 and 12 (Rossman, 1992).

Even the time of assessment relevant to the potentially traumatic experience may make a difference in gender-reported symptomatology.

The sexually abused preschool boys observed by Kiser and colleagues (1988) were more likely than sexually abused girls to be withdrawn immediately after their abuse was discovered; whereas, a year later, girls were more likely to be withdrawn. Posttraumatic stress symptomatology among boys after a nuclear waste disaster decreased over time, whereas it increased among girls (Korol, Green, & Gleser, 1999). Similarly, displaced boys in wartime Bosnia showed more symptoms of anxiety, overarousal, and intrusive thoughts than girls at first assessment, but 8 months later, girls were more symptomatic in these areas than boys (Stein, Comer, Gardner, & Kelleher, 1999).

Ethnic and Cultural Variations

There is ample evidence that PTSD occurs among children of different cultural and ethnic backgrounds (Ahmad & Mohamad, 1996; Beals et al., 1997; DeJong, Emmett, & Hervada, 1982; Diehl, Zea, & Espino, 1994; DiNicola, 1996; Jones, Dauphinais, Sack, & Somervell, 1997; Lindholm & Willey, 1986; Pierce & Pierce, 1984). On the whole, when exposed to Type I, acute, nonabusive stressors of high magnitude, children of non-European descent may present with more severe levels of posttraumatic symptomatology than children of other ethnic backgrounds. Of the 5,587 youth ages 9–19 whose reactions to Hurricane Hugo were assessed (Shannon et al., 1994), the majority were of European American descent (67.3%), whereas 25.8% were African American, 3.6% were Asian American, 1.4% were Hispanic American, and 1.9% were from “other minority” groups. Even after controlling for the severity of the traumatic experience and for levels of trait anxiety, African American children and adolescents reported more symptoms of criteria A through D of DSM-III-R PTSD than did the European American or other, non-African American minority children and adolescents. At the same time, the proportion of African Americans (6.3%) who met the core criteria, A through D for PTSD, did not differ significantly from the proportion of other children and adolescents (5.1%) who met the same criteria.

On the other hand, ethnic group differences were observed in a prospective study of the reactions to Hurricane Andrew of 442 fifth, sixth, and seventh graders (La Greca et al.,

1996). European American children constituted 45.7% of the sample, whereas Hispanic American and African American children each comprised 23.5% of the sample, and Asian Americans, 3.4%. The Hispanic American and African American children reported similar levels of posttraumatic symptomatology, at levels that were approximately one-half a standard deviation higher than those reported by the European American children. Moreover, the African American and Hispanic American children were less likely to demonstrate improved PTSD symptomatology over time. As the authors remarked, "These ethnic differences in PTSD reporting may be related to other variables associated with minority status, such as the limited availability of financial resources" (p. 721), but the reasons for the differences remain unclear.

Cultural and ethnic differences become more complex when Type II chronic or abusive stressors of high magnitude are considered. Upon review of the medical records of four groups of American children—80 of African, 69 of Asian, 89 of European, and 80 of Hispanic origin—referred to a clinic for sexual abuse, several differences among the groups emerged (Rao, DiClemente, & Ponton, 1992). Sexual acting out was least likely to be observed among Asian American children (1.4% vs. 15.0% among African Americans, 17.5% among European Americans, and 12.8% among Hispanic Americans). Asian American children were also the least likely to display anger (8.7% vs. 21.3% among African Americans, 22.5% among European Americans, and 20.0% among Hispanic Americans). Urinary problems were least frequently found among Asian American children (2.9%) and most frequently among European Americans (17.5%), with the frequency among African Americans (10.0%) and Hispanic Americans (6.3%) in between the two extremes. On the other hand, suicide attempts or ideation occurred most frequently among Asian American children (21.7% vs. 11.3% among African Americans, 15.0% among European Americans, and 10.0% among Hispanic Americans).

Cultural background may affect how PTSD symptomatology is manifested (Cohen et al., 1998). DSM-IV (APA, 1994) notes that children of Hispanic or Latin American origins, for example, may manifest symptoms as the culture-bound syndrome of *susto*, also known as "fright sickness," literally meaning a loss of the soul from the body (Rubel, O'Neil, &

Collado-Ardon, 1984). The cause is a sudden frightening experience such as an accident, a fall, witnessing a relative's sudden death, or any other potentially dangerous event. Symptoms include nervousness, anorexia, insomnia, listlessness, despondence, involuntary muscle tics, and diarrhea. A diagnosis is based on the symptom complex and the associated history of a traumatic event. Unfortunately, research on the impact of culture and ethnicity among non-American cultures, especially immigrants and refugees, is in its early stages at best (Jaycox et al., 2002; Sattler et al., 2002).

The many issues surrounding cross-cultural and multiethnic assessment of trauma are far too complex to consider here in depth (Manson, 1997; Marsella, Friedman, Gerrity, & Scurfield, 1996; Stamm & Friedman, 2000). However, it was considered of such importance that Appendix I of DSM-IV is devoted to an "Outline for Cultural Formulation and Glossary of Culture-Bound Syndromes." Manson (1997), a member of the NIMH-sponsored Culture and Diagnosis Group that wrote that appendix for DSM-IV (Mezzich, 1995), provides a discussion and example of how to conduct a cultural formulation when taking a client's history. Every clinician should be able to conduct a cultural formulation, not only because immigrants, and in particular refugees from war torn third-world countries, are increasingly likely to settle in areas other than their traditional ports of entry, but because even within the United States there are ethnic and cultural differences that should be considered when assessing and treating trauma with Native Americans, Hispanics who themselves are not a homogeneous culture, and black Americans born in this country. The National Child Traumatic Stress Network (Ko, 2005, p. 1) notes the extent of the problem in the United States:

Research indicates that children and adolescents from minority backgrounds are at increased risk from minority exposure and development of Post-traumatic Stress Disorder [PTSD; Jaycox et al., 2002; Norris, Byrne, Diaz, & Kaniasty, 2002]. For example, African American, American Indian, and Latin American children are overrepresented in reported cases of child maltreatment, and in foster care [U.S. Department of Health and Human Services, Administration for Children and Families, 2002]. Further, research indicates that disasters pose particular burdens in mental health for ethnic minority and developing country popu-

lations, especially for children, due to social, economic, and political marginalization, deprivation, and powerlessness [Sattler et al., 2002]. Consequently, minority children fare worse in the aftermath of trauma, often experiencing more severe symptomatology for longer periods of time, than their majority group counterparts [Cohen, Deblinger, Mannarino, & de Arellano, 2001; Jones, Hader, Carvajal, Chapman, & Alexander, 2006; Norris & Alegria, 2005].

Acute Stress Disorder

If posttraumatic reactions are restricted to 1 month after traumatic exposure, PTSD may not be diagnosed. ASD, however, can be, if symptomatology meets DSM-IV criteria. Whereas some of the symptomatology of ASD (see Table 9.2) parallels that of PTSD, the pri-

mary distinction, besides timing of responses, is dissociative symptomatology. Although this includes the absence of emotional responsiveness, a general sense of detachment or emotional numbing, which is included as a symptom of avoidance or withdrawal in PTSD, it includes additional symptoms not considered essential for PTSD diagnosis. Survivors might experience a reduction of awareness of the surroundings, of “being in a daze,” for example, and may find it difficult to recall some or all aspects of their experience. A feeling that their experience cannot have been real (derealization) is also possible. Their sense of detachment from their experience may become so extreme that they begin to feel that what they are living is not happening to them, that it is all a dream (depersonalization). To meet criteria for diag-

TABLE 9.2. DSM-IV-TR Diagnostic Criteria for Acute Stress Disorder

-
- A. The person has been exposed to a traumatic event in which both of the following were present:
- (1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
 - (2) the person’s response involved intense fear, helplessness, or horror
- B. Either while experiencing or after experiencing the distressing event, the individual has three (or more) of the following dissociative symptoms:
- (1) a subjective sense of numbing, detachment, or absence of emotional responsiveness
 - (2) a reduction in awareness of his or her surroundings (e.g., “being in a daze”)
 - (3) derealization
 - (4) depersonalization
 - (5) dissociative amnesia (i.e., inability to recall an important aspect of the trauma)
- C. The traumatic event is persistently reexperienced in one (or more) of the following ways: recurrent images, thoughts, dreams, illusions, flashback episodes, or a sense of reliving the experience or perceptions; or distress on exposure to reminders of the traumatic event.
- D. Marked avoidance of stimuli that arouse recollections of the trauma (e.g., thoughts, feelings, conversations, activities, places, people).
- E. Marked symptoms of anxiety or increased arousal (e.g., difficulty sleeping, irritability, poor concentration, hypervigilance, exaggerated startle response, motor restlessness).
- F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or impairs the individual’s ability to pursue some necessary task, such as obtaining necessary assistance or mobilizing personal resources by telling family members about the traumatic experience.
- G. The disturbance lasts for a minimum of 2 days and a maximum of 4 weeks and occurs within 4 weeks of the traumatic event.
- H. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition, is not better accounted for by Brief Psychotic Disorder, and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.

nosis, survivors must manifest three or more of these symptoms. On the other hand, they are not required to have more than one symptom of each of the “core” PTSD symptoms: re-experiencing, avoidance of stimuli associated with the traumatic event(s), and increased arousal. Note that symptoms of *both* avoidance and numbing or dissociation are required to meet the criteria for diagnosis of ASD, unlike the criteria for PTSD, which require three symptoms of avoidance, withdrawal, or numbing (but not dissociation). Moreover, the symptoms of dissociation can manifest *during* the traumatic event(s), as well as immediately after.

The definition of ASD has been controversial since its inception in DSM-IV (Davidson et al., 1996; Marshall, Spitzer, & Liebowitz, 1999; Rothbaum & Foa, 1993). The objective was to allow identification of clinically important responses to high-magnitude stressors in the immediate aftermath of the experience, during the 4-week period in which PTSD could not be diagnosed, while avoiding the possibility of assigning a diagnosis to survivors who would eventually recover on their own (Davidson et al., 1996; Marshall et al., 1999). At that time, several studies found that dissociative responses during or immediately after traumatic experiences were predictive of eventual diagnosis of PTSD (see Cardeña, Lewis-Fernández, Bear, Pakianathan, & Spiegel, 1996, for a review). Information on the incidence of ASD after exposure to high-magnitude stressors has yet to be explored adequately. Nor is there currently much generally agreed-upon information about the risk factors for developing ASD after exposure to extreme stressors, the association of its occurrence with the development of PTSD, or other factors that might influence its etiology and prognosis. What little evidence exists regarding ASD among children and adolescents suggests that the incidence of dissociative symptoms after high-magnitude stressors, key criteria for diagnosis of ASD, is considerably less than that found among adults (Daviss, Mooney, Racusin, Fleischer, et al., 2000; Daviss, Mooney, Racusin, Ford, et al., 2000; Kassam-Adams & Winston, 2004) and does not predict later incidence of PTSD. The requirement for symptoms of dissociation has thus far led to lower incident rates for diagnosis of ASD than for subsyndromal ASD. Rates of ASD among children and adolescents after hospitalization for injuries were 7.4%, whereas rates for subsyndromal ASD were 22% (Daviss, Mooney,

Racusin, Ford, et al., 2000). Similarly, rates for full versus subsyndromal ASD were 8% versus 14% among traffic accident survivors (Kassam-Adams & Winston, 2004), and 19.4% versus 24.7% among children and adolescents involved in assaults or motor vehicle accidents (Stedman, Yule, Smith, Glucksman, & Dalgleish, 2005). In all of these studies, however, although diagnosis of ASD was a good predictor of later PTSD, dissociation did not play a significant role in the prediction. The number of ASD symptoms (which does not depend on endorsement of dissociative symptoms) is what predicts later PTSD rather than the diagnosis of ASD (which does depend on endorsement of dissociative symptoms). Much more research is clearly needed regarding the incidence of ASD among children, with special attention to the predictability of later PTSD from ASD severity versus diagnosis. The development of good measures of ASD symptomatology is required for such research. Fortunately, work has begun in this area, as described in a later section of this chapter.

Complex PTSD

The DSM-IV-TR (APA, 2000) definition of PTSD implicitly acknowledges the development of more severe symptoms as the duration of the condition increases, noting that duration of symptoms for less than 3 months is indicative of acute PTSD, whereas longer duration indicates chronic PTSD (see Table 9.1). The literature has increasingly noted the greater likelihood of comorbid conditions developing the longer PTSD persists (Keane & Kaloupek, 1997; van der Kolk et al., 2005). Foa, Friedman, and Keane (2000) note that more than 80% of patients with PTSD suffer from comorbid conditions. Many PTSD researchers and clinicians have proposed that most of the symptoms that DSM-IV lists as associated symptoms actually provide a description of complex PTSD, and that this syndrome “provides a clear delineation of the enduring developmental effects of trauma” and “is helpful in conceptualizing the complex adaptations to trauma over the lifespan” (van der Kolk & Courtois, 2005, p. 386).

Pain (2002) has suggested that this conceptualization of complex PTSD fits Kardiner’s original (1941) conceptualization of the developmental course of traumatic reactions. She noted that he

postulated a two-stage response to trauma that also takes into account how the disorder changes as it becomes long-standing. He described the core response to trauma and first stage as expressed in the symptoms of PTSD. Stage two—the change from simple PTSD to PTSD with comorbidity, or what we are calling complex PTSD or DESNOS—represents the personality's adaptation and reorganization in response to the compromised function caused by failure to recover from the original trauma(s). This concept is salient in the case of individuals who suffered repeated and prolonged psychological trauma during childhood, which disturbed the normal developmental trajectory. (p. 13)

Because complex PTSD is not a recognized disorder in DSM-IV, there is no formal definition of the syndrome. However, criteria for complex PTSD were created for the DSM-IV field trial for PTSD, which also explored the viability and utility of a separate diagnostic category for complex PTSD (Kilpatrick et al., 1998; van der Kolk et al., 1996). Since that time various listings of symptom categories have been suggested, but most include the following seven categories: (1) difficulties regulating affect and impulses, (2) alterations in attention or consciousness, (3) somatization, (4) distorted self-perception, (5) distorted perceptions of the perpetrator, (6) difficult relations with others, and (7) alterations in systems of meaning. Descriptions of the kinds of symptoms in each of the seven categories may be found in Table 9.3, in which categories and symptoms are based on similar listings in Herman (1992), Pelcovitz and colleagues (1997), and van der Kolk and colleagues (2005).

Very little is known about the manifestation of complex PTSD symptoms among children and adolescents. However, the DSM-IV field trial for PTSD included adolescents age 15 years and older who were identified as meeting criteria for complex PTSD (van der Kolk et al., 1996, 2005). Moreover, research has shown that traumatized children have problems with unmodulated impulse control and aggression (Cole & Putnam, 1992; Steiner, Garcia, & Matthews, 1997), may be prone to dissociation and to problems maintaining attention (Perry, 2001; Perry, Pollard, Blakley, Baker, & Vigilante, 1995; Teicher et al., 2003), and have difficulties forming trusting relationships with both caregivers and peers (Schneider-Rosen & Cicchetti, 1984). Thus, growing evidence indi-

cates that children, adolescents, and young adults can and do develop clusters of symptoms that bear a strong resemblance to the proposed syndrome of complex PTSD. Even if this cluster of symptoms is not accepted as an official syndrome, clinicians should be alert to the possibility of such associated and related symptoms of PTSD developing among children exposed to abuse and neglect of any kind, especially if the abuse started when they were young and continued over a prolonged period of time.

Other Comorbid Disorders

As noted earlier, survivors of traumatic experiences who react with symptoms of PTSD are more likely than not to show signs of other disorders as well. For children and adolescents these include substance abuse (Kilpatrick et al., 2000), adjustment, panic, depressive (Kilpatrick et al., 2003), anxious, dissociative, attention deficit (Saigh, Yasik, Sack, & Koplewicz, 1999), and eating disorders (Breslau, Davis, Andreski, Peterson, & Schultz, 1991; Cloitre, Chase Stovall-McClough, Miranda, & Chemtob, 2004; Finkelhor & Kendall-Tackett, 1997; Zlotnick et al., 1996). There is increasing evidence that adults who suffered childhood abuse may have long-term medical problems as well, including cardiovascular, immunological, metabolic, and sexual problems (Briere & Elliott, 2003; Dube et al., 2001; Felitti et al., 1997; Hulme, 2000; van der Kolk et al., 2005). Clinicians need to be aware of the possible existence of such comorbid disorders, both when assessing and treating children clearly identified as survivors of high-magnitude stressors and when seeing children with these conditions who have not been identified as survivors of potentially traumatic events.

ASSESSMENT OF PTSD IN CHILDREN

Practice parameters for the assessment and treatment of children and adolescents with PTSD have been published by the American Academy of Child and Adolescent Psychiatry (AACAP; Cohen et al., 1998). This article includes a review of several measures of childhood PTSD, as does another review (Ohan, Myers, & Collett, 2002) by the same journal. The AACAP practice parameters appear to be directed primarily toward the clinician situated in the clini-

TABLE 9.3. Complex PTSD Symptom Constellation Arranged into Categories

<u>I. Difficulty regulating affect and impulses</u>	
<p>A. Affect regulation</p> <ul style="list-style-type: none"> • Easily upset. Difficulty calming down once upset. • Persistent dysphoria. <p>B. Modulation of anger</p> <ul style="list-style-type: none"> • Persistent feelings of anger. • Difficulty controlling anger. <p>C. Self-destructive</p> <ul style="list-style-type: none"> • Either deliberate hurting of self or involvement in an unusual number of serious “accidents.” 	<p>D. Suicidal preoccupation</p> <p>E. Difficulty modulating sexual involvement</p> <ul style="list-style-type: none"> • Sexual preoccupation, from fantasy to situations that put self at risk or in danger. <p>F. Excessive risk taking</p>
<u>II. Alteration in attention or consciousness</u>	
<p>A. Amnesia</p> <ul style="list-style-type: none"> • Unable to remember important parts of life history, or confusion or uncertainty about whether certain events did or did not take place. <p>B. Transient dissociative episodes</p> <ul style="list-style-type: none"> • Difficulty keeping track of time in daily life. • “Spacing out” when feeling frightened or under stress. 	<p>C. Depersonalization or derealization</p> <ul style="list-style-type: none"> • Feeling unreal or as if living in a dream. Events do not seem real. <p>D. Reliving the traumatic experiences</p> <ul style="list-style-type: none"> • Through intrusive memories, etc., as in PTSD, or through ruminative preoccupation with the events or similar kinds of events.
<u>III. Somatization</u>	
<p>A. Digestive system</p> <ul style="list-style-type: none"> • Unexplained nausea, abdominal pain, intolerance of food, vomiting, diarrhea. <p>B. Chronic pain</p> <ul style="list-style-type: none"> • Recurrent, unexplained pain in arms, legs, back, joints, genitals, while urinating, headaches. <p>C. Cardiopulmonary symptoms</p> <ul style="list-style-type: none"> • Shortness of breath, dizziness, heart palpitations, chest pain. 	<p>D. Conversion symptoms</p> <ul style="list-style-type: none"> • Unexplained difficulties remembering things, difficulties swallowing, losing one’s voice, blurred vision, actual blindness, fainting and losing consciousness, seizures and convulsions, difficulties walking, muscle weakness or paralysis, difficulties urinating. <p>E. Sexual symptoms</p> <ul style="list-style-type: none"> • Unexplained burning sensations in sexual organs or rectum (not during intercourse); impotence for males; irregular menstrual periods, excessive premenstrual tension, excessive menstrual bleeding for females.
<u>IV. Distorted self-perception</u>	
<p>A. Ineffectiveness</p> <ul style="list-style-type: none"> • Feelings of having no control over what happens to self. • Can manifest as paralysis of initiative. <p>B. Permanent damage</p> <ul style="list-style-type: none"> • Feelings of having something wrong with self that can never be fixed. <p>C. Guilt and self-blame</p> <ul style="list-style-type: none"> • Persistent and recurring feelings of guilt about many things. • A readiness to assume guilt in new situations. 	<p>D. Shame</p> <ul style="list-style-type: none"> • Feelings of deep shame. • Poor self-esteem. <p>E. Nobody can understand</p> <ul style="list-style-type: none"> • Feelings of being different and set apart from others. <p>F. Minimizing</p> <ul style="list-style-type: none"> • Minimizing one’s own victimization and the victimization of others.
<u>V. Distorted perceptions of the perpetrator</u>	
<p>A. Adopting distorted beliefs</p> <ul style="list-style-type: none"> • Believing that one deserved to be hurt or “punished.” <p>B. Idealization of the perpetrator</p> <ul style="list-style-type: none"> • Unrealistic attribution of total power to perpetrator. • Paradoxical gratitude. 	<p>C. Preoccupation with relationship with the perpetrator, including preoccupation with revenge</p> <ul style="list-style-type: none"> • Sense of special or supernatural relationship. <p>D. Identification with the perpetrator</p> <ul style="list-style-type: none"> • Acceptance of beliefs or rationalizations of the perpetrator.

(continued)

TABLE 9.3. (continued)

<u>VI. Difficult relations with others</u>	
A. Inability to trust <ul style="list-style-type: none"> • Difficulties forming and keeping intimate relationships. B. Isolation and withdrawal <ul style="list-style-type: none"> • May alternate with repeated search for rescuer. 	C. Revictimization <ul style="list-style-type: none"> • Vulnerability to being victimized in a manner similar to the original trauma and in new kinds of traumas. D. Victimizing others <ul style="list-style-type: none"> • Victimizing others in a manner similar to the original trauma.
<u>VII. Alterations in systems of meaning</u>	
A. Despair and hopelessness	B. Loss of previously sustaining beliefs <ul style="list-style-type: none"> • Loss of belief in the meaningfulness of life. Loss of religious beliefs or other previous sustaining beliefs.

cal setting. As such, they do not address the particular needs of assessment outside the clinical setting. Assessment needs in the field during and immediately after the occurrence of a high-magnitude stressor, such as Hurricane Katrina, call for a different approach to assessment—a two-stage process: a quick screening, followed by a more intensive assessment for individuals who screen positive for posttraumatic stress reactions. Because clinicians may be asked to assist in crisis situations, the unique assessment needs associated with the initial screening for the possible presence of ASD or PTSD are considered here as well. Since the AACAP Workgroup on Quality Issues made its recommendations (Cohen et al., 1998), and since Ohan and colleagues made their recommendations in 2002, much more has been learned about the assessment of children's reactions to high-magnitude stressors, and many more assessment tools have been created and tested. As such, measures recommended in this chapter frequently differ from the AACAP and Ohan and colleagues recommendations.

Factors to Consider When Choosing Assessment Tools

As noted earlier, simply being exposed to a potentially traumatic event does not necessarily mean a child will develop ASD, PTSD, complex PTSD, or any other adverse reaction. Children's and adolescents' responses to high-magnitude stressors may be affected by quite a few factors, many of which need to be considered during the assessment process (for more detailed consideration of these factors, see

Fletcher, 2003; Nader, 1997; and, in particular, Nader, in press). Some of the more salient factors were discussed briefly earlier. Additional factors that need to be considered in assessment include the age and developmental stage of the youth, the youth's reading level and verbal comprehension, the purpose of the assessment, the type of stressor to which the youth was exposed, how close the youth was to the central aspects of the stressor, how long the exposure lasted, and how the youth's parents reacted to his or her experience. It is particularly important to be mindful of the psychometric properties of the measures.

Clinical Utility

One criterion for choosing a clinical measure that is more often assumed than explicitly considered, both by clinicians and by those who develop such measures, is clinical utility. Of course, no one would create or choose to use a clinical measure unless it was thought to have some sort of clinical utility. Just what that utility might be, however, is not always considered beyond accurate assessment and diagnosis, and perhaps as a measure of success or failure of clinical interventions (a use that unfortunately is found more often in research than in clinical practice). Part of the reason for the lack of clarity on the clinical utility of such measures may be the lack of a formal definition for the term, especially as it relates to clinical measures. One notable attempt to define "clinical utility" has been made as it relates to the clinical utility of psychiatric diagnoses. First and colleagues (2004) define clinical utility in this regard as

the extent to which DSM assists clinical decision makers in fulfilling the various clinical functions of a psychiatric classification system. These functions include assisting clinicians and other users with the following:

1. Conceptualizing diagnostic entities
2. Communicating clinical information to practitioners, patients and their families, and health care systems administrators
3. Using diagnostic categories and criteria sets in clinical practice (including for diagnostic interviewing and differential diagnosis)
4. Choosing effective interventions to improve clinical outcomes
5. Predicting future clinical management needs (p. 947)

With minimal revision this could be applied to a definition of the clinical utility of a clinical assessment tool. Measures of ASD, PTSD, and complex PTSD should be able to guide the clinician's conceptualization of each of these diagnostic entities. Inasmuch as a measure includes assessment of all suggested symptoms and rules for determining whether requirements are met for each criterion associated with these syndromes, it can be said to meet the first requirement of clinical utility set forth by Fast et al. Many measures of childhood PTSD do not explicitly address criterion E (the duration of symptoms must be more than 1 month posttrauma) or criterion F (the symptoms must lead to clinically significant distress and substantial social dysfunction). The clinician needs to consider whether associated symptoms should also be measured, in addition to the required symptoms, such as criteria A–F for PTSD. In some cases, for example, among the very young, some relevant symptoms may not even be considered by most of the child PTSD assessment tools currently available, as noted in the later discussion of developmental issues related to the assessment of childhood PTSD.

Communicating clinical information to the child and family, as well as to other practitioners and administrators, not to mention health insurance agencies—the second point in the First and colleagues (2004) definition of clinical utility—can be facilitated by an assessment tool that allows the clinician to determine the child's precise responses to his or her traumatic experience during the event, immediately after it, and over time. Information obtained using a reliable and valid instrument can provide in-

sight to clinician, child, and family, as well as detailed and documented support for the clinician's diagnosis. Copies of the responses to standardized interviews or surveys placed in the child's medical record can help to ensure that other clinicians and therapeutic caregivers have an adequate understanding of the child's reactions as well.

The third part of the definition of clinical utility is perhaps the most salient reason for creating and using diagnostic assessment tools: diagnostic interviewing and differential diagnosis. It is important to remember that differential diagnosis is a necessary part of the assessment, however. It is also important to remember that PTSD is frequently comorbid with other disorders that also are responses to the same traumatic circumstances. Grief or depression, for example, may also be post-traumatic responses, not just ASD, PTSD, or complex PTSD. Most current PTSD measures (other than the general diagnostic measures described in Appendix 9.3) do not provide screening for other responses so clinicians need to supplement PTSD-specific measures with assessment tools for other possible responses. This is especially the case for children referred for violent, interpersonal stressors of long duration, such as abuse, in which case symptoms of complex PTSD should be assessed, as well as the DSM-IV symptoms of PTSD.

The last two points of the definition of clinical utility—choosing effective interventions and predicting future clinical needs—are clearly related. The results of the first assessment should provide guidelines for how the clinician may best proceed with the initial stages of any intervention. An overemphasis on symptoms of avoidance, numbing, and overarousal may suggest to the clinician that the child is not ready to be asked to focus attention on the details of the traumatic experience at this point. Perhaps issues of trust, therapeutic bonding, and reassurance of security would be good places to start with this particular child. At the same time, the clinician should be alert to the fact that such heightened attention to defending against reminders may indicate the intensity with which such reminders are likely to return once the child does gain a minimum sense of safety and reassurance, and be prepared for the fear that such intense reminders are likely to inspire in the child.

The anticipation of dynamic changes over time in presenting symptomatology when treat-

ing individuals with posttraumatic stress suggests another aspect of the clinical utility of measures of PTSD that is not explicitly considered in First and colleagues' (2004) definition: the ability to monitor a child's changing symptomatology. For the most part, of course, clinicians monitor the progress of their client's symptomatology on a regular but unstructured basis as they discuss their progress. However, an occasional formal assessment of current symptomatology can ensure that no possible symptoms are being overlooked. Such assessments also provide an opportunity to examine the child's progress by comparing the child's current and previous responses. This can be particularly productive in the group setting, where some children may tend to participate in group discussion less than others. Formal assessment also assists in the evaluation of different types of intervention. In fact, only in this context has the ability of a measure to monitor children's progress been assessed to any degree thus far. For a measure to serve as a useful monitoring tool, it needs to be able to reflect actual changes accurately in children's posttraumatic stress symptomatology; that is, it needs to be responsive to true change in symptomatology. There are formal methods of assessing a measure's responsiveness to change, but these methods have yet to be used to test the responsiveness of any of the currently available measures of childhood ASD, PTSD, or complex PTSD.

The Clinical Assessment

In what follows, the terms "child" and "children" include infants, children, adolescents, and young adults unless otherwise noted. A clinician attempting to determine a child's reactions to high-magnitude stressors ideally should collect information from as many sources as possible, including not only the child and one or more caregivers, but also others who knew the child prior to, during, and after the event(s). Additional reporters might include relatives other than the primary caregivers, siblings, teachers, peers, and others who were affected by the event(s), especially those who lived through it with the child. When the stressor involves abuse or domestic violence, any alleged offending caregiver need not be interviewed, although a report from sources involved with eliciting the offender's report of the event(s) can be helpful.

OBTAIN A HISTORY

The article "*Practice Parameters for the Assessment and Treatment of Children and Adolescents with Posttraumatic Stress Disorder*" (Cohen et al., 1998) recommends the same course of assessment for the parent and the child. The first step is to obtain a thorough history of the child. Whenever possible, information should be sought regarding the child's psychiatric history, including any partial or inpatient hospitalizations, medications (especially psychotropic), and outpatient psychotherapy. This would include any history of mood disorders, anxiety disorders, PTSD symptomatology, and substance abuse, as well as medical conditions that may present as anxiety or mood disorders, such as thyroid disease. An understanding of the medical and psychiatric history of other members of the family may also be very helpful.

The clinician is encouraged to assess the extent to which other stressors have played a part in the child's life, both in the distant past and more recently. As noted earlier, previous exposure to other stressors may have an important impact on the child's reaction to the event(s) under consideration. The clinician should inquire not only into the child's history of exposure to high-magnitude stressors such as abuse or neglect, and exposure to domestic or community violence, but also into the occurrence of and reaction to other, lesser stressors, such as family illnesses, deaths, conflict, separation, or divorce, as well as frequent moves, school changes, or problems in the school or with peers.

Any parental history of exposure to potentially traumatic events also should be considered, whether or not the child might be aware of this history. Any familial history of PTSD is particularly important to determine, because this can have repercussions on the child's outlook on life and ability to cope with stressful events. It also can affect the caregiver's reactions to the child's potentially traumatic experience, especially if that experience mirrors the caregiver's own traumatic experience. The reactions of mothers to their children's abuse experience may be greatly complicated if the mothers themselves have a history of childhood abuse, for example. The clinician should ascertain whether the caregiver was exposed to the same event(s) as the child and if so, the nature of the caregiver's own reactions during and af-

ter experiencing the event(s), and the extent to which the caregiver may have reacted to the experience with symptoms of posttraumatic stress. The parents' own reactions to the *child's* traumatic experiences also should be explored, because children, especially younger children, often use their parents' reactions to the experience to determine how they themselves should be reacting (Fletcher, 2003).

DEVELOPMENTAL CONSIDERATIONS

During the assessment process, the clinician must make an effort to pay attention to developmental variations in the child's reactions. This is particularly important when assessing preschool-age children. Scheeringa, Peebles, Cook, and Zeanah (2001; Scheeringa & Zeanah, 1995; Scheeringa, Zeanah, Myers, & Putnam, 2003) devised and examined the predictive ability of a revised set of particularly interesting criteria for this age group. Their criteria are dependent more on behavioral observations than on verbal descriptions of symptoms (Scheeringa et al., 2003):

Some symptoms had to be developmentally modified because they were derivative functions of memory, abstract thought, emotional processing, or language, which are all in a state of emerging development in young children. Several symptoms could not be used because they were inappropriate for the developmental capacities of young children (e.g., sense of a foreshortened future). The A(2) criterion (the person's immediate response must show extreme emotional or behavioral reactions) was not required, because if the child is perverbal, and an adult is not present to witness the child's reaction, then this symptom is undetectable. One completely new symptom—loss of previously acquired developmental skills such as toileting or speech—was added to cluster C. It was a common symptom in prior studies and fit conceptually with the avoidance/numbing symptoms. An entirely new cluster was added that contained three symptoms that had also been frequently observed: new separation anxiety, new aggression, and new fears that seemed unrelated to trauma reminders. These symptoms did not fit conceptually into the existing cluster so they were placed in a new cluster for further research. Finally, the algorithm threshold was changed so that only one avoidance/numbing symptom (cluster C) was needed instead of three. Only one hyperarousal symptom (cluster D) was needed instead of two. One symptom from the new cluster was needed. (pp. 561–562)

Among 62 children exposed to high-magnitude stressors, none met DSM-IV criteria for PTSD, though 67.9% had at least one symptom of criterion B, reexperiencing (Scheeringa et al., 2003). After examining several alternatives, the researchers concluded that the optimal algorithm was one symptom of both criteria B and C and two of criterion D. Scheeringa and colleagues used this algorithm to diagnose 26% of the young children with PTSD. Children diagnosed with PTSD using this method (Scheeringa, Zeanah, Myers, & Putnam, 2005) were significantly more likely than those not diagnosed with PTSD to show functional impairment 1 and 2 years later, and were more likely 2 years later to be diagnosed with PTSD using DSM-IV criteria per the National Institute of Mental Health (NIMH) Diagnostic Interview Schedule for Children, Version IV (DISC—Shaffer, Fisher, & Lucas, 2000; see Appendix 9.3). Importantly, other research has replicated these findings (Ippen, Briscoe-Smith, & Lieberman, 2004; Ohmi et al., 2002). Much of the criteria used in Scheeringa and Zeanah's measure (see Posttraumatic Stress Disorder Semistructured Interview and Observational Record for Infants and Young Children in Appendix 9.4 for the current version of the measure used) has been adopted for use in the Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood: Revised Edition (DC:0–3R; Zero to Three, 2005) diagnosis of PTSD in this age group.

UNDERSTANDABILITY OF QUESTIONS

It also is important to determine the extent to which all informants, child and adult, are able to understand the meaning of each question asked of them. Too many assessment tools for children and adolescents have been based on adult measures, with no attempt to rewrite questions to make them more child-friendly. One of the original and most widely used measures of childhood PTSD, the Child Posttraumatic Stress Reaction Index (CPTSD—Frederick et al., 1992; see Appendix 9.5), is an unfortunate example of this problem. The clinician should carefully read and assess each measurement tool prior to administering it to caregiver or child and be ready to provide clarifying prompts or explanations, if respondents do not appear to understand any question.

ASSESS THE FULL RANGE OF RESPONSES

The assessment of posttraumatic symptomatology should include the full range of possible reactions. Thus, it should ideally include an assessment of ASD symptomatology, especially if the event occurred less than 1 month prior to the assessment. The dissociative symptoms of ASD are rarely assessed in measures of the core DSM-IV criteria of PTSD, even though the presence of such symptoms more than 1 month after the occurrence of the event(s) may be indicative of more severe reactions to the traumatic event(s). Moreover, if the event(s) to which the child's reactions are being assessed might qualify as "early onset, multiple, extended, and sometimes highly invasive traumatic events, frequently of an interpersonal nature, often involving a significant amount of stigma or shame" (Briere & Spinazzola, 2005, p. 401), then the clinician should attempt to assess possible symptoms of complex PTSD as well. This is particularly important because, as noted earlier, there is evidence that treating the distinctive symptoms of complex PTSD as comorbid conditions rather than as an integral part of the posttraumatic response can lead to markedly reduced response to treatment (van der Kolk & Courtois, 2005; van der Kolk et al., 2005).

Approximate onset dates of traumatic symptoms should be ascertained as often as possible. Only those symptoms with onset after exposure can be considered diagnostic of ASD or PTSD. Duration of symptoms can provide evidence regarding the severity of the traumatic response as well. Some assessment tools ascertain whether symptoms have occurred within the past week or past month. Others specifically determine dates of onset for symptoms that children endorse. Clinicians should be mindful that children younger than 8 years vary in their ability to answer reliably time-related questions about date of onset and duration, or even whether symptoms have occurred within a specific time frame, such as 1 month ago. Certainly children younger than 6 years have great difficulty with such concepts, and caregivers must be relied upon for such information. Caregivers, too, however, are often limited in their ability to answer such questions, particularly if the symptoms refer to internal states. Even their dating of externalizing behaviors may be inaccurate, if onset occurred

outside their purview, such as during recess time at school or afterschool play. Therefore, assessments of onset and duration of symptoms should be considered approximations rather than definitive responses.

When responses from different sources conflict, the child's responses should be considered the most compelling, particularly if the questions concern internal processes, unless there are reasons to question the veracity of the child's statements or his or her ability to recall or articulate the experiences. Generally, the older the child, the more weight his or her responses should be accorded. Responses of primary caregivers, whether parent, grandparent, stepparent, or other, should generally carry nearly as much weight as the child's responses, perhaps even more in some cases, such as those regarding externalizing behaviors. When considering the responses of others who have some knowledge of the child, keep in mind the circumstances under which the respondent and the child normally interact. Teachers, for example, tend to interact with their students in a much narrower set of situations than do primary caregivers, even though the teachers spend several hours a day, 5 days a week with their students. Fathers, or the family's primary source of income, too, may spend less time with the child than do mothers, or the family's primary caregiver, in general. In the final analysis, children who are age 8 and older might be considered to know more about their own experiences, especially their own internal processes, than any adult who knows or cares for them.

Caregiver Assessment

When possible, it is often helpful to obtain as much information as possible from adults in the child's life regarding the stressor(s) to which the child has been exposed, and the child's reactions to the stressor(s), before interviewing the child in any depth concerning his or her experience. In addition to providing valuable information regarding specific details of the traumatic event or stressor(s), caregivers also can supply information about the child's level of functioning. Primary caregivers provide the most detailed and accurate reports about the child's experiences, behavior, and emotional and social life prior to and after the occurrence of the stressful event(s). If the child is of school

age, a report on the child's performance at school, including academic performance, social behavior at school, activity level, and interactions with teachers and other authority figures, may provide information complementary to that of the caregiver regarding the child's post-traumatic functioning outside the home, in situations where the caregiver is rarely present.

Child Assessment

After interviewing the child's caregiver, the clinician should then interview the child, and starts by eliciting the child's understanding of the reason for the referral. The clinician encourages the child to describe the experience(s) from his or her own point of view. Asking for some description of the stressful experience(s) is useful in many ways, because it allows the clinician to develop a picture of the child's subjective experience during and immediately after the traumatic event, and provides an indication of the detail and accuracy of the child's memories of the event(s). It is primarily the child's *perception* of the experience and its consequences, rather than the "objective" description of the event(s) or the caregiver's perceptions of the event, that affects the child's reactions: what he or she saw and experienced, what those experiences meant to the child during the event and afterwards, and, in particular, what thoughts and feelings the experience evoked in the child. At the same time, the child should be allowed to give as much, or as little, information as he or she is willing to divulge during the first interview. More information may be forthcoming as the child becomes more comfortable with the interviewer and the interview process itself.

The clinician tries to discover who or what the child considers responsible for the event(s), whether the child feels responsible to any degree, and whether the child feels that he or she reacted inappropriately to the event(s), or could or should have reacted differently. It is important to determine the extent to which the child *perceives* caregivers and important others to have been distressed by the experience themselves. The younger the child, the more likely his or her reactions are a reflection of the reactions of caregivers and important others (Fletcher, 2003). The interviewer should also attempt to evaluate the level of support the child feels he or she has received from caregivers and important others. In addition, an

understanding of the extent to which the child feels the experience has resulted, or will result, in stigmatization or ostracism by family or peers may be helpful during both the assessment process and treatment. In a similar vein, the interviewer should attempt to determine the child's perceptions concerning his or her reactions to the stressful event(s), in particular, whether the child feels that his or her reactions are "normal." Reassuring children regarding misattributions of self-responsibility for the event(s) and the "normality" of any reactions to it may encourage children to describe their experiences and reactions more openly and honestly, as well as relieve some of their distress.

Assessing the Stressor

Prior to assessing the child's reactions to exposure to a potentially traumatic event or events, the clinician must first develop an understanding of the stressful experience itself. When possible, a detailed description of the events leading up to, during, and following the stressor is important when assessing the child's reactions to the stressful event(s). Discrepancies between the child's description and the "actual" event may provide useful diagnostic information. If a primary caregiver was not present, reports from other sources, including police reports, news reports, and reports of emergency response teams, may be useful in developing a description of the stressor prior to hearing the child's own description.

Assessing Exposure to High-Magnitude Stressors

In some cases, the clinician may not know whether the child has ever been exposed to a high-magnitude stressor. This is often the case when a child is being administered a general psychiatric examination, for example. In those situations, it may be necessary to ask whether or not the child has ever experienced any of a list of potential high-magnitude stressors. Such lists are included in the PTSD module of nearly all of the general child psychiatric interviews listed in Appendix 9.3. There are also stand-alone measures of exposure to stressful experiences available. These are described in Appendix 9.1. Some of these measures assess only exposure to high-magnitude stressors. Other measures assess a wide array of stressors, including not only potentially high-magnitude

stressors, such as abuse, kidnapping, torture, or natural disasters, but also stressors of generally lesser magnitude (e.g., overnight stay in a hospital prior to routine surgery to remove the child's tonsils, the death of a pet, or extended periods of separation from the caregiver, especially at earlier ages), to which past exposure might contribute to the child's reactions to a more current high-magnitude stressor.

Few of the measures that assess only exposure to high-magnitude stressors described in Appendix 9.1 have been examined for their psychometric properties, and none have had both their reliability and validity assessed. Of those with some evidence of acceptable to good test-retest and interrater reliability, the Traumatic Events Screening Inventory (TESI; Ford et al., 2002) seems to show the most promise. Available in both child and parent forms, the TESI is an interview that comprises 16 questions regarding high-magnitude stressors, arranged so that questions about exposure to the lowest magnitude stressors are first and those regarding sexual abuse are last, to help the child and parent tolerate the potentially stressful nature of the questions. Probes assist the interviewer to determine whether or not any endorsed event met both parts of criterion A of DSM-IV PTSD diagnosis. If criterion A is met for a particular type of stressor, the interviewer asks for more specifics about the event(s), the age of the child when it occurred, who else was involved, and whether anyone was hurt and needed medical attention. The TESI is designed to assess exposure to high magnitude stressors among children aged 8 to 18. The parent form (TESI-P—Ghosh Ippen et al., 2002; see Appendix 9.1) was designed to assess children ages 0–18 years. The interviewer should be a qualified mental health professional, or an advanced trainee supervised by a qualified mental health professional.

Assessing Exposure to a Range of Stressors

The AACAP practice parameters for the assessment and treatment of children and adolescents with PTSD (Cohen et al., 1998) emphasize that to develop a full understanding of the child's reactions to any particular high-magnitude stressor, the clinician must understand the child's history of and reactions to a wide range of possible stressors, such as significant family conflict, separation or divorce, frequency of moves, school changes, family deaths, illnesses,

and exposure to domestic and community violence. To accomplish this, it is recommended that some measure of exposure to lifetime stressors be administered to the parent and/or child—preferably both, whenever possible—to help determine the extent to which the child has been exposed to a range of stressors, *in addition to* high-magnitude stressors.

Several instruments are available to assess both high-magnitude stressors and those of a generally lesser magnitude. The appropriateness of the measures described in Appendix 9.1 depends on the developmental level of the child, adolescent, or young adult who is being assessed.

ASSESSING STRESSORS IN PRESCHOOL AND SCHOOL-AGE CHILDREN

There are currently no measures that assess a full range of high-, moderate-, and low-magnitude stressors among preschool or school-age children. Only some of the interviews and self-report measures with good psychometric properties that assess a child's exposure to community violence also assess sexual abuse, physical abuse, and neglect, and none assesses stressors of lesser magnitude. The Juvenile Victimization Questionnaire (JVQ—Finkelhor, Hamby, Ormrod, & Turner, 2005; see Appendix 9.1), a very promising new measure with good psychometric properties, assesses exposure to (1) conventional crime, (2) child maltreatment, (3) peer and sibling victimization, (4) sexual victimization, and (5) witnessing and indirect victimization. Exposure is assessed for the previous year and over the lifetime of the child. As an interview, the JVQ can be used with children 8 years and older. It can be administered in a self-report format with juveniles 12 years and older, including young adults. A parent version of the JVQ can be used to assess the exposure history of children age 2 years and older.

The Preschool Age Psychiatric Assessment (PAPA) Life Events Scale (Egger & Angold, 2004; Appendix 9.1) is part of the full PAPA psychiatric assessment interview (see Appendix 9.3). The Life Events Scale assesses a particularly good selection of high- and lesser-magnitude stressors in the lives of the very youngest children, ages 3–6 years, such as a reduction in the family's standard of living, attending unsafe day care, a detailed history of accidents and hospitalization, separation from

significant attachment figures for more than 1 week, and becoming homeless. These potentially stressful experiences for very young children are rarely assessed by other stressor scales and interviews. Related interviews include life events scales for older children and adolescents ages 9–17 (Child and Adolescent Psychiatric Assessment [CAPA] Life Events Scale; Angold & Costello, 2000, Tables 5 and 6) and for young adults 18 years or older (Young Adult Psychiatric Assessment [YAPA] Life Events Scale; Angold & Costello, 2000, Tables 5 and 6).

The Tough Times Checklist (Fletcher, 1996f; Appendix 9.1) is a self-report measure for children with a third-grade or higher reading level (approximately age 7 years and older), that assesses the child's lifetime exposure to stressors of both high and moderate magnitude. It does not assess any type of sexual abuse or neglect, although the child is asked whether any peers, adult strangers, or known adults ever made him or her do "something horrible." Assessors are then required to inquire as to the nature of that event, if the child endorses it. Children indicate whether they have ever experienced each of the stressors. A version for adolescents, the Teen Tough Times Checklist (Fletcher, 1996f; Appendix 9.1) assesses exposure in the previous year and over the lifetime to the same stressors included in the Tough Times Checklist. Rather than a simple checklist, respondents rate each stressor on a 4-point scale: *Never happened* (0); *Happened, but the worst time was not upsetting* (1); *Happened, and the worst time was somewhat upsetting* (2); and *Happened, and the worst time was very upsetting* (3). A caregiver version for children of any age, the Child's Upsetting Times Checklist (Fletcher, 1996f; Appendix 9.1) asks the caregiver to rate the child's exposure to the same stressors, using the same response format as the Teen Tough Times Checklist. Of these three related measures, the Child's Upsetting Times Checklist is the only one that has any psychometric information. It has been shown to correlate significantly with both the child's own report and the parent's report of the child's PTSD symptomatology (Fletcher, 1996b).

ASSESSING STRESSORS IN ADOLESCENTS AND YOUNG ADULTS

The Young Adults Upsetting Times Checklist, a paper-and-pencil self-report measure (Fletcher, 1996f; Fletcher & Skidmore, 1997), is cur-

rently the only available measure of stressor exposure for adolescents and young adults that assesses both moderate- and high-magnitude stressors, including a variety of sexual abuse experiences, both prior to and after age 18 years. It has accumulated good evidence for its reliability and validity. The measure is suitable for adolescents, young adults, and older adults. Depending on the maturity of the child, it might be suitable for children as young as 11 or 12 years. Respondents rate each item as *Never happened* (0); *Happened, but the worst time was not upsetting* (1); *Happened, and the worst time was somewhat upsetting* (2); *Happened, and the worst time was very upsetting* (3); and *Happened, and the worst time was extremely upsetting* (4). Two additional items ask respondents to rate (1) the worst thing that happened to them in the past year and (2) the worst thing that ever happened to them prior to the last year. Total scores can be computed for the previous year, for any time before the past year, and for any time over the lifetime, including the past year. Each of these totals correlates significantly with measures of post-traumatic stress (see Appendix 9.1 for more details).

Assessing the Traumatic Characteristics of Stressful Events

Simple assessment of the kinds and number of potentially stressful events to which children have been exposed can provide useful information, but it is unlikely to tell the whole story regarding the child's peritraumatic experience. No two events are exactly alike. Even stressful events of the same type are likely to differ substantially from each other. Moreover, the same event is never experienced either subjectively or objectively in exactly the same way by people who live through it together. Each stressful event is a unique phenomenological experience for everyone who lives through it. The fact that not everyone who lives through the same high-magnitude stressor develops PTSD illustrates this point. Despite this, the literature does suggest that specific characteristics or dimensions of high-magnitude stressors increase the likelihood that anyone exposed to events that manifest these dimensions will react with symptoms of PTSD (Fletcher, 2003).

The Dimensions of Stressful Events (DOSE) scale (Fletcher, 1996d) was designed to assess the characteristics or dimensions of high-

magnitude stressor events suggested by the literature to increase the likelihood of a child or adolescent responding with PTSD symptomatology. The measure is divided into two sections. The first section contains 25 items that assess such things as the child's proximity to the event; viewing of blood; whether anyone was injured or killed; whether the child was separated from caretakers; the child's relationship to any perpetrator and other victims; the perception of stigmatization associated with the experience(s); the suddenness and unexpectedness of the event(s); the perceived uncontrollability of the event(s); the duration and frequency of exposure to the event(s); whether the event was caused by humans rather than nature; whether the adverse consequences of the event(s) are long lasting, irreversible, and liable to recur; whether the event(s) involved moral conflicts for the child; whether the child perceived the event(s) as a threat to family or friends; and whether the event(s) originated within the family. The second DOSE section contains 24 items that assess the frequency and degree of child abuse experiences, as well as experiences that may mitigate the child's responses, such as the extent to which the parents support the child's claim. The psychometric properties of the first section (none are yet available for the second section) are very good. Scores on the DOSE appear to provide better prediction of adverse outcomes than do counts of the number of lifetime stressors to which a child has been exposed (Fletcher, 1996b; Fletcher, Cox, Skidmore, Janssens, & Render, 1997; Fletcher, Spilsbury, Creedan, & Friedman, 2006). These results suggest that the DOSE might provide a means of screening for posttraumatic stress responses without asking about any DSM-IV symptomatic responses. See Appendix 9.2 for more details on psychometric properties of the measure.

ASSESSING EMOTIONAL RESPONSES TO HIGH-MAGNITUDE STRESSORS

Interviews. Determining that the child has been exposed to high-magnitude stressors with characteristics that increase the likelihood of traumatic responses meets only the first half of DSM-IV criterion A. The clinician also must determine that the child's "response involved intense fear, helplessness, or horror" or "disorganized or agitated behavior" (see Table 9.1). Most of the general psychiatric interviews that

have PTSD modules (see Appendix 9.3) include questions designed to assess the child's response to their potentially traumatic experience, although some interviews are more thorough than others in that they ask about several specific kinds of possible responses, while others try to make do with one or two very general questions. It is generally best to be more specific when asking questions of children and adolescents. Few interviews that ask about specific responses sacrifice much time to do so; therefore, when choosing from among general psychiatric interviews, the Child and Adolescent Psychiatric Assessment (CAPA) Scale (Angold & Costello, 2000) and its associated versions for preschool children (the PAPA) and for young adults (the YAPA), would seem the best choice, because each explores the child's responses in more detail than do others, while not sacrificing too much time in the process. If one prefers to focus only on the assessment of PTSD and does not wish to conduct a full-scale diagnostic interview but would still like to conduct an interview, the Children's PTSD Inventory (CPTSDI; Saigh, 1998a, 1998b) is a good choice. It asks preliminary questions about four types of high-magnitude stressors to which children might be exposed, followed by four questions on their reactions to any stressor.

Self-Report Questionnaires. If an interview is not possible, or if a self-report assessment tool is required to examine children's responses to high-magnitude stressors, perhaps as part of a screening process, then the choices currently are limited. For exposure to high-magnitude stressors that do not involve abuse, the Exposure Questionnaire (EQ—Nader, 1993, 1999; see Appendix 9.2) might be a good choice. Similar to the DOSE, the EQ assesses aspects of the event(s) associated with increased PTSD symptomatology—such as whether there was threat to life, threat of injury, subjective proximity to the events, relationship to victims, worries about others, property damage, and helping efforts. In addition, it assesses the child or adolescent's emotional reactions during the event, such as helplessness, fear, horror, panic, and guilt, both during and after the traumatic experience. It inquires about the frequency and intensity of the reactions. Two versions are available, one for Postwar Questions and one for Postdisaster or Violence Questions. Scores on the EQ have been shown to be associated

with exposure and severity levels for children in war zones (Nader & Fairbanks, 1994; Nader, Pynoos, Fairbanks, Al-Ajeel, & Al-Asfour, 1993), providing some preliminary evidence of the validity of the measure. Another, shorter scale that might be considered, the Peritraumatic Response Scale (Pfefferbaum et al., 2002), consists of just 12 questions that address the child's peritraumatic responses of fear, arousal, and dissociation at the time of the incident. Unfortunately, no information about its psychometric properties is currently available.

When assessing the peritraumatic responses of children who have been abused, the Children's Peritraumatic Experiences Questionnaire (CPEQ—Wolfe & Birt, 1993; see Appendix 9.2) is an appropriate choice. The CPEQ is a 33-item scale designed to assess children's emotional reactions during their sexual abuse experiences, or for nonabused children, their most negative life experience. The CPEQ assesses feelings and thoughts of helplessness, fear, terror, sadness, and anger related to DSM-IV criterion A2. Items are divided into five subscales, derived from a principal components analysis: Extreme Reactions (e.g., thoughts of being killed or killing the perpetrator, fear of death and injury, becoming ill, wanting to throw something, terror, or fainting), Fear/Anxiety, Negative Affect, Dissociation, and Guilt. The measure appears to have good psychometric properties (Wolfe & Birt, 2002b; see Appendix 9.2). The CPEQ is now included with the Children's Impact of Traumatic Events Scale—II (CITES-II—Wolfe et al., 1991; see Appendix 9.5).

Assessing the Full Range of Posttraumatic Stress Reactions

Assessing ASD

ASSESSING ASD WITH A GENERAL PSYCHIATRIC INTERVIEW

There are currently very few measures of ASD available for children ages 6–18 (see Appendix 9.3). An exception is the Children's Interview for Psychiatric Syndromes (ChIPS—Rooney, Fristad, Weller, & Weller, 1999; Weller, Weller, Fristad, Rooney, & Schecter, 2000; Weller, Weller, Rooney, & Fristad, 1999), a highly structured interview that screens for 20 DSM-IV Axis I disorders, as well as psychosocial stressors such as emotional, physical, or sexual abuse and neglect. In doing so, it assesses both ASD and PTSD. If the stressor occurred within

4 weeks of the interview, children are asked six questions to assess whether they reacted with symptoms of dissociation or derealization, such as whether they have felt as if they were not themselves and as if they were no longer real (depersonalization), and whether they have trouble remembering things about the event(s). Then seven questions are asked that assess reexperiencing symptoms, two that assess feeling “upset” by reminders of the experience(s), and one that assesses physical reactions to reminders, such as stomachaches or trouble breathing. If none of these symptoms is endorsed, the rest of the Stress Disorder questions are skipped. Otherwise, 10 questions are asked that assess symptoms of avoidance and withdrawal. If at least one of these is answered in the affirmative, one question is asked about changes in moods or emotions since the event(s), one about feelings of numbness since the event(s), and two about anticipating a foreshortened future (feeling as if one will not live a long life). Then six questions are asked about symptoms of overarousal, anger, and difficulty concentrating. If none of these questions is endorsed, one question is asked about a tendency to startle easily.

The interviewer is provided with two algorithms to determine whether the child meets criteria for ASD or PTSD, or neither. Next the child is asked when the symptoms began, then whether he or she is still troubled by the symptoms; if not, an attempt is made to determine when the symptoms stopped. Children who meet criteria for ASD are asked whether the symptoms began within 4 weeks of the event(s), lasted more than 2 days, and lasted for less than 4 weeks. Children who meet criteria for PTSD are asked whether the symptoms have lasted longer than 1 month. Finally, children are asked whether “these problems cause you trouble” at home, at school, and with other kids. If the duration of symptoms can be determined, the interviewer can indicate whether the PTSD can be classified as acute or chronic in duration, and whether or not symptoms had a regular onset (within 6 months of the event[s]) or a delayed onset (more than 6 months after the event[s]). ChIPS is designed to be administered by people with at least a bachelor's degree in a field associated with mental health. It is recommended that a clinician familiar with DSM-IV who has undergone similar training on ChIPS train lay interviewers. Unfortunately, the psychometric properties of

the ChIPS have yet to be established satisfactorily (see Appendix 9.3).

ASSESSING ASD WITH A CARETAKER REPORT OF ASD AND PTSD

The Child Stress Disorders Checklist (CSDC; Saxe, 2004) is a 42-item, paper-and-pencil scale that asks parents, guardians, or other observers to report on the child's reaction to high-magnitude stressors. Unlike most other child PTSD measures to date, the CSDC allows assessment of symptoms of both DSM-IV PTSD and ASD. The respondent is first asked to indicate whether the child has been exposed to any of eight kinds of high-magnitude stressors, including an "other" category. Age of exposure is requested for all endorsed stressors. Next, five questions are asked regarding the child's emotional reactions to the experience(s), then seven items assess symptoms of reexperiencing, five assess avoidance, eight assess numbing and dissociation, six assess increased arousal, and four assess functional impairment. Responses to each question can be either *Not true* (as far as you know), *Somewhat true*, or *Very true*. Psychometric properties for the measure are currently sparse but encouraging (see Appendix 9.5).

ASD SELF-REPORT

There is currently only one self-report measure devoted to the assessment of ASD in children. Fortunately, it appears to have very good psychometric properties (see Appendix 9.7 for details). The Acute Stress Checklist for Children (ASC-Kids; Kassam-Adams, 2006), a 29-item self-report measure, comprises 25 items assessing ASD according to DSM-IV criteria: 4 items assessing whether the experience was horrible, frightening, beyond the child or adolescent's control, or whether the child feared for his or her life; 4 items assessing emotional numbing, derealization, and dissociation; 15 items assessing the remaining DSM-IV criteria; 1 item assessing the degree to which the child or adolescent was emotionally upset by the experience; 1 item assessing disruptions to social interaction with meaningful others; 2 items assessing social functioning at school and with the immediate family; 1 item assessing social support; and 1 item assessing self-perceived coping skill. Most response categories are *Never/Not true* (0), *Sometimes/Somewhat* (1) and *Often/Very true* (2). Items rated a score of 2 indicate that

a DSM-IV symptom is present. Symptom category subscales include Dissociation, Re-experiencing, Avoidance, and Overarousal/Anxiety. The ASC-Kids is appropriate for children ages 8–17, although the author suggests that the items should be read to children age 9 and younger, as well as to any 10- or 11-year-old who appears to require assistance.

Assessing PTSD

ASSESSING PTSD WITH A GENERAL PSYCHIATRIC INTERVIEW

Several general psychiatric interviews for children that include PTSD modules are available (see Appendix 9.3). Of these, the Diagnostic Interview for Children and Adolescents—Revised (DICA-R; Kaplan & Reich, 1991) was among the first to include a PTSD module. A semi-structured interview, the DICA-R is a modification of the Diagnostic Interview for Children and Adolescents (DICA; Herjanic & Reich, 1983a, 1983b), developed to allow the assessment of diagnoses in children 6–17 years old. The DICA-R, a modified form of the DICA, allows assessment of DSM-III-R criteria. Questions were rephrased in a more conversational manner, and questions related to DSM-III-R diagnoses were added (Kaplan & Reich, 1991), including a PTSD module. The DICA-R was then itself revised to allow assessment of DSM-IV diagnoses. There are versions for younger children, ages 6–12 years, for adolescents, and for parents. The time required for administration of the full DICA-R is approximately 1.5 hours. With training, the interview may be administered by research assistants with no more than a bachelor's degree.

Unfortunately, psychometric information on the DICA-R is questionable. Some 7-year-olds have been reported to have difficulty understanding some of the DICA-R questions, supposedly written for interviewing 6- to 12-year-olds (reported in Nader, 1997). The PTSD module was unable to distinguish between adolescents who were exposed to wildfires and those who were not (Jones, Ribbe, & Cunningham, 1994). To add to the confusion, the DICA-R has been replaced by the Missouri Assessment of Genetics Interview for Children (MAGIC—Reich & Todd, 2002; see Appendix 9.3), for which full psychometric information is still unavailable.

The Child and Adolescent Psychiatric Assessment Scale (CAPA; Angold & Costello,

2000) appears to be one of the few general child psychiatric interviews containing a PTSD module for which there is specific information regarding its reliability and validity. However, psychometric properties for the PTSD module are still sketchy at this point. The CAPA was designed to be administered to children between the ages of 9 and 17 years. A version for young adults, the Young Adults Psychiatric Assessment (YAPA; see Appendix 9.6) is also available, although there is not yet any psychometric information for the interview. The Preschool Age Psychiatric Assessment (PAPA—Egger & Angold, 2004; Egger, Ascher, & Angold, 1999; Egger et al., 2004; see Appendix 9.3) is a substantial rewrite of the CAPA for preschool children ages 3–6 years. Changes include DSM-IV and ICD-10 criteria that better reflect experiences of younger children. Symptoms and diagnoses included in the Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood, Revised Edition (DC:0–3R; Zero to Three, 2005) were added to the PAPA as well. Relevant items from other preschool measures not covered by the CAPA also were included. Changes appropriate for preschool children were made to the family functioning and relationships sections. Alternate PTSD and reactive attachment disorder diagnostic criteria were based on criteria suggested by Zeanah, Boris, and Scheeringa (Boris, Zeanah, Larrieu, Scheeringa, & Heller, 1998; Scheeringa et al., 1995, 2001; Scheeringa & Zeanah, 1995). Detailed information is gathered by the PAPA regarding 21 changes in the child's behaviors, emotions, or relationships that might have occurred as a result of exposure to the potentially traumatizing event(s), such as new fears or anxieties, increased crying, increased aggression, regression of toileting skills or language, and changes in the child's interactions with others (Egger & Angold, 2004). Each symptom is rated for frequency, intensity, duration, and date of onset. If the caregiver indicates that at least one high-magnitude stressor has occurred in the child's life, and if the caregiver believes that experience is related to at least one symptom (new fears, separation anxiety, etc.), then the interviewer asks the questions in the PTSD section. PAPA requires the same type and duration of training as is required for the CAPA and YAPA. Certification by a qualified PAPA trainer is required before using the PAPA in the field. Unfortunately, very little psycho-

metric information is yet available for the PAPA.

Another promising general psychiatric interview for children, the ChIPS (Rooney et al., 1999; Weller et al., 1999, 2000) was discussed earlier in the section that describes measures of ASD, because it assesses both ASD and PTSD.

PTSD-SPECIFIC CHILD INTERVIEWS

PTSD Interviews for Preschool Children. Levonn: A Cartoon-Based Structured Interview for Assessing Young Children's Distress Symptoms (Martinez & Richters, 1993; Richters, Martinez, & Valla, 1990) was written for young, school-age children. Shahinfar, Fox, and Leavitt (2000) devised a version for preschool children. Levonn, a 39-item, cartoon-based, structured interview of children's distress symptoms, is based on an earlier cartoon-based interview of general psychiatric symptoms, Dominique (Valla, 1989). The Dominique interview was revised, so that the main character Levonn represents an urban child. The Levonn includes cartoons of symptoms associated with PTSD, with two- or three-sentence scripts included for each cartoon. The response format comprises three thermometers filled with varying degrees of mercury, indicating increasing levels of frequency. Thermometers are labeled *Never*, *Some of the time*, and *A lot of the time*. Before administration of the PTSD interview, children are taught how to use the thermometer response format correctly.

After each cartoon is described by the interviewer, children draw a circle around a thermometer to indicate how often they have felt like Levonn. On one page, for example, the three thermometers take up the top one-third of the page. On the right, lower half of the page are three cartoons, laid out vertically, one over the other. In the top cartoon, a frowning young boy with a white face is shown in his pajamas walking somewhat slouched over away from a bed, with his head slightly bent down. The middle cartoon shows the boy, now dressed for school, walking, again slouched over, head bent, and frowning, dragging a book bag along the ground. In the bottom cartoon, Levonn, again in pajamas, stands facing his bed, frowning, with his head bent. In the middle of the left bottom portion of the page is the following script, which the interviewer reads to the child being interviewed: "Here is Levonn feeling very sad for a whole day. He gets up in the morning

feeling sad, he feels sad all day, and he still feels sad at bedtime. How many times have you felt like Levonn?” (Martinez & Richters, 1993, p. 26). The scale comprises four subscales measuring Depression, Anxiety/Recurring Thoughts, Sleep Problems, and Impulsiveness.

In the revised version for preschoolers (Shahinfar et al., 2000), the symptoms assessed include sadness, lack of appetite, fear of going outside because of possible violence, intrusive traumatic memories, and nightmares. Thus, a DSM-IV diagnosis is not possible with Levonn. In a study of 155 primarily (98.8%) African American children between the ages of 3.5 and 4.5, the authors carefully debriefed children after administering the revised Levonn. Shahinfar and colleagues reported that very few of the children indicated either verbally or behaviorally that they had been upset by the interview. Unfortunately, most of the available psychometric data are based on the original Levonn for school-age children.

PTSD Interviews for School-Age Children and Older. The Clinician-Administered PTSD Scale for Children and Adolescents (CAPS-CA—Newman et al., 2004; see Appendix 9.5) is an interview based on the Clinician-Administered PTSD Scale for adults (CAPS; Weathers et al., 2004). The CAPS-CA is currently considered the “gold standard” interview for childhood PTSD. Comprising approximately 53 items that assess things such as the intensity of the experience and its duration, it is an extremely complete, detailed, well-thought-out interview. The PTSD-specific items inquire about the occurrence, intensity, and frequency of endorsed symptoms both for the past month and over the lifetime. The interview begins with a script to establish the meaning of a month’s time for those younger children who might have trouble with the concept. To establish criterion A, 17 different types of high-magnitude stressors are described one by one, and the child or adolescent is asked to indicate whether each event actually happened to him or her, or whether he or she *Saw it, Learned about it, is Not sure, or it Never happened* to him or her. If none of the 17 events is endorsed, four additional prompts are provided to attempt to elicit an experience of a high-magnitude stressor. If three or more events are endorsed, the interviewer tries to determine whether the experiences evoked fear or terror, a sense of helplessness, horror, or disorganized

agitation. Various optional prompts for eliciting this information are provided the interviewer, using wording appropriate for children and adolescents. The interviewer rates whether each event was a life threat, a serious injury or threat to physical integrity, and whether each of the four emotional reactions just listed occurred when the exposure occurred.

When a child’s responses meet DSM-IV criterion A, questions related to each symptom listed in DSM-IV are administered. First, a practice question teaches the child or adolescent how to respond to the questions about frequency and intensity of events. After questions that assess DSM-IV criteria B–D, two questions related to the duration of symptoms (criterion E) are then asked, followed by four questions regarding subjective distress and social, scholastic, and developmental (loss of acquired skill) functioning (criterion F). Three global rating scales are available: (1) overall validity of the responses, (2) overall severity of PTSD symptoms, and (3) improvement for instances of repeated administration of the interview over time. Six items examine the presence of seven associated features: guilt over acts of commission or omission, survivor guilt when there were multiple victims, shame, reduction of awareness of surroundings, derealization, depersonalization, and changes in attachment. Three open-ended questions determine how the child or adolescent thinks the event has affected his or her life, what has helped him or her feel better since the event, and what coping strategies he or she uses.

The interviewer’s guide and summary scoring sheet for the CAPS-CA (Newman et al., 2004) includes scoring for ASD, although no algorithms are provided for actually deriving a diagnosis of ASD. There is a lot to like about the CAPS-CA but, unfortunately, despite the general conception that the CAPS-CA represents the “gold standard” for the assessment of childhood PTSD, the psychometric properties of the interview have yet to be thoroughly explored. Moreover, although no information is available on the average administration time required by the interview for children who have PTSD symptoms, the level of detail required by the full interview is likely to take a considerable amount of time. However, the authors do indicate that “it is possible to customize the interview by eliminating less relevant components or changing the time frames” (p.

4). Still, the dearth of psychometric information for the CAPS-CA (see Appendix 9.5 for details) means it cannot yet be recommended for clinical use.

The Children's PTSD Inventory (CPTSDI; Saigh, 1998a, 1998b), an interview for children ages 7 years and older, has excellent psychometric data (see Appendix 9.5). In fact, the procedures followed by Saigh and his colleagues (2000) for developing and assessing the psychometric properties of their interview could serve as a model for anyone who wishes to examine the psychometric characteristics of a new measure. The CPTSDI is a 47-question interview designed to provide a DSM-IV diagnosis of childhood PTSD. The child is first read a sample list of traumatic events, then is asked four questions to examine exposure to high-magnitude stressors, and four questions to assess possible traumatic reactivity to the exposure, per both parts of criterion A of DSM-IV. If this criterion is not met, the interview terminates. Eleven questions examine the presence or absence of symptoms of intrusion (criterion B of DSM-IV). Sixteen questions address criterion C, avoidance and numbing symptoms. Seven questions address criterion D symptoms of overarousal. Five questions assess the duration of symptoms (criterion E) and significant impairment in functioning (criterion F). Each item measures a symptom or criterion and is scored as present or absent. The interview requires 15–20 minutes when administered to youth with a trauma history, and only 5 minutes to administer to youth with no trauma history (Saigh et al., 2000). The psychometric properties of the CPTSDI make it the best choice for a PTSD-specific interview for children age 7 years and older.

PTSD-SPECIFIC CHILD PAPER-AND-PENCIL SELF-REPORTS

Self-reports for preschool children are rare, and the few that are available tend to be cartoon based (e.g., Levonn, described above; see Appendix 9.4), and tend to assess symptoms that are not directly associated with DSM-IV PTSD criteria. The Posttraumatic Symptom Inventory for Children (PT-SIC; Eisen, 1997), a promising self-report measure for children ages 4–8 that does attempt to assess the DSM-IV PTSD criteria, is a 30-item questionnaire that assesses PTSD symptoms based on DSM-IV criteria. Questions are read to the child by the clinician or administrator and are addressed in two

stages. A child is first asked if a symptom ever happens. If the child answers affirmatively, he or she is asked to indicate the frequency of such occurrences: *A real lot—like everyday* (scored 2) or *Just sometimes* (scored 1). The PT-SIC includes a checklist to screen for 11 high-magnitude stressors (e.g., car crashes, sexual abuse, witnessing or being a victim of community violence). The PT-SIC is a newer scale and cannot yet be considered to have established psychometric properties, but its use with children ages 4–8 years might provide useful insight into the young child's personal reactions to exposure to high-magnitude stressors.

Although several child paper-and-pencil self-report measures are currently available, few assess all of the core DSM-IV criteria A–F symptoms or have amassed enough evidence of reliability and validity to make them good candidates for clinical use. The Child Posttraumatic Stress Reaction Index (CPTS-RI—Frederick et al., 1992; also known as the PTSD-RI and the CPTSD-RI) was one of the first measures written to assess childhood PTSD. It has become the most frequently used outcome measure in research on childhood PTSD. Based on Frederick's (1985a, 1985b) measure of PTSD in adults, the CPTS-RI does not appear to have ever been assessed for readability or reading level among children, which is troubling, because some of the language might be considered confusing for adults. Originally intended to be used as an interview, the CPTS-RI has frequently been used as a self-report measure in research, with little or no evidence that it is suitable for such use. Information on the psychometric properties was nonexistent for quite some time, and that currently available is minimal (see Appendix 9.5). Moreover, the measure was never intended to be used to make PTSD diagnosis, nor is it possible to do so in its current form. It does not assess the full range of DSM-IV symptomatology. Items are assessed with a 5-point Likert-like scale, which makes it difficult to decide what kind of response indicates the presence of a symptom. Estimates of diagnosis obviously vary depending on whether one decides to use the middle, or the second highest response or higher as the indicator of symptom endorsement, as demonstrated by Schwarz and Kowalski (1991).

A revised version of the CPTS-RI has been created: the UCLA PTSD Reaction Index for DSM-IV (UPRID—Pynoos, Rodriguez, Steinberg, Stuber, & Frederick, 1998; see Ap-

pendix 9.5). The UPRID has been selected to be the primary PTSD screening measure for the National Child Traumatic Stress Network. It is a 49-item scale derived from the CPTS-RI, but with much better written questions. A parent version is available. An original adolescent version (Rodriguez, Steinberg, Saltzman, & Pynoos, 2001a) was eventually merged with the child version (Steinberg, Brymer, Decker, & Pynoos, 2004). Two shorter versions, one with seven items and the other with nine, are available for screening. The measure is designed to be administered three different ways: (1) as a self-report; (2) as one-on-one "interview," wherein the items are read to the child; and (3) for group administration.

The first 13 items of the UPRID assess exposure to different high-magnitude stressors for children. Stressors assessed include community violence, natural disaster, medical trauma, and abuse. These are followed by an item that asks children to select the experience that bothers them the most and rate how bothersome it was for them, using a 3-point scale: *A little* (1), *Somewhat* (2), or *A lot* (3). The next 13 items assess different responses to the experience that children might have had at the time. These items are intended to establish whether children responded with fear, helplessness, or horror, per DSM-IV criterion A2, but one item is about reactions of confusion, another is about upset or disorganized behavior, and still another is about feelings of unreality. These are rated as either yes or no. Of the final 22 questions, 20 assess the presence of symptoms related to DSM-IV criteria B–D, and, in addition, fear of recurrence of the trauma and trauma-related guilt are assessed by one item each. These items are rated from *None of the time* (0) to *Most of the time* (5). The questionnaire is accompanied by a frequency rating sheet that visually assists children in providing accurate responses about how often the reaction has occurred over the past month. Although the instrument was not created to be a diagnostic tool, there also is a score sheet that allows one to make a preliminary DSM-IV diagnosis. It is recommended that the instructions and questions be read aloud to children under the age of 12 or to youth with reading comprehension problems. When children meet criterion A, and when they sufficiently endorse each of the B–D criteria categories at the top two rating categories (*Much of the time* or *Most of the time*), a likely diagnosis of PTSD is made. When chil-

dren meet criterion A and only two of symptom criteria B–D, they are scored as "partial" PTSD. A cutoff of 38 or greater has the greatest sensitivity and specificity for detecting PTSD (Rodriguez et al., 2001a, 2001b).

It is difficult to evaluate the psychometric properties of the UPRID, because the authors appear to report results of CPTS-RI psychometric testing as if they were representative of the psychometrics of the UPRID (Steinberg et al., 2004). To further complicate the matter, both the CPTS-RI and the UPRID have undergone several revisions, and the reported psychometric properties of the UPRID as reported by Steinberg and colleagues (2004) appear to be based on tests of different iterations of both scales. Needless to say, this is confusing at best, as well as misleading. The two measures are not the same: Their structures differ; the questions are worded very differently; the response categories differ; and each measure contains questions that are not included on the other measure. The psychometrics of one measure cannot be substituted for the psychometrics of the other. On the other hand, some of the earlier reports regarding the measure (Rodriguez, 2001; Rodriguez et al., 2001a, 2001b), as well as the latest (Rodriguez, in press), do seem to report solely on the psychometric properties of the UPRID. Thus, although it is currently difficult to determine with certainty the reliability and validity of the UPRID, its psychometric properties as reported by Rodriguez (2001, in press) do suggest that it is a promising PTSD-specific measure for use with children age 7 years and older. It is certainly to be preferred as an alternative to the CPTS-RI.

The Child PTSD Symptom Scale (CPSS—Foa, Johnson, Feeny, & Treadwell, 2001; see Appendix 9.5) is one of the best of the currently available self-report measures of childhood PTSD that may be used to make a tentative clinical diagnosis of PTSD in children 8 years or older. It is based on a psychometrically sound measure of PTSD in adults, the Posttraumatic Diagnostic Scale (Foa, Cashman, Jaycox, & Perry, 1997). The language of the adult scale was modified to be more appropriate for children. The 26-item CPSS includes 2 items assessing exposure to a high-magnitude stressor (DSM-IV criterion A); 17 items assessing symptoms of reexperiencing, avoidance, and overarousal (criteria B–D); and 7 items assessing impaired functioning (criterion F). Children and adolescents are asked to indicate how of-

ten the 17 PTSD symptoms bothered them in the past month, with responses of *Not at all* (0), *Once a week or less* (1), *2 to 4 times a week* (2), and *5 or more times a week* (3). The 17 PTSD symptoms yield a total symptom severity score ranging from 0 to 51, as well as symptom severity scores for each of the three core DSM-IV criteria B–D. These items can also be scored dichotomously, presumably scoring ratings of 2 or 3 as symptom present; thus, a tentative DSM-IV diagnosis can be made based on responses to the 2 criterion A items, the 17 criteria B–D items, and the 7 criterion F items. Children indicate whether or not their symptoms cause them difficulty in each of the following seven areas of functioning: prayers, chores and duties, relationships with friends, fun and hobbies, schoolwork, relationships with family, and general happiness with life. These responses are scored as either *Absent* (0) or *Present* (1).

The psychometrics of the CPSS are impressive, although they may be considered preliminary in some respects, because they are based on a study wherein the measure was administered by examiners who read the questions aloud to children. Also assessed were reactions to a high-magnitude stressor that had occurred over 2 years prior to the administration; the primary measure of convergent validity, the CPTS-RI (Frederick et al., 1992; see Appendix 9.5), as described earlier, may not represent a “gold standard” against which to measure, especially because it neither assesses the full spectrum of DSM-IV symptoms of PTSD nor does it allow diagnosis of PTSD according to DSM-IV standards (as the authors themselves note; Foa et al., 2001, p. 377). Nonetheless, the psychometric studies are relatively thorough compared to those conducted for other paper-and-pencil, child self-report measures, and the results suggest that the CPSS is an excellent self-report measure of PTSD among school-age children, adolescents, and young adults.

ASSESSING CHILDREN'S PTSD WITH CAREGIVER REPORTS

Most parent or caregiver versions of children's PTSD assessment measures are versions of child self-report measures. Of the interviews that include PTSD as part of a broader assessment of several psychiatric disorders, those associated with the CAPA are among the best and most useful, especially if the child is to be interviewed with the CAPA (see Appendix 9.3) or

one of its variants, the PAPA (see Appendix 9.3) or the YAPA (see Appendix 9.6). Two of the PTSD-specific measures, one an interview and the other a parent self-report on the child's reactions, that currently appear to have the best psychometrics are the Childhood PTSD Interview—Parent Form (Fletcher, 1996b, 1996c) and the Parent Report of the Child's Reaction to Stress (PRCRS; Fletcher, 1996b, 1996e). These measures are from the same author and ask similar but not entirely parallel questions.

The Childhood PTSD Interview—Parent Form (Fletcher, 1996b, 1996c; see Appendix 9.5) is a semistructured interview of the caretaker regarding the child's reactions to the stressor(s). It allows DSM-IV criteria to be assessed and diagnosis to be made. It contains one item that allows the interviewer to rate how well the caregiver's description of the event(s) matches that of the child. Sixty-two questions assess DSM-IV PTSD criteria A–D. Unlike most other measures of childhood PTSD, all symptoms are assessed by at least two different questions to increase the reliability of the measure. Four questions assess criterion A. Nineteen questions assess the five symptoms of criterion B. The seven symptoms of criterion C are assessed by 24 questions. The five criterion D symptoms are assessed by 15 questions (see Appendix 9.5 for details).

An optional, additional 26 questions on the interview assess associated symptoms. Interviewers may choose to ask some, all, or none of these questions. Five questions assess symptoms of anxiety; three assess symptoms of depression; two assess indications of whether the child perceives certain prestressor events as omens; two assess symptoms of survivor guilt; and two assess symptoms of guilt or self-blame, at which point the interviewer is asked to indicate to what extent the child might actually be considered to have some responsibility for events. Two questions assess indications of fantasy denial; three assess possible self-destructive or suicidal thoughts and behaviors; four assess symptoms of dissociation; three assess antisocial behavior; two assess risk-taking behavior; and a final two assess changed eating habits. Answers to these questions can provide indications of whether the child should be assessed for ASD or complex PTSD.

The PRCRS (Fletcher, 1996b, 1996e; see Appendix 9.5) is a 78-item, paper-and-pencil report by the parent about the child's reaction to

exposure to a high-magnitude stressor. The first 51 questions allow the assessment of DSM-IV PTSD criteria A–D. The first 4 questions assess criterion A; 20 questions assess the five symptoms of criterion B; 21 assess the seven symptoms of criterion C; and 12 assess criterion D's five symptoms. Associated symptoms are assessed by an additional 27 questions on the PRCRS (see Appendix 9.5 for details). Most items are answered using 6-point, Likert-like response categories, ranging from *Never to Always*, and many include a seventh *Don't know* category. Children's positive responses to some of the items are followed by a request that they explain or describe the reason for the response. Scorers of the responses are cautioned to consider these explanations carefully before rating the response. For example, parent or guardians are asked to explain what makes them believe their child behaves in new and unusual ways since the event(s).

Psychometrics for these two parent reports are promising, but they are based on a small sample of only 30 caregivers (Fletcher, 1996b). Of particular interest is the degree to which each of these parent measures demonstrated good agreement with child reports. The Parent Interview correlated .69 with the Childhood PTSD Interview—Child Form (Fletcher, 1996c; see Appendix 9.5) and .59 with the When Bad Things Happen scale (WBTH—Fletcher, 1996g; see Appendix 9.5) self-report. The PRCRS correlated .60 with the Parent Interview and .54 with the WBTH self-report.

Assessing Complex PTSD

SELF-REPORT ASSESSMENT OF COMPLEX PTSD AMONG PRESCHOOL CHILDREN

The Angie/Andy Cartoon Trauma Scales (Praver & Pelcovitz, 1996; Praver, Pelcovitz, & DiGiuseppe, 1998; see Appendix 9.7) were created specifically to assess complex PTSD in children ages 3–4 years and older. Modeled on the cartoon-based child interview, Levonn: A Cartoon-Based Structured Interview for Assessing Young Children's Distress Symptoms (Richters et al., 1990; see Appendix 9.4), this interview is a child version of the Structured Interview for Disorders of Extreme Stress Not Otherwise Specified (SIDES; see Appendix 9.7 and description below). It contains 44 full-page cartoons illustrating DSM-IV symptomatic responses to high-magnitude stressors plus the

additional symptoms associated with complex PTSD (see Table 9.3). As such, it is primarily a measure of reactions to prolonged, repeated abuse; thus, it is probably more appropriate for assessing complex PTSD among young children. However, it does allow posttraumatic stress symptomatology to be assessed. The Angie/Andy Cartoon Trauma Scales include scales of Attention and Consciousness, Dysregulation of Affect and Impulses, Relations with Others, Self-Perception, Somatization, and Systems of Meaning. Symptoms such as despair, hopelessness, and loss of previously sustained beliefs are included. Two summary scores are computed: one for Posttraumatic Stress symptoms and one for Total Associated symptoms. The associated items are relevant for the assessment of complex PTSD. The child rates how often he or she feels like the child in the drawing, using four separate thermometers that are filled to levels corresponding to a response of *Never, Just a few times, Some of the time, and A lot of the time*. There are parallel Angie/Andy Parent Rating Scales available, which ask the parent to assess the same symptoms in the child, minus the cartoons.

The Structured Interview for Disorders of Extreme Stress Not Otherwise Specified (SIDES; Pelcovitz et al., 1997), a 48-item interview, can also be administered as a paper-and-pencil self-report measure. It was designed to assess the suggested criteria for complex PTSD (also known as disorder of extreme stress not otherwise specified, or DES NOS). The SIDES was used to investigate the viability of a separate diagnostic category for complex PTSD during the DSM-IV field trials (Kilpatrick et al., 1998; van der Kolk et al., 1996). Questions on the SIDES assess specific symptoms of the domains of complex PTSD. In the domain of alteration in regulation of affect and impulses, three questions assess problems with affect regulation in general; four assess problems modulating anger; three assess self-destructive behaviors; one assesses suicidal preoccupation; seven assess difficulty modulating preoccupation with sexual involvement; and one assesses excessive risk-taking behavior. In the domain of alterations in attention or consciousness, one item assesses amnesia, four assess transient dissociative episodes and depersonalization, and one assesses a sense of ineffectiveness. The domains alteration in self-perception, sense of ineffectiveness; sense of permanent damage to the self; guilt and responsibility; shame; feeling

that nobody can understand; and minimizing the traumatic experience(s) are all assessed with one question each. In the domain of alterations in perception of the perpetrator, the adoption of distorted beliefs about the perpetrator; idealization of the perpetrator; and preoccupation with hurting the perpetrator are assessed with one question each. In the domain of alterations in relations with others, three items assess the inability to trust others, one assesses the occurrence of revictimization experiences, and one assesses the tendency to victimize others. In the domain of somatization, problems with the digestive system and chronic pain are assessed by one question each, whereas cardiopulmonary symptoms are assessed with one item, wherein the respondent can indicate whether any of four different symptoms have been experienced; conversion symptoms are assessed with one item, wherein the respondent can indicate whether any of nine different symptoms have been experienced; and sexual symptoms are assessed with one item, wherein up to four symptoms can be endorsed. In the domain of alterations in systems of meaning, three items assess a pessimistic attitude toward the future (also known as foreshortened future), and two items assess a loss of previously sustaining beliefs. Endorsement of complex PTSD is met when criteria for all scales except that assessing alterations in perceptions of the perpetrator are met (Pelcovitz et al., 1997).

FUTURE DIRECTIONS

Measures written specifically to assess PTSD in children did not exist 15 years ago. As this chapter demonstrates, there is now a large but potentially confusing array from which to select. Which measure or measures the clinician chooses depend on the purposes of the assessment, the respondents, time constraints, and other logistical and procedural considerations. However, a great deal of the choice also should depend on the psychometric properties of the measure(s) to be used. Instruments that are without empirical support and that do not measure what they purport to measure are of little use. Similarly, important decisions about the state of mind and emotions of a child who has been exposed to a potentially traumatic experience should not rely on unreliable measures that cannot be assumed to reflect the true state of affairs from one day to the next. I hope that

the information in this chapter helps readers make better informed choices of the most empirically supported and clinically practical assessment tools for assessing childhood PTSD in the full range of its manifestation.

At the same time, it must be admitted that very few of the many measures of childhood PTSD now available have sufficient data on their psychometric properties. Fortunately, clinicians and researchers alike are becoming increasingly aware of the necessity for testing the reliability, validity, and clinical utility of measures that may ultimately help determine the welfare of traumatized children, adolescents, and young adults. One of the developments we are most likely to see in the near future are more reports regarding the assessment of the psychometric properties of many of the measures described in this chapter. Important information regarding certain psychometric properties is still lacking on nearly all of the measures discussed in this chapter. Few have had their factor structure examined, for example. Fewer still have been assessed using Item Response Theory, which can provide more precise information regarding the contribution of each item to the overall score. Nearly all of the measures of childhood PTSD currently available lack information regarding how well their scores are able to reflect progress shown in treatment. Knowledge of a measure's responsivity to intervention can help guide clinicians in their choice of measures to use when monitoring a child's response to treatment. To date no measures of childhood PTSD have been formally assessed for their ability to detect treatment response. However, a few have demonstrated an ability to detect effective interventions for posttraumatic stress. These include the Child and Adolescent Trauma Survey (CATS; March, Amaya-Jackson, et al., 1997; March, Amaya-Jackson, Murray, & Schulte, 1998), the CPTS-RI (Frederick et al., 1992; Goenjian et al., 2001), the CAPS-CA (March et al., 1998; Newman et al., 2004), and the Kauai Recovery Index (KRI—Hamada, Kameoka, & Yanagida, 1996; Hamada, Kameoka, Yanadiga, & Chemtob, 2003) (see Appendix 9.5 for all of these measures).

Another current shortcoming in the field is the fragmentation or compartmentalization of measures that assess the full range of posttraumatic stress symptomatology. Newer measures do seem to be developing in the direction of integrating assessment of the related symptomatology of ASD and PTSD. This is particularly

true of general psychiatric interviews for children, such as the CAPA, PAPA, YAPA, and ChIPS. However, far too many measures still tend to focus only on PTSD symptomatology, and, in fact, the majority do not evaluate all DSM-IV A (both parts) through F criteria, assessing only the 17 symptoms listed in DSM-IV for the core criteria B, C, and D instead. This may be adequate for screening purposes. However, by not evaluating the full range of possible reactions to high-magnitude stressors, these measures make it all too easy to misdiagnose children and to miss additional and “associated” symptomatology that may in fact be more relevant for treatment of dysfunctional children. This is particularly likely to occur among children exposed to the most horrendous experiences over extended periods of time: sexual, physical, and emotional abuse and neglect. Any clinician who evaluates maltreated children but does not examine the possibility that the children are experiencing symptoms associated with such traumatic experiences, symptoms that go far beyond the 17 core symptoms of PTSD listed in DSM-IV, places those children at risk for a lifetime of increasingly disabling behavioral and medical problems, ranging from chronic, unexplainable medical problems to substance abuse, social and sexual problems, and borderline personality disorder. The few currently available measures that include questions about at least some of the additional and associated symptoms included in DSM-IV can sometimes provide important insight into symptoms associated with more extreme traumatization. However, none of today’s measures, not even the interviews, allows for assessment of the full range of symptoms associated with complex PTSD, with the possible exception of the Angie/Andy Cartoon Trauma Scales (Praver & Pelcovitz, 1996; Praver, Pelcovitz, & DiGiuseppe, 1998) and its associated measure for parents (see Appendix 9.7).

Measures that provide assessment of the full spectrum of posttraumatic stress responses should be able to evaluate whether a child has ever been exposed to a stressor with the qualities most likely to lead the child to respond with symptoms of posttraumatic stress. The clinician, in addition to probing for exposure to known high-magnitude stressors, would consider other experiences that the child him- or herself experienced as extremely stressful. Assessment of the experience should go beyond

simply noting whether exposure to a potentially traumatic event has taken place. It should include the child’s emotional reactions to the event as it took place and immediately afterward, with questions that help elucidate the extent to which the child’s emotional reactions meet criterion A2 of DSM-IV. It would also mean attempting to come to a more detailed understanding of the actual circumstances surrounding the child’s experience of the event. Particularly important is the extent to which the event involved those characteristics that, according to the literature, increase the likelihood of children responding with posttraumatic stress symptomatology, measured in a standardized manner similar to that employed by the DOSE scale.

Once a clinician develops an understanding of the child’s experience, he or she can assess the child’s initial and continuing responses. This involves assessment of a full complement of the possible reactions, including those associated with ASD, PTSD, and complex PTSD, as well as other important possibilities, such as grief reactions or changes in cognitive processing. Elaboration of the assessment of disruptions in the child’s functioning as a result of the traumatic experience (criterion F of DSM-IV diagnostic criteria for PTSD) is useful as part of both the assessment process and treatment planning and monitoring.

Beyond refining and integrating assessment tools for the full spectrum of a potentially traumatic event and the child’s reactions to it, both during the event and afterward, the field is ready to move into areas of assessment that go beyond the mere determination of symptomatology and diagnosis. It is time to make tools available to examine further ramifications of the traumatic experience and its aftermath. This already is starting to happen. A good example of a new measure that assesses important, possibly long-term reactions to traumatic experiences not captured by DSM-IV symptomatology is the World View Survey (Fletcher, 1996h; Skidmore & Fletcher, 1997; see Appendix 9.7), which assesses important beliefs about the self and others that appear to be the result of traumatic experience. Several theorists have suggested that posttraumatic stress responses represent a survivor’s attempt to accommodate to and assimilate experiences that challenge the victim’s whole worldview (e.g., Chemtob, Roitblat, Hamada, Carlson, & Twentyman, 1988; Foa et al., 1989; Horowitz,

1976a, 1976b). Some theorists (Epstein, 1990; Janoff-Bulman, 1989; McCann & Pearlman, 1990a, 1990b; Norris & Kaniasty, 1991) contend that stressful events become traumatic when they shatter certain basic beliefs that people normally assume about themselves and the world in which they live. Alteration in meaning is one of the symptoms of complex PTSD (see Table 9.3), but beliefs related to meaning are not the only beliefs that can be affected by traumatic experiences. High-magnitude stressors can pose overwhelming threats to beliefs about the safety and security of the world—its certainty, orderliness, predictability, and controllability—and to beliefs in one's competence and general self-esteem, not to mention the trustworthiness of important others (Fletcher, 1988; Janoff-Bulman, 1989, 1992; Norris & Kaniasty, 1991).

The World View Survey (Skidmore & Fletcher, 1997) assesses 50 beliefs that reflect the basic assumptions thought to be affected by traumatic experience (Epstein, 1990; Janoff-Bulman, 1989). The measure also includes potentially positive beliefs (e.g., that it is good to be alive, or that having lived through traumatic experiences, one now feels capable of handling anything). The authors determined the psychometric properties of the measure using responses of undergraduate college students, but the measure has been used successfully with adolescent psychiatric inpatients as well, most of whom had a diagnosis of PTSD (Skidmore & Fletcher, 1997). Factor analysis produced nine factors, and a second-order factor analysis suggested that the nine factors fell under two superordinate factors.

The first higher-order factor comprised six of the original factors, all of which were related to the basic assumptions put forth by Epstein (1990) and Janoff-Bulman (1989): (1) Anxious Uncertainty (exemplified by beliefs such as "Life does not seem to make much sense anymore"); (2) Inadequacy (e.g., "I am a jinx"); (3) Dangerous World (e.g., "The world is a dangerous place to live"); (4) Self-Abnegation (e.g., "Sometimes I think I am not a very good person"); (5) Lack of Control (e.g., "I feel like I have control over my life"—if disagreed with); and (6) Poor Attachment (e.g., "It is easy for me to make friends"—if disagreed with). The second higher-order factor comprised four of the original factors, most of which were originally intended to indicate positive beliefs, but which correlations with PTSD symptoms indi-

cated should be scored in a negative direction: (1) Poor Ego-Strength (e.g., "Since I have lived through some bad times, I have a better idea of what is important to me and what is not"—if disagreed with); (2) Poor Attachment (e.g., "It is easy for me to make friends"—if disagreed with); (3) Lack of Personal Empowerment (e.g., "I feel like nothing can keep me from getting what I want out of life anymore"—if disagreed with); and (4) Negative Outlook (e.g., "Nowadays I feel like every new day I am alive is a gift"—if disagreed with). Poor Attachment loaded on both higher-order factors.

Examination of the ramifications of a traumatic experience for the adolescent's or young adult's belief system with a measure such as the World View Survey can provide guidance relative to the goals and progress of treatment for these youth. This is an example of the possibilities for assessment that go beyond determining the degree to which a child meets DSM-IV criteria for PTSD.

In summary, this chapter has emphasized the need to consider much more than just DSM-IV's 17 core symptoms of PTSD when attempting to assess the reactions of infants, children, adolescents, and young adults to high-magnitude stressors. During the process of making such an assessment, the clinician will do well to keep in mind several key ideas. First, exposure to even the most extreme stressor does not automatically lead to reactions symptomatic of posttraumatic stress in anyone of any age. Second, whenever possible, the child should be allowed to give an account of his or her experience of, and reactions to, the stressor, although accounts of important others, especially caregivers, should also be given due consideration. Third, children should be interviewed in a manner appropriate to their developmental stage and in language suitable to their ability to comprehend. A corollary to this is that when children are asked to respond to standardized measures, the interview should endeavor to ensure that they have an adequate grasp of the possible response categories. It is not good practice to assume that the questions and response categories will be clearly understandable to a child just because the measure has been published and/or used by others to assess PTSD in children. Fourth, possible responses to traumatic events are not limited to PTSD. Some children who exhibit few or no symptoms of PTSD possibly exhibit other symptoms that seem to be related to the trau-

matic experience (e.g., depression, fear, or panic attacks), and others who clearly have PTSD symptoms also may exhibit additional symptoms that need more immediate attention than the core symptoms of PTSD (e.g., self-cutting or suicidal behavior). In short, the child's experience is uniquely her or his own and should be examined as such, rather than as something that one assumes it *should* be or is *supposed* to be. The best assessment tools help the clinician, child, and caregiver to come to a collaborative understanding of the child's experience. This collaborative understanding then provides a sound basis for a treatment plan that will help the child respond more adaptively to the earth-shattering experience and move beyond it to more positive growth experiences.
